Colonel Burns' finding of rabies antibodies in blood pools of asymptomatic bats caught in enzootic areas, a finding which should be confirmed by other workers, suggests that bats may be a reservoir of the disease.

On Human Prophylaxis

KOPROWSKI: Now we have to return to the treatment of the children who were bitten in Simona. What should be done?

Since time is getting short, I would like to limit our remarks on human treatment to two items: first, the use of antiserum, and, second, preliminary results with chick embryo vaccine.

SELLERS: Georgia has been using rabies antiserum since 1948. We've given it to 60 or 70 individuals, limiting its use to those with severe bites on the face, neck, or hands, and to cases where the exposures were not more than 48 hours old. In all instances the antiserum was followed by appropriate courses of antirabies vaccine, and during this time there were no deaths among those receiving vaccine alone. We therefore have no convincing field evidence of the part played by antiserum in protection. The laboratory protocols, however, are very convincing, and I definitely endorse the use of antiserum in principle.

DEAN: Hyperimmune serum promises to be of value. Since the serum is of equine origin, however, it possesses the hazards inherent in products of this nature. We have observed two serious cases of serum sickness among 35 treated individuals.

FOX: At Tulane University, we have been trying the live Flury virus vaccine in prisoner volunteers to see if it can be used to replace current forms of the Pasteur treatment. The volunteers cooperating are inmates of the Mississippi and Louisiana State prisons. All of our work has been with high-passage virus, about 180th passage level, although 3 or 4 years previously Dr. Koprowski used the low-passage

virus, now used for dogs, in about 30 persons. In all, we have given one or more inoculations of this virus to about 170 or 180 persons, and one important fact is that we have observed no adverse effects.

The more important point, however, is that, although we know the Flury virus vaccine works well in dogs, we are still trying to find out if it does in man. A single injection of two dog doses does not induce development of detectable neutralizing antibody. However, it apparently has some effect because a second booster injection of equivalent size usually does produce antibody. Increasing the amount of virus inoculated by giving multiple doses often, and in proportions increasing with the amount, gives rise to antibody. Because of this we feel that the Flury virus probably does not multiply in man, at least when placed extraneurally.

The question arises at this point as to whether demonstrable antibody is essential to the protection of man. Without challenge experiments this cannot be answered. Our feeling is that appearance of antibody is our only possible index of success and that, before we can recommend Flury virus vaccine in place of currently accepted vaccines, we must find a way of using it that will result in as uniform an appearance of antibody as that following current forms of Pasteur treatment. Our goal, of course, is an effective vaccine free from the risk of neuro-paralytic accidents.

Currently, we are working with small intramuscular or intradermal inocula. Fairly good results have followed a schedule of 4 doses, 5 days apart. We are now trying more doses with a shorter interval. Because in giving the Pasteur treatment one is working against time, we

have set 15 days as the maximum length of a practical dose schedule, even though we have evidence that good results follow as few as 2 inoculums spaced 30 days or more apart. Also, since vaccine may have to be given together with hyperimmune serum, we are trying to determine whether the active response to vaccine is altered by the presence of passively acquired antibody.

DEAN: The use of the Flury strain in man is still in the experimental phase. It is important also that we emphasize presently approved methods of treatment. Thorough local treatment of wounds with 1 percent aqueous zephiran or 20-percent soap solution remains of paramount importance. Local treatment should be followed by a series of injections of brain tissue vaccine containing killed virus with or without the use of hyperimmune serum.

KOPROWSKI: I would like to tell you about the results of the use of antiserum in Iran last summer. In August, a rabid wolf (the virus was isolated from the animal's brain after its death) bit 27 people, of whom 17 received severe head and neck bites. Of the 5 persons who received Semple type vaccine alone, 3 died, while of the 12 persons receiving serum and vaccine, only 1 died. One child, who had a penetrating wound of the head and direct exposure of the brain to the saliva of the biting animal, survived—he was given 6 injections of serum at 2-day intervals, followed by vaccine.

Thus, we are leaving Simona and Neutralia and hope that when we return next year rabies will be eradicated. I should remind you, however, about the epigram of Jerrold concerning hope. "In all the wedding cake, hope is the sweetest of the plums."

smaller segments of time, the minimal period can be determined.

Time must be accurately recorded. In most time studies, the starting time and the total time for each activity are recorded in appropriate columns. Although this technique is satisfactory, the Yale project found that a time bar was simpler for participants to use and worked just as effectively.

Participants must code their own activities. Theoretically, it would be better for participants to record their activities in narrative form and for the research staff to code the activities. In practice, however, it proved impossible in the Yale project to secure narrative time logs from most public health workers in sufficient detail to permit adequate analysis.

The system of classification must be simple.

If the workers are expected to classify and code their own activities, the categories must be relatively few in number and so clearly defined that, after proper instruction and a trial run, the workers can classify their activities with ease and without appreciable error. Further analysis of any one category of activities can be made by the research staff, if detailed activity inventories of the workers are obtained simultaneously through interviews, and if the activity inventory classification is related to the time-study classification. Ultimately, such analyses were possible in the Yale project.

Initial Developmental Efforts

Answers to two questions were fundamental to the conduct of the time study. What infor-

List of Activity Categories

1. **Other Agencies.** (Not joint program planning, which is No. 9.) Organizing and participating in the planning of relationships with, and securing support for program from, other agencies and officials. Examples: hospitals, voluntary agencies, boards of education, mayor, legislature, civil service, finance department, welfare agencies, health departments at same level.

2. **Other Health Departments.** (Not at same level, which is No. 1.) Organizing and participating in the planning of relationships and consulting with health departments at different governmental levels. Examples: planning for financial support, exchange of services or personnel, joint programs.

3. **Giving Professional Education.** (Not inservice, which is No. 17 and No. 18.) Planning, organizing, participating in the giving of professional education. Examples: preparing, organizing and conducting workshops, formal classes in colleges and professional schools, lectures at professional societies.

4. **Group Organization.** Planning for, organizing, and training specific purpose groups. Examples: X-ray survey committees, fact-finding groups, study groups, volunteers in clinics.

5. **Talks to Public.** Planning, preparing, and delivering talks to public. Examples: mothers' classes, high schools, service clubs, PTA's, food handlers.

6. **Planning Mass Media.** (Not its preparation, which is No. 10.) Planning content and employment of mass media of communication. Examples:

audiovisual aids, pamphlets, newspaper publicity, radio scripts.

7. **Information Service.** (Not as part of case visit, which is No. 10.) Answering individual requests for information and escorting visitors through the health department.

8. **Health Department Program Planning.** Within the health department, planning research into health needs and planning the initiation, revision, scope, methods of execution, operating policy, and evaluation of health programs.

9. **Joint Program Planning.** Working with other agencies to plan research into health needs and to plan the initiation, revision, scope, methods of execution, operating policy, and the evaluation of health programs.

10. **"Technical."** (Not arithmetic computations, posting, adding and transcribing reports, distributing mass media, which are No. 11.) Primary medical, professional, technical activities such as:

Examination and treatment of patients, home visits, environmental sanitation visits, advice to clients and patients, taking medical and social histories, epidemiological investigations.

Laboratory and other test procedures, reading X-rays, preparation of mass media, planning and editing the annual report, preparing budgets and diets, statistical analysis.

11. **"Ancillary."** (Not giving information to clients, which is No. 7.) Essential supporting activities, such as:

mation was the time study to elicit? How was the desired information to be obtained?

The initial plan was to match with time allocations the detailed activity information obtained from interviews and observation. The time information was to be obtained from time logs kept by participants in their own words.

Toward the end of 1950, the first formulation of time-study content and method was completed. A time-log form was designed to determine what activities a public health worker performs, how the worker performs them, and the approximate time involved. It consisted of three columns: a narrow left-hand column in which fixed time intervals were specified and two broad columns, one headed "What: Job Duty or Activity," and the other, "How: Means Employed." Instructions for the use of the log

suggested simply that each activity be recorded in terms of what, how, and how long. A partial list of activities and the way in which these activities might be performed was furnished as a guide. The list named about 60 possible activities, such as investigation, survey, clinic examination, sample collection, and school visit, and about 50 areas in which these activities could be performed, such as tuberculosis, civilian defense, epidemiology, and venereal disease. Coding and analysis of the completed time logs were to be performed by the research staff in accordance with the basic activity codes developed for the interview part of the project.

A pilot run of this time study, including careful orientation of the participants, was undertaken in one local health department. The inadequacies of this approach were soon appar-

List of Activity Categories—Continued

Preparation for clinic and obtaining identifying information (name, address, etc.) from clients. All record and report keeping, compilation of reports, designing and filling out of forms (includes daily time log), car servicing.

Glassware preparation, media making, issuing of biologicals, taking and developing X-rays.

Issuing supplies, distributing mass media, filing, taking dictation, mimeographing, opening and distributing and sending out mail, transferring and placing telephone calls, making appointments.

12. Financial Management. (Not activities with other agencies or officials, which are No. 1, and not processing purchase orders, keeping accounts, preparing financial statements, performing computations, which are No. 11.) Planning, preparing, justifying, and controlling the budget. Examples: planning initial purchases with vendors, planning cost studies, discussing budget plans, authorizing purchases or adjustments between accounts, allotting funds, reviewing financial statements.

13. General Services Management. Planning and controlling organization "housekeeping" activities. Examples: planning and controlling report, record, and filing systems; space usage, construction and installations; custodial and grounds services; building and equipment repair.

14. Personnel Management. (Not supervising personnel, which is No. 15.) Recruiting, selecting, transferring, counseling personnel; and authorizing vacation, leave, and travel. Examples: interviewing candidates, preparing qualification standards,

reviewing credentials, recommending or giving disciplinary action, counseling re personal problems or vocational guidance, writing letters of recommendation.

15. Personnel Supervision. (Not training, which is No. 17.) Giving immediate personal direction to a staff member. Examples: giving assignments, review through observation, discussions, analysis of records or reports.

16. Receiving Supervision. Receiving the services described in No. 14 or the supervision described in No. 15.

17. Individual Inservice Training. Planning, organizing, and giving inservice training and education for individuals. Examples: conferences, close collaboration, field trips, provision of study outside the department.

18. Group Inservice Training. Planning, organizing, and giving inservice training and education for groups of workers. Examples: lectures, staff meetings, field trips.

19. Own Education and Training. Attending professional meetings, classes, workshops, staff meetings; reading professional literature; field orientation; receiving inservice training.

20. Social Activities. Achieving and maintaining rapport with co-workers, "passing the time of day," social conversations, arranging for office parties.

21. Personal. Meals, coffee hours, rest periods, sick leave, dentist and doctor appointments.

ent. The participants found it extremely difficult to relate their activities to the fixed time intervals on the log and to identify the what and the how of the activities in a few short words or phrases. In addition, the participants attempted to fit their own activities into the suggested list, with resulting distortion and inaccuracy in their reporting.

In an attempt to remedy these faults, the time study was revised early in 1951 in the direction of a more nondirective instrument. The time-log form and the instructions were modified to give the recorders more freedom, and codes were developed especially for the time study. Coding and analysis were still to be done by the research staff. This edition of the study was administered to the personnel of health departments in Michigan, and the returns revealed that the information was adequate only for an analysis of time distribution by program. It was not possible to classify the activities according to the nature of the activity or the persons or organizations with whom the activity was performed, as had been planned. (The method and findings of this portion of the study are reported in a separate article, which appears on p. 577 of this issue.)

Since the primary objectives of the time study had not yet been accomplished, further explorations into content and method were undertaken. One of these was an attempt to develop a code based on classification of public health activities according to level of difficulty. Five levels were established, and an effort was made to allocate the hundreds of individual activity items to these levels. Difficulties were soon encountered. Agreement as to the proper level of difficulty for some of the activity items could not be reached. The number of items which had to be included if coding was to be uniform was tremendous. The most important factor in the decision to abandon this approach, however, was the growing realization that it would probably prove impossible to obtain narrative time records in sufficient detail for accurate classification.

At this stage of the study, it became evident that two major difficulties were blocking its effective execution. One was the emphasis on the differences among the several types of public

health personnel, with the resultant development of a different, very detailed code for each type. The other was the impossibility of obtaining narrative reports of sufficient clarity and in sufficient detail to permit classification into the hundreds of activity code items.

The Final Method

From this experience, the project staff concluded that the narrative time study was not feasible in research of this kind, and that the investigation should be founded on the broad similarities of activity among the several kinds of public health workers. This decision required that the number of categories for classification of activities be relatively small and that the categories be clearly defined. It was felt also that the time study should give promise of yielding new knowledge. Toward these ends, an entirely different instrument was developed.

The new instrument was designed to reveal the distribution of time in accordance with a broad, functional classification of activities which cut across both programs and services. It contained 21 activity categories applicable to all public health personnel (p. 572). For purposes of analysis these categories were grouped into four major classes of activity: technical, category 10; ancillary, category 11; administration, categories 8 and 12 through 19; and community relations and organization, categories 1 through 7, and 9.

Participants were to code their activities according to the list of 21 categories and to enter the code number on a daily time log. The time log is actually a time bar, or time scale, in which time segments are delineated by drawing two vertical lines (see p. 575). The activity list, a sample time log and illustration of its use, and simple directions for recording the time data were included in an instruction booklet, which was given to each participant.

Following a pretest in a local health department, in which difficulties encountered were remedied, the time study was administered to personnel in the State health department and selected county health departments in Maryland during the fall and winter of 1952-53. The participants were asked to keep the time study daily for 2 days each month for 5 months.

Sample Daily Time Log and Illustration of Its Use

10 - 12	10:00 15 30 45 11:00 15 30 45 12:00

The following activities have been placed on the time log above:

- | | | | |
|-------------|--|-------------|---|
| 8:45- 9:00 | Sorting the mail, straightening desk, signing letters secretary typed previous afternoon (11). | 12:00- 1:00 | Lunch (21). |
| 9:00- 9:25 | Phone calls to manufacturers' representatives to decide type of refrigerator to purchase for lab (12). | 1:00- 1:25 | Holding educational staff conference to report on new drug (18). |
| 9:25- 9:45 | Letter to president of PTA about talk she wants given at organization's next meeting (5). | 1:25- 1:45 | Interviewing candidate for staff nurse position (14). |
| 9:45-10:00 | Visiting various sections of department (20). | 1:45- 3:10 | Travel to Lincoln School and filling in for physician at well child conference (10). |
| 10:00-10:10 | Coffee (21). | 3:10- 3:15 | Phone call from staff sanitarian seeking advice on closing restaurant (15). |
| 10:10-11:30 | Travel to mayor's office, meeting with him to discuss getting several agencies together to plan for medical defense service, return to office (1). | 3:15- 4:05 | Continuing well child conference and return to office (10). |
| 11:30-12:00 | Meeting with division heads to plan civil defense program (8). | 4:05- 5:30 | Outlining TB pamphlet with health educator (6). Then left for home. |
| | | 6:45-10:35 | Travel to and attending medical society meeting to give talk on school health program, travel home (3). |

The days were assigned so that each part of the month and each part of the week were represented.

The time study was administered in the following manner. One or two days prior to the scheduled beginning of the first 2-day period, two of the project's staff workers, who were interviewing members of the department, held a time-study orientation session with all selected participants. These sessions lasted approximately an hour and consisted of a presentation and explanation of the time-study code, a review of samples of completed time logs, and a "dry run" in which the participants coded and recorded activities for a typical day. Discussion and questions were encouraged. Then, on the first day of the time study a member of the research staff visited each participant in order to check on procedure and to answer any questions which might have arisen.

Secretaries of health department units were made responsible for the mechanics of administering the time study after the first month. They distributed the daily time logs, collected them after they had been completed, and forwarded them to the project headquarters. This procedure helped to keep the information confidential.

The cooperation of the participants was gratifying. More than 85 percent of the people who were asked to execute the final time-study instrument did so until completion of the study.

The time-log data were transferred to punch cards by the clerical staff of the research project and then machine tabulated. The research staff made analyses, for the State and the local health departments separately, of the average daily working time, of the proportion of time spent in the several major categories of activity, and of the relative number of individuals participating in these activities by service and by administrative level. In addition, the relationships between type of activity and level of education, public health training, and salary (as revealed in the interviews) were studied.

Conclusions

After a number of false starts, a method for a time study of public health personnel was developed. Experience with this method in one

State and in several local health departments indicates that the coding concepts involved are, with minor exceptions, sufficiently clear-cut to enable participants to keep accurate daily time logs with a minimum of effort and that, as a consequence, the time study can be easily and successfully administered. It was found, furthermore, that the accumulated time-log data lent themselves to expeditious analysis and yielded knowledge not heretofore available.

The present time study differs from previous similar studies of public health personnel in two important respects. The daily time log is a time scale, or time bar, which simplifies the mechanics of recording. The system of classification employed is built upon broad, functional categories of activity which are not limited to either specific programs or specific services.

It is believed that this time-study method can serve as an important instrument in public health research. When used in conjunction with well-planned interviews, possibly supplemented by spot observations, the time study can produce quantitative information fundamental to progress in public health administration.

Program Distribution of Working Time in Health Departments

By EDWARD M. COHART, M.D., and WILLIAM R. WILLARD, M.D.

EARLY in the Yale Public Health Personnel Research Project, a time study was conducted in the State health department and in eight selected local health departments in Michigan. The study was intended to determine the distribution of time according to (a) programs, (b) professional and administrative activities, and (c) persons with whom activities were carried on. The method used did not fulfill all these objectives, but it was possible to analyze the data for program distribution of time, in a fashion similar to that used by Milne and his co-workers in Mississippi (1). Moreover, the experience in Michigan contributed to the development of another time study method, as reported in a separate article (this issue of *Public Health Reports*, p. 570).

The Study Method

The time log used for this study was a simple instrument. It consisted of six blank columns: a narrow left-hand column headed "When: Time Started," a broad center column headed

"What, With Whom, and How," and four narrow right-hand columns headed "Travel," "Reports and Records," "Correspondence," and "Telephone." Instruction sheets included several sample time logs and suggestions for keeping the record. Each activity was to be reported by recording its starting time, its general nature in a one- or two-word summary, what was done, its purpose, how it was done, and with whom it was done. Time spent in travel, in reading and writing reports and records, in correspondence, and in telephone conversations for each activity was to be entered in the appropriate right-hand column. Activities were to be recorded to the nearest 5 minutes.

All full-time professional and semiprofessional personnel with the exception of secretarial and clerical workers performing routine tasks only and the staff of the State biological laboratory were eligible to participate in the study. When a number of workers in the same professional category in the same health department were performing essentially the same activities—school nurses with almost identical assignments, for example—only one of these workers was asked to keep a time record. The time allocations of this worker were then multiplied by the number of workers in the group.

Of 185 eligible workers in the State health department, 108 (58 percent) participated either directly or through a representative. This relatively low percentage resulted from the fact that only 29 percent of the laboratory personnel participated, as compared with 80 percent or more of the personnel in the other

Dr. Cohart and Dr. Willard were co-directors of the Yale Public Health Personnel Research Project. Dr. Cohart is associate professor of public health at Yale University, and Dr. Willard is now dean of the College of Medicine at Syracuse, State University of New York. The Yale project was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

services. With one exception, the laboratory participants were all workers in branch laboratories, the central laboratory having declined to participate in the study.

Of 181 eligible workers in the eight local health departments, 166 (92 percent) participated either directly or through a representative. The percentage of participating personnel in all services except the medical service was high, and even in the medical service 57 percent participated.

Thus, the eight local health departments are adequately represented in the sample, but the State health department sample is definitely biased by the exclusion of a major portion of the laboratory service.

The participants were asked to keep the time log daily for one week during the fall and winter months of 1951-52. It was felt that one week would be sufficient length of time to test the method used, which was the primary purpose of the study in Michigan. Recently, Milne and his associates (1) have reported, on the basis of a time study in Mississippi, that a reasonably accurate estimate of the distribution of time can be obtained from a 1-week sample, provided that an unusual week, such as one during the summer months, is not chosen.

Approximately one-third of the time of both State and local health department personnel could not be identified with a program, a proportion somewhat greater than the 29 percent of "interrelated time" found in the Mississippi study. It is believed that a truly discriminating instrument would yield a smaller residue of time which would defy program identification. The time log used in this study would appear to be less efficient than the daily time sheet with checklist used in the Mississippi study.

The time not identified with any specific program was allocated to specific programs according to the distribution of program-specified time. This was done for each service in the State and local health departments separately. The results are, therefore, comparable with the results that Milne reported for Mississippi on the basis of the distribution of "interrelated time according to the percentage distribution of total identified time." It is recognized that the validity of this procedure for allocating uncategorized time can be questioned, especially when it involves such a sizable proportion of the total time. However, in the absence of more accurate data, this would appear to be the only practical expedient. The results are shown in tables 1 and 2.

¹ Estimate on basis of the allocation of uncategorized time to program areas according to distribution of program-specified time.

Allocation of Time to Programs

In the State health department, 21 percent of the time is devoted to industrial hygiene, and a similar proportion of the time to venereal disease control. Ten to fifteen percent is spent in each of the following programs: environmental sanitation, acute communicable disease control, tuberculosis control, and maternal and child health, including school health. Dental hygiene and the chronic diseases, including cancer and heart disease, each accounts for 5 percent of the time. One percent of the time is devoted to mental hygiene, and 1 percent to civil defense.

In the local health departments, the greatest emphasis is on health programs for children. Thus, 27 percent of the time is devoted to school health; 16 percent to maternal and child health; and 3 percent to crippled children. Furthermore, it can be assumed that children are the major recipients of services in the programs for acute communicable disease control and for dental and mental hygiene. Ten percent of the time of personnel in local health departments is devoted to the former, and 2 percent to each of the latter programs. Environmental sanitation absorbs 22 percent of

the time. There is practically no industrial hygiene activity on the local level. About 13 percent of the time is devoted to tuberculosis control, and 2 percent to venereal disease control. Chronic diseases, including heart disease and cancer, account for 1 percent of the time.

Discussion

The authors do not possess the intimate knowledge of the situation in Michigan that would be necessary to evaluate the distribution of time shown by this study. Nevertheless, there appear to be a number of findings that call for investigation. It would seem, for example, that insufficient attention is being given to mental health and to the noninfectious diseases and disabilities of adult life.

The emphasis placed on any health department program is determined by such factors as the nature and magnitude of the problem, the knowledge and ability to do something about it, the need for organized social action for control, the interests and desires of individuals in authority and pressure groups, the availability of funds, and the dictates of tradition. It can be accepted as axiomatic that

services. With one exception, the laboratory participants were all workers in branch laboratories, the central laboratory having declined to participate in the study.

Of 181 eligible workers in the eight local health departments, 166 (92 percent) participated either directly or through a representative. The percentage of participating personnel in all services except the medical service was high, and even in the medical service 57 percent participated.

Thus, the eight local health departments are adequately represented in the sample, but the State health department sample is definitely biased by the exclusion of a major portion of the laboratory service.

The participants were asked to keep the time log daily for one week during the fall and winter months of 1951-52. It was felt that one week would be sufficient length of time to test the method used, which was the primary purpose of the study in Michigan. Recently, Milne and his associates (1) have reported, on the basis of a time study in Mississippi, that a reasonably accurate estimate of the distribution of time can be obtained from a 1-week sample, provided that an unusual week, such as one during the summer months, is not chosen.

Approximately one-third of the time of both State and local health department personnel could not be identified with a program, a proportion somewhat greater than the 29 percent of "interrelated time" found in the Mississippi study. It is believed that a truly discriminating instrument would yield a smaller residue of time which would defy program identification. The time log used in this study would appear to be less efficient than the daily time sheet with checklist used in the Mississippi study.

The time not identified with any specific program was allocated to specific programs according to the distribution of program-specified time. This was done for each service in the State and local health departments separately. The results are, therefore, comparable with the results that Milne reported for Mississippi on the basis of the distribution of "interrelated time according to the percentage distribution of total identified time." It is recognized that the validity of this procedure for allocating uncategorized time can be questioned, especially when it involves such a sizable proportion of the total time. However, in the absence of more accurate data, this would appear to be the only practical expedient. The results are shown in tables 1 and 2.

European Approaches to Aging

By WILMA DONAHUE, Ph.D., and CLARK TIBBITTS

AMERICAN PARTICIPANTS in the Third International Gerontological Congress in London who took advantage of the opportunity to observe programs for older people in the United Kingdom and in nearby countries came home inspired by the extent and variety of activity they found (1).

The appearance of large proportions of older people in the populations of European countries occurred about a generation earlier than in the United States. Hence, it is natural that these countries should have done a good deal of pioneering in meeting their needs. This brief report presents the highlights of activity in the countries with the most advanced approaches.

Financing the Later Years

Most European countries have federally operated contributory, work-connected pension

Dr. Donahue is chairman of the division of gerontology, University of Michigan. She organizes the annual conferences on aging sponsored by the university with the cooperation of Federal, State, and voluntary agencies and edits the series of conference proceedings. Dr. Donahue assisted in the programing of the Third International Gerontological Congress in 1954 and spent 3 months visiting leaders and programs in aging in 9 countries. Clark Tibbitts is chairman of the Committee on Aging, United States Department of Health, Education, and Welfare. He served as vice president of the Second International Gerontological Congress in 1951 and participated in the third congress as a representative of the Department.

systems similar to our Old-Age and Survivors Insurance, with supplementation through assistance grants. Eligibility is usually based on retirement from gainful employment or survivorship. Pensionable age for men varies from 65 years in Denmark, England, and Switzerland to 67 in Sweden and 70 in Norway.

Cash benefits are normally insufficient to meet all requirements, particularly those of persons with problems of infirmity, illness, living arrangements, or social isolation. Recognizing this circumstance, most countries offer many services and facilities on a community support basis, subsidized by either public or voluntary funds.

Medical Care

All European countries have infirm, long-term ill, and invalided older people who present an increasing demand for health services and custodial care. The United Kingdom, Norway, and Sweden are undertaking to meet medical needs through universal coverage schemes which guarantee the availability of the best the countries can afford. Denmark and Switzerland have health insurance schemes, compulsory for individuals in certain income brackets and administered by local societies, usually under the supervision of state authorities.

Most of the hospitals are community operated and many include special geriatric units. Frequently, especially in the Scandinavian countries, the chronic hospital or geriatric unit is a part of a total housing plan for old people. A special geriatric ward is to be found in Stockholm's Municipal Hospital.

Hospitals for the mentally ill are mainly

state-operated but are crowded and generally considered understaffed and inadequate in number. Some efforts are being made to make more effective use of present space since there is little construction in this field. In England patients who have become old in mental hospitals, but who no longer need special psychiatric care, are being released to live in special homes for the confused senile. Results thus far indicate that many such old people improve in the homelike, nonrestrictive atmosphere. In Amsterdam, plans are under way for a "transition hospital" for confused patients where treatment for physical and mental disorders will be carried out with the expectation that a significant proportion of the patients will be able to return to their homes instead of being committed. Cities in most countries have begun to establish outpatient health department services for the mentally ill.

Perhaps the most striking feature of medical programs is the emphasis placed on rehabilitation. Most hospitals have extensive facilities for thermal and mechanical therapy. Dictated in part by construction and operating costs, the underlying objective is to enable older people to remain functional and at least partially self-sufficient in their own homes. Accordingly, in addition to the hospital services, such aids as spectacles, hearing aids, dentures, occupational therapy, and chiropody are widely available in Great Britain, Scandinavia, and, to some extent, in Holland and Switzerland.

Home Services

Remaining in one's own home becomes possible for many old people because suitable housing and community services are becoming available. The principle of home living is rooted in several factors: the conviction that most want the dignity and the security it affords; the knowledge that people generally recover more rapidly at home; the costliness of hospital and domiciliary facilities.

Many infirm elderly people are enabled to remain at home, alone or with children, through the close integration of hospital and home medical services, visiting nurse, housekeeping help, night attendants, laundry and bath services, friendly visitors, community kitchens to which

older people may go for meals and from which meals are taken to elderly shut-ins. Even in France, where relatively little has been done for older people, these special home helps are available for a limited number of older people through money raised by the National Old People's Day. In Scandinavia, where home helps are being developed on both a paid and a voluntary basis, many people of the middle class are volunteering to go into the homes of older people needing domestic or other services and are ready to accept training for that work.

Community clubs for older people are becoming popular in England, Holland, and Switzerland but not in the Scandinavian countries, Germany, Italy, and France. In some communities vacations are provided, thus taking the old person out of his children's home for a few weeks a year.

Day hospital programs where old people receive treatment and take part in occupational therapy are common in the geriatric hospitals of England. Hostels and halfway houses relieve hospitals of patients who are mending but not yet ready to go home.

Many of these services are coordinated by the district medical officer of health. In the borough of Finsbury, London, the health officer has added an SOS card system. Older people living alone summon help by placing the card in the window. Neighbors notify the health department when such a card appears.

Housing and Living Arrangements

Both independent and group housing for pensioners have been developed in Europe in great variety. The Swedish Government makes it incumbent upon every community to provide housing for its elderly people. Government subsidies are generally available in most countries though, in some cases, communities have built such dwellings on their own initiative.

In all these countries there has been a good deal of experimentation ranging from single detached dwellings to large organized villages containing acute and chronic hospitals, communal dwellings for the frail, and individual modern apartments for the able-bodied. From many experiments a number of useful principles have emerged.

One of these is that the greatest possible degree of privacy should be afforded, preferably in one's own flat or apartment, or, at least, in a private room in a boarding or old age home. Some that have provided dormitory living are now being remodeled to afford individual rooms and apartments.

The second principle is that housing must be located in the city in proximity to friends and institutions and not in remote, rural locations. Most of the countries of northwest Europe are building housing to replace that knocked out during the war. Scattered through these developments, in single units or in blocks, are a good many flats, modern apartment buildings, and row houses built especially for older people.

The third principle, now taking hold, is that housing and medical facilities should be separated. Incorporation of a hospital into a housing development suggests illness, it is believed, and tends to make for expensive multiplication of facilities. Accordingly, new housing facilities are being built as housing, and attention is given to facilitating transfer to medical and custodial institutions if the need arises.

Institutional homes for the aged date back many years in Europe. Many of them are still in use and are heavily endowed by voluntary societies. While the newer homes are generally public facilities, there are still many being built by religious organizations and labor groups, especially in Holland and Germany.

One aspect of housing that strikes the observer is that adult children are expected to provide homes for their aged parents if at all possible. In Great Britain, almoners attached to hospitals and welfare agencies make great effort to achieve this arrangement. In Germany, Switzerland, Italy, and France it is a matter of expectation that the family will care for its older members. There is less emphasis in the Scandinavian countries upon keeping the old person at home, and attempts are made to place the older person under circumstances best for all ages concerned. In Denmark, adult children are legally liable for the support of their parents. Until recently, the pension program accommodated such economic pressure, but present difficulties have increased the need of the aged to depend on their children, with resulting friction and resentment on the part of

both generations. But in all countries, the home helps mentioned earlier have been developed, in part, to ease the burden on families trying to accommodate aged parents.

Activity Programs

The prevailing attitude in most European countries has been that older persons are worn out and eager to rest. Relatively little effort has been made to find new roles for retired people or opportunity for creative or recreational pursuits in housing projects or in old age homes.

Yet, there are some outstanding exceptions. One is the Finsbury employment scheme for the elderly, sponsored by the health department, in which older men and women of the community work 2 hours a day testing fountain pens, assembling electric switches, packaging bandages, and on other light work. Beyond the experimental stage, the workshop is now housed in its own modern building where it affords social contacts and income supplement to its workers.

Employment

Primarily to hold down pension costs but also to overcome worker shortages in some occupations, attention is being given to continued employment of older people. Pension systems contain financial incentives to remain at work. In Great Britain, a national commission is trying to correct the factors which make for inadequate utilization of older people's services. Employers are being urged to examine their practices to see whether more older workers can be engaged and retained.

Scandinavian countries have developed practically no recreational activities for older people. Currently, these countries are giving attention to the question of whether gainful employment should be further extended beyond age 65 and to the question of training for crafts in which there is already a rich background.

Organization

Public agencies and funds are involved in programs for older people to a much greater extent than in the United States. The princi-

state-operated but are crowded and generally considered understaffed and inadequate in number. Some efforts are being made to make more effective use of present space since there is little construction in this field. In England patients who have become old in mental hospitals, but who no longer need special psychiatric care, are being released to live in special homes for the confused senile. Results thus far indicate that many such old people improve in the homelike, nonrestrictive atmosphere. In Amsterdam, plans are under way for a "transition hospital" for confused patients where treatment for physical and mental disorders will be carried out with the expectation that a significant proportion of the patients will be able to return to their homes instead of being committed. Cities in most countries have begun to establish outpatient health department services for the mentally ill.

Perhaps the most striking feature of medical programs is the emphasis placed on rehabilitation. Most hospitals have extensive facilities for thermal and mechanical therapy. Dictated in part by construction and operating costs, the underlying objective is to enable older people to remain functional and at least partially self-sufficient in their own homes. Accordingly, in addition to the hospital services, such aids as spectacles, hearing aids, dentures, occupational therapy, and chiropody are widely available in Great Britain, Scandinavia, and, to some extent, in Holland and Switzerland.

Home Services

Remaining in one's own home becomes possible for many old people because suitable housing and community services are becoming available. The principle of home living is rooted in several factors: the conviction that most want the dignity and the security it affords; the knowledge that people generally recover more rapidly at home; the costliness of hospital and domiciliary facilities.

In all these countries there has been a good deal of experimentation ranging from single detached dwellings to large organized villages containing acute and chronic hospitals, communal dwellings for the frail, and individual modern apartments for the able-bodied. From many experiments a number of useful principles have emerged.

The habits and interrelationships of rodent species in the Hamakua District of Hawaii are found to be favorable to the perpetuation of enzootic plague.

Observations on Rats in an Enzootic Plague Region of Hawaii

LEO KARTMAN, Sc.D., and RICHARD P. LONERGAN, M.P.H.

THE INTERRELATIONS of different rodent species, their survival, movements, feeding habits and, in general, their ability to coexist are fundamental conditions for the maintenance and spread of wild rodent plague. Expert opinion considers that infection per saltum is operative under unusual circumstances, whereas the spread of the disease is primarily by contiguity, probably by "an accumulation of small movements among rodents" (1) and by normal dispersal (2-4). In a discussion of this problem, Davis (5) distinguished between intracolony and intercolony spread of plague among South African rodents and concluded that spread by the former method was more usual.

The extent of movement and the home range of small mammals generally has been found to be quite restricted (6-9) and the movement rate

of *Rattus norvegicus* is known to be very low in constant environments (10). Similarly, a study of rats in Hawaii indicated both limited movements and a restricted home range on the island of Oahu (11).

A project on methods for the control of fleas on wild rodents inhabiting an enzootic plague region on the island of Hawaii provided observations pertinent to a discussion of the relation of rat characteristics to the perpetuation of wild rodent plague.

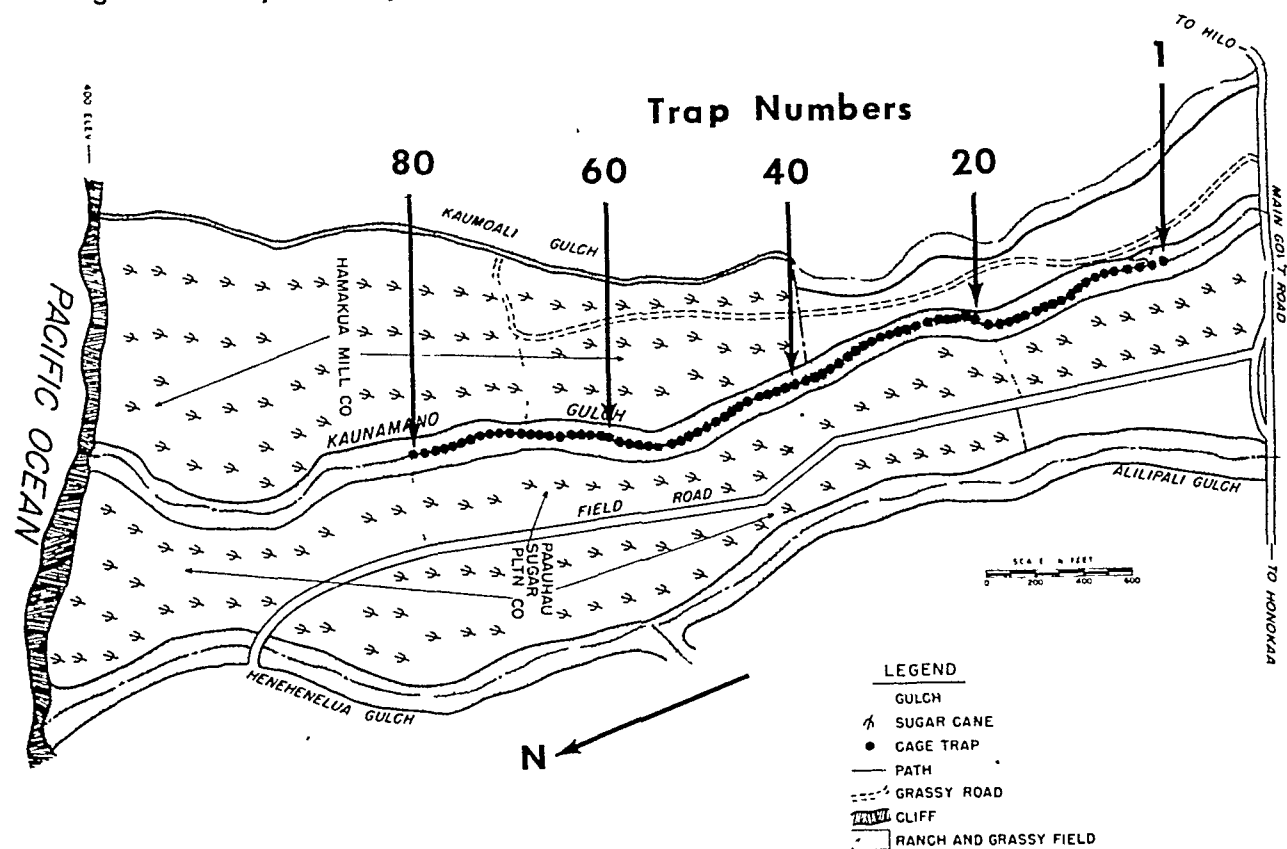

Study Areas and Methods

A detailed description of the study areas and materials and methods employed already has been presented (12). The work, which was concerned primarily with wild rodent flea control, was conducted from February 1952 to May 1953 in a field of sugarcane and in a gulch near the town of Honokaa, Hamakua District, Hawaii. Plague is both enzootic and endemic in this region.

Most of the work was done in Kaunamano gulch, one of numerous ravines bordered by sugarcane fields, grassy slopes, and small cultivated areas. Eighty trapping stations were established within an area of about 4,000 feet in the gulch, where the elevation ran from 400

Dr. Kartman, now medical entomologist with the San Francisco Field Station of the Communicable Disease Center, Public Health Service, was chief of the CDC Hawaiian Field Station during 1951-53. Mr. Lonergan also participated in the study and is now sanitary engineer at the Technical Development Laboratories of the center at Savannah, Ga.

Figure 1. Map of study area in Kaunamano gulch, showing the location of trap sites.

to 750 feet (fig. 1). Each station was supplied with cage traps at 50-foot intervals. The traps were similar to the kind shown in the report by Spencer and Davis (11).

At one time during the work, bait boxes were placed at intervals of 5 stations beginning with station No. 1. Rodent activity at these bait boxes was estimated on the basis of bait con-

sumption (12) and numbers of fecal pellets. The fecal pellets were counted and the boxes were thoroughly cleaned at each visit.

A small part of the work, lasting about 1½ months, was conducted in a field of sugarcane (field No. 1). This consisted of about 103 acres of mature cane at an elevation of from 200 to 900 feet. An area of approximately 40 to

50 acres around the periphery of the field was supplied with 200 cage traps at 35-foot intervals.

The traps were baited either with small coconut squares or small pellets made of commercial dog food mixed with rolled oats and wrapped in waxed paper. Rolled barley or rolled oats was used in the bait boxes in amounts that could not be completely consumed between visits.

In a few cases, traps were modified so that an attached clock would be stopped at the moment the trap trigger was released. By setting the alarm in the morning for 8 p. m., the time of capture could be determined by whether or not the alarm spring had unwound.

Captured rats were anesthetized with ether (rarely with chloroform), marked by toe amputation, combed for ectoparasites, checked for pertinent physical data, and released at the point of capture. The results of blood examinations and body temperature determinations have been published elsewhere (13, 14). Individual record cards were kept for each animal captured.

During the course of the major portion of the study, the rats were subjected to the effects of 10 percent DDT powder in pyrophyllite. During October and November 1952 the main effect of warfarin-poisoned oats was studied. The DDT appeared not to have a noticeable influence upon the rats. The warfarin decimated the commensal rat population, and data during this period have been eliminated for purposes

of the present report, unless otherwise indicated.

The pressure of other work prevented the use of a grid system of trapping and a more extensive study of the rodents in the plague region. Nevertheless, although the methods employed do not give the detailed results desirable in an investigation of rodent ecology, the data represent a definite contribution to the knowledge of rodent behavior in this region inasmuch as little or nothing has been published in this regard.

Results and Discussion

The four species of rodents found in the Hamakua District are: *Rattus rattus* subspecies *R. r. rattus* and *R. r. alexandrinus*; *Rattus norvegicus*; *Rattus hawaiiensis*, and *Mus musculus*. For present purposes, all subspecies of *R. rattus* are considered together and no data are presented on the house mouse. All of these species live wild in the field, but the native rat, *R. hawaiiensis*, is the only truly wild rodent in Hawaii—it lives only in the field and never in human habitation.

The number of rats of each species trapped during each month in Kaunamano gulch is shown in table 1. The predominance of *R. hawaiiensis* and *R. rattus* in this region corroborates a former study (15). The average number of rats of all species per acre in gulch areas of the Hamakua District has been estimated at

between 40-60 (15). Application of the Lincoln index (16)

$$\frac{\text{animals marked in precensus period}}{\text{other animals present in precensus period}} = \frac{\text{marked animals trapped in census period}}{\text{other animals trapped in census period}}$$

to some of the data recorded here showed, for example, that the estimated total populations of all rat species in the gulch study area during the periods July-August 1952 and January-February 1953 were respectively, 182 and 223. The actual number of captures of all rat species made during these periods was respectively, 110 and 109.

In another report (12), the commensal rat species, primarily *R. rattus*, were shown to be the predominant populations feeding at the bait boxes. The report also showed that bait consumption could be maintained at an almost constant level in the manner shown by Chitty

for *R. norvegicus* (17). The counting of fecal pellets may also provide a means of determining the population level (fig. 2). The generally greater abundance of small fecal pellets suggests that young individuals predominated among rats feeding in the bait boxes.

Rolled barley was used from the first baiting on May 21 to July 2. During this time the fecal pellet curve rose to a maximum and leveled off. However, on July 3 the bait was changed to rolled oats. This introduced two new factors—a change in the appearance and odor of the food, and a more highly processed food not requiring the time-consuming task of removing the hulls. Thus, many rats may have been shy of the new food for varying periods, and those that fed did not linger in the bait boxes as long as they had when the rolled barley was used. The result was a sharp drop in the fecal pellet curve which began to rise again as more rats adjusted to the new situation.

Figure 2. The number of fecal pellets removed from bait boxes at each visit and the effect of warfarin poisoning on this measure of rat activity.

¹ *Rattus rattus rattus* and *Rattus rattus alexandrinus*.

On August 11, a harvest of sugarcane in a field adjacent to the study area was initiated and lasted until August 22. This forced new rats into the gulch area, as was indicated by the trapping, and may be partially responsible for the rising curve of fecal pellets.

Finally, the introduction of warfarin-poisoned rolled oats on September 15 produced the second sharp depression in the curve. These considerations suggest that a controlled count of fecal pellets is a fairly sensitive index of a rat population level as it is influenced by various environmental factors.

No significant differences were found in the proportion of the sexes of the three rat species in either of the study areas (table 2). However, the paucity of *R. norvegicus* did not allow a valid comparison for this species.

Some idea of the survival of the rats can be obtained by an analysis of recaptures, or what amounts to the disappearance of retrappable rats over a period of time (18). These data indicate a high probability of disappearance for all three species (table 3). This corroborates findings on the island of Oahu (11). The reasons for the high disappearance rate are obscure and appear to contradict the fairly constant level of bait consumption (12) and rodent activity (fig. 2). Since an equal number of rats disappeared after their initial capture as were recaptured, some difficulty in retrapping appears to have influenced the results. Among the known factors, the inefficiency of individual traps and frequent springing of traps by mice, *M. musculus*, are probably of importance.

In field No. 1, where trapping lasted less than 2 months, almost 50 percent of the traps failed to capture a single rat, whereas captures of rats in Kaunamano gulch were more consistent (fig.

3). Although the establishment of trap-frequenting orientations by rats over a period of time is undoubtedly a factor in trapping success, the ecological difference between the gulch and field also may have been a factor since 100 percent of the stations became active in the gulch area in less than 2 months (12). However, a good deal of variation in success of trapping small mammals has been found to be correlated more with bait attractiveness than with population level (19). Thus, the above factors must be considered in an evaluation of rodent survival and other ecological factors.

The coexistence of several rodent species within the same environmental sector is undoubtedly of prime importance for the maintenance of wild rodent plague (20), and this idea is implicit in the observations of Eskey (21) in his classic study of plague epidemiology in Hawaii. Data published elsewhere have shown that all three rat species in Hawaii may be in-

duced to feed in the same bait box and are hosts to the same species of plague vector fleas and trypanosomes (12, 13). These findings are supported by data on the number of times all species of rats were captured in the same trap (fig. 4).

The number of each rat species attracted to any particular trap generally corresponded to the percentage species composition of the different rat populations in the area (table 1). Although thought to be extremely shy (22, 23), the Hawaiian rat predominated in the majority of trap captures. The probability that the time of feeding does not intervene as a limiting factor in this connection is suggested by a few data on the exact time rats were captured. The available records follow:

<i>R. hawaiiensis</i>		<i>R. rattus</i> group		<i>R. norvegicus</i>	
a. m.	p. m.	a. m.	p. m.	a. m.	p. m.
3:30	1:00	3:30	7:45	3:55	
5:17	3:20	4:53	11:30	5:40	
7:10	8:00	5:10	11:40		
	9:50	9:00			
	9:55				

There are enough overlapping times to suggest that many rats of each species undoubtedly seek food in the same area at approximately similar times. Whether or not there is any

serious interspecific competition, more aggressive species are present. The weaker are factors which have not been determined. All three species of rats live in very close proximity on the islands, and the possibility of predation on *R. hawaiiensis* was suggested.

The Hawaiian rat is thought to be a primary wild plague reservoir, and other species periodically become infected (24). The possible role of the *R. rattus* group, is not known, but this species is frequently taken in the traps and captures. The population in the study area was small. In the areas studied, there existed a community of rats composed of the species mentioned.

Other evidence of the stability of the nature of the rodent population was obtained by a study of recaptures of the rats. A summary of the recaptures is presented in table 4. The individual rat movements are not known. The restricted amount of movement of all three species of rats is not known, but much as these animals would be

Figure 3. Trapping efficiency as shown by frequency of live captures of rats by traps No. 1, and B—Kaunamano gulch.

Figure 4. The number of times three species of *Rattus* were captured alive in the same trap in Kaunamano gulch.

a small area until profound environmental change occurred. Thus, the following percentages of captures were made between 0 and 100 feet from the location of the original capture:

	Field No. 1	Kauna- mano gulch
<i>Rattus hawaiiensis</i> -----	74. 1	94. 6
<i>Rattus rattus</i> group-----	78. 2	80. 5
<i>Rattus norvegicus</i> -----	28. 5	71. 4
All spp. (both locations)--	86. 7	

This indicates predominantly exploratory rather than migratory movement. Few extreme movements were recorded. Two exceptions were: rat No. 130, a female *R. r. alexandrinus*, which was recaptured after 5 months 3,450 feet from the place of original capture, and rat No. 155, a male *R. norvegicus*, recaptured after 6 months 1,500 feet from the site of original capture.

It cannot be asserted that these movement data shed light upon the home ranges of the

various rat species since home range is a measure of area. In line with the contentions of Holdenried (25), many of the rat movements recorded here are probably measurements of maximal movement which is thought to represent the longest axis of a home range. It must be borne in mind that these so-called maximal movements are determined within the limits set by the arbitrary spacing of traps. In many cases they are probably only fair approximations of the true maximums.

The observations recorded here suggest that, in the region studied, the three species of rats do not carry out extensive migrations, are more or less sedentary populations, and appear to coexist in an environment which favors their close physical proximity with a minimum of adverse interspecific-coaction. These characteristics, together with observations already recorded regarding their ectoparasites and disease relationships (12, 13, 21, 24), appear to favor the perpetuation of wild rodent plague.

Summary

Observations are reported concerning wild rodents inhabiting areas within an enzootic plague region on the island of Hawaii. The rat species *Rattus hawaiiensis*, *Rattus rattus* subspecies, and *Rattus norvegicus* were captured alive, marked, released, and recaptured to gain some idea of their survival, movements, and interrelations. Results suggested that none of the rat species migrates extensively, that they constitute more or less sedentary populations, and that they appear to coexist in an environment which favors their close physical proximity. Thus, in the areas studied, there appears to be a continuous rodent population having characteristics favorable for the perpetuation of wild rodent plague.

A policy of kindness to patients, established a hundred years ago by the founders of the pioneer Federal mental hospital, survives the test of time and experience.

St. Elizabeths Centennial

By WINFRED OVERHOLSER

THE INSTITUTION known today as St. Elizabeths was established in Washington, D. C., 100 years ago, March 3, 1855, as the Government Hospital for the Insane. The change of names, a consequence of popular usage, is characteristic of a policy which has distinguished its practice since the great humanitarian, Dorothea Lynde Dix, penned the words which Congress approved in the basic legislation: "Its object shall be the most humane care and enlightened curative treatment of the insane of the Army and Navy of the United States, and of the District of Columbia."

The name St. Elizabeths was applied originally by early Maryland settlers to a tract of land which was occupied eventually by the hospital. When a part of the original building, now known as the center building, was used for surgical care of patients from the Union Army, it was called St. Elizabeths Hospital. Patients and staff eventually applied the gentle name to the entire institution. In 1868, Dr. Charles H. Nichols, the hospital's first superintendent, commented on the "happy circumstance that gave this establishment a designation of so much beauty and of such sacred association." In 1916, the Congress made the title official.

In the past 100 years, there have been many

advances in the care of the mental patient—technical, institutional, administrative, medical, legal, and social advances—with St. Elizabeths often in the forefront. The hospital has been the originator of many contributions to mental health. But its first contribution, the concept of kindness, formulated by Dorothea Dix, remains outstanding.

The atmosphere of kindness earned St. Elizabeths the title of "The Hospital with a Heart," from Sam Stavisky in an article published in *Colliers* magazine. The patients are given as much latitude as their condition warrants. They experience restraint only when they may injure themselves or others.

The administration of Howard Hall, the maximum security section of the hospital, reflects this policy in a place where it might seem least likely to succeed. The patients there, many of them under criminal charges, are considered to require close observation, yet they successfully conduct a limited form of self-government.

Once a month, the Howard Hall patients participate in an "administrative meeting," conducted by officials other than those engaged in treatment. It offers patients an opportunity to air their opinions and discontent and to have their suggestions and complaints discussed by fellow patients.

These patients also publish their own journal, a mimeographed magazine, edited, illustrated, and duplicated entirely by and written almost exclusively for patients in that hall. Last De-

Dr. Overholser is the superintendent of St. Elizabeths Hospital, Washington, D. C.

ember, the *Howard Hall Journal* reprinted from the *American Mercury* an article, "Medicine is Curing Me of Crime," written by its former editor. An example of a patient's contribution to the *Howard Hall Journal* is the brief statement on the following page, giving a patient's experience with, and reaction to, television programs.

Patients are encouraged to offer administrative suggestions and criticisms in their journal, and these suggestions are carefully reviewed by the superintendent for constructive guidance. This is true also of *The Elizabethan* published by and for patients in other branches of the hospital. Although the superintendent has found and used constructive suggestions in these publications, their pages are relatively free of critical comment.

Other contributions of St. Elizabeths have been reported elsewhere. St. Elizabeths pioneered the use of malaria fever for treatment of paresis, hydrotherapy, the use of a photographic department, pathologic museums as an adjunct of training, a psychological laboratory, forensic psychiatry, and the therapeutic value of the creative arts and crafts including the psychodrama. In 1942, St. Elizabeths was the first public mental hospital to use the psychodrama as developed by Moreno.

St. Elizabeths is today pursuing with high hopes the application of drugs which appear to bring about a therapeutic effect with their ability to quiet and relax the patients. On the other hand, it looks with great skepticism on such drastic therapies as shock treatment and lobotomy.

St. Elizabeths is distinguished, in another sense, by the fact that its chief administrator, the superintendent, has always been a professional psychiatrist. This practice conforms with the principles laid down by Dorothea Dix. The American Psychiatric Association has for years advocated that the administrative head of a mental hospital should be a psychiatrist. Superintendents of St. Elizabeths all have been honored with the presidency of the American Psychiatric Association.

The importance of having a professional psychiatrist at the head of any mental hospital is based on the principle that all details of administration are part of the psychiatric treatment.

The situation is not comparable with that of a general hospital. Every item of finance is subject to consideration by a physician of the effect on medical care of the patients. Although 40 percent of the staff of 2,500 have no direct contact with the patients, all contribute to the patients' welfare and receive some instruction as to behavior whenever they come in touch incidentally with the patients.

St. Elizabeths is a complex of more than 50 principal buildings occupying 360 acres on a hill across the Anacostia River. The view from its parks and porches surveys the Capitol, the Washington Monument, and the memorials to Jefferson and Lincoln. Its facilities include a firehouse, a library, a beauty parlor, several cafeterias, a private railroad for carrying coal to the steam plant, an incinerator, a police and fire department, a laundry, 9 kitchens, and a 400-acre farm a few miles away at Oxon Hill, Md. The assessed value of this property is in the neighborhood of \$18,000,000, although it could not be duplicated for that sum. The new geriatric building alone represents an investment of \$3,500,000.

The hospital population is in the neighborhood of 7,500. The admissions are approximately 1,500 a year; discharges are about 1,000 a year. A majority of the discharged patients leave after a stay of no more than a few months, although one patient recently was discharged as cured after 26 years' residence. Roughly, a fourth of those admitted have been patients in a mental hospital on earlier occasions.

A hundred years ago the official view was that not more than 250 beds should be the capacity of any mental hospital. The original plans for St. Elizabeths called for about 90 beds. But with the growth of the population, St. Elizabeths has reflected the increasing number of patients eligible for admission to St. Elizabeths. As noted originally the hospital was intended to accommodate only personnel from the defense forces and, incidentally, residents of the District of Columbia. Today it is authorized to receive patients from more than 20 sources, including Indian reservations, veterans from the Soldiers' Home, and others in beneficial relation to the Federal Government.

Scientific advancement in the treatment of mental patients has helped to offset the rise in

admissions. Effective treatment and prevention of paresis has reduced the number of patients suffering from that disease from about 6 percent of the admissions to almost zero. In common with other mental hospitals, St. Elizabeths has been receiving an increasing proportion of aged patients. Nearly 40 percent of the hospital's admissions today are persons above 60 years of age.

With the opening this summer of the new Dorothea Lynde Dix Pavilion, an admission and treatment building, there will be greater opportunity for improving diagnosis of patients upon admission. This will permit a greater degree of intense individual attention with the possibility that the patient may be cured and discharged that much more promptly.

In addition to the recognized psychiatric treatment, St. Elizabeths has long been known for its careful attention to the physiological basis of mental illness and for its generally comprehensive interest in patient health. It is the only public mental hospital in the United States which is approved for a rotating internship, in recognition of the high caliber of performance and equipment at its medical and surgical

building. Interns at this hospital do their pediatric and obstetrical and laboratory work at other hospitals.

In appraising the accomplishments of St. Elizabeths, it is difficult to assign credit to any particular technique. Studies of the value of psychotherapy are always difficult to frame. The response of the patient may result from a variety of factors. Although some techniques, such as drug therapy, appear to give a relatively clear-cut basis of evaluation, the complications of the individual personality frustrate most efforts at evaluation of treatment. Intensive attention to the individual is the key to improvement. This conviction dates back to the hospital's report for 1888 which regarded individual attention to the patient as more important than anything else.

No less important than the new diagnostic center, the Dix Pavilion, is the plan for revised and improved statistical methods of analyzing patients on a cohort basis. When this plan is applied, new facts will be ready to aid in the evaluation of mental hospital care. St. Elizabeths is confident that the facts will justify its traditional policy.

The World on a String

A mental patient's views on television are here reprinted with minor editorial change from the journal written and published by residents of Howard Hall, St. Elizabeths Hospital. They illustrate the character of creative expression in the Howard Hall Journal, and they suggest also the opportunity for evaluating the influence of TV programs on mental health, both in and out of the hospital.

This is one of those rare cases where the mountain comes to Mohammed. Only in this instance it is we, the hospital shut-ins, that are unable to go to the mountain, and it really isn't a mountain at all, it's the outer world. To us shut-ins, the world is divided into two parts, our own little isolated inside world and the outer world of people free to pursue their ends. One of the major problems to a shut-in is not that he is a shut-in, but rather that the outer

world is shut out. Perhaps most of us can understand and accept the fact that because of varying degrees of mental illness we are, out of necessity, shut-ins, but what many of us find so difficult to accept and understand is why so much of the outer world is shut out. Fortunately, we are not alone with our problems, for the administrative doctors of Howard Hall are well aware of our dilemma as evidenced by their unceasing efforts to bring to us as

much of the outer world as is practically possible. Certainly they are aware of our psychological need for contact with the outer world. One of the steps taken by the administration has done more to alleviate this situation than all others combined.

They presented us patients with the world on a string. They have brought the outer world, in all its entirety, into our recreational day rooms!

An ordinary, common garden variety electric world is the string that is tied to the world which in turn is encased in a small, square box: a television receiver! With a twist of the wrist and a flip of a dial, the outer world flows to meet our eyes! Mohammed's mountain was mere child's play in comparison with our wondrous little box. Instantaneously we are in the midst of a downtown crowd watching the parade of the Legionnaires, or we are riding in a brand new 1955 auto or watching the sports attraction of the day. There's the news and we are in Korea and then swiftly join a group of firemen in Chicago; then on to Washington for a meeting with the President and his Cabinet. We see the latest fashions and meet the outstanding personalities of the day. All of these things would be impossible were it not for this amazing little box.

One would think that the ability of this small box to bring the outer world to us is miracle enough, but no; it doesn't stop there. It goes beyond just mechanical function. It has dynamic effect on our morale, attitude, and emotions. It assumes a therapeutic role in every sense of the word. The rollicking laughter

that echoes down the hall when favorite comedians perform, the anxiety expression that comes with suspense and the intentness of concentration that comes with drama and quiz show are emotional entertainment. Our miraculous box constantly reminds us that there are comfortable living rooms with families gathered around a dinner table; that there are happy people, situations and circumstances. This serves to jar us out of the "just existing" attitudes and probes and jabs at our slumbering will to get well and "go home." It serves as a deterrent to keep the mind from becoming single tracked or in a rut or as some of us say, "institutionalized."

For it brings to us, at the exact moment, events that are taking place; it expands our isolated little community until it is as vast in scope as is the outer world. To those of us who are convalescing, it helps to prepare us for our return to society. It keeps us abreast of the times and the pulse of things so that when we do reach this outer world it is not a strange and unfamiliar place to adjust to. It gives its viewers a mutual sense of participation and interest. Educationally, its lessons are extensive in that it teaches us and gives plenty of practice in dem-

ocratic relationships with our fellow men. The selection of TV committees, scheduling programs, and the operation of the TV set help form the habit patterns of cooperative group spirit, teaching us to respect the other fellow's opinions, rights, and privileges.

In pausing to consider the significant role TV plays in our shut-in world, one can readily agree that this ingenious little box should never be taken for granted or underestimated. And in realizing the importance of TV, we should also take precautionary measures to insure its continued future use. A deeper sense of responsibility for this "World on a String" should be accepted by us all. We must all adjust ourselves to our neighbors' desires, opinions, and preferences so that all of us may enjoy the benefits of it without infringing upon the rights and privileges of fellow patients. In doing this we not only create more viewing pleasure for ourselves and others but we insure continued performance by our mechanical friend. Most important, it will give all of us practice and experience in getting along in a community of people. It will have its therapeutic effect and this is of primary concern to us shut-ins.

PHS Staff Announcements

Dr. Louis C. McCabe has been appointed staff adviser on air pollution to Mark D. Hollis, Assistant Surgeon General and chief engineer officer of the Public Health Service. Since 1951, Dr. McCabe has been chief of the Fuels and Explosives Division, Bureau of Mines, Department of the Interior. He served for 2 years as director of the Los Angeles County Air Pollution Control District.

Arthur C. Stern, formerly chief industrial hygiene engineer of the New York State Department of Labor, has assumed direction of the Public Health Service program of air pollution research and technical assistance to States and local agencies. He will be stationed at the Robert A. Taft Sanitary Engineering Center, Cincinnati.

The Health Maintenance Clinic Program of the Fife-Hamill Memorial Health Center.

By GULDEN MACKMULL, M.D., HYMAN MENDUKE, Ph.D., and JOSEPH J. CAVA, M.D.

A HEALTH maintenance clinic was established in 1948 at the Fife-Hamill Memorial Health Center by the department of preventive medicine of the Jefferson Medical College of Philadelphia.

Persons presumed to be healthy were to be registered at the clinic for periodic physical examination and instruction in health habits and proper hygiene as well as advice on environmental, economic, and personal problems relating to the early detection of health hazards or prodromes of disease.

The existence of the clinic was publicized by local South Philadelphia newspapers, parent-teacher associations, handbills taken home by school children, and by public health nurses.

A comprehensive history and environmental

details were obtained for each individual on his first visit to the clinic. This was followed routinely (1) by a complete physical examination, including pelvic examination in women, a complete blood count, urinalysis, serology for syphilis, stool examination for parasites, and X-ray of the chest. Special laboratory tests were made when indicated. As far as practicable, home visits were made by public health nurses accompanied by senior medical students of the medical college. These contacts permitted a personal appraisal of pertinent environmental factors which influenced the final disposition of cases.

After the initial examination, recommendations concerning the patient were given. If no disorders were discovered, the person was offered advice calculated to help maintain health, and he was urged to return for reexamination, usually within a year. When some disorder was discovered, pertinent suggestions were made, and the individual was referred to his personal physician, hospital clinic, or to an appropriate agency best suited for handling the particular problem.

The time elapsing between the initial and the return visit depended on the individual situation. At most it was a year. At this second examination, recommendations were reiterated, or new advice was offered if necessary. All persons were notified by mail several weeks before the date of the reexamination; notification was frequently repeated by a telephone call the day before the appointment date.

Drs. Mackmull, Menduke, and Cava are closely associated with the Jefferson Medical College of Philadelphia and with the college's health maintenance clinic program at the Fife-Hamill Memorial Health Center. Dr. Mackmull, assistant professor of preventive medicine, is chief of clinic and director of the division of clinical preventive medicine at the center. The associate director, Dr. Cava, is instructor in medicine and clinical assistant in preventive medicine. Dr. Menduke, assistant professor of biostatistics, serves the health maintenance clinic as statistical consultant. The center is located at Sereneth and Delancey Streets, Philadelphia.

Area Served by the Clinic

Most of the patients included in this study lived in the section of Philadelphia between Chestnut and Mifflin Streets on the north and south and between the Delaware River and Broad Street on the east and west. This area in southeast Philadelphia has a total population of about 110,000, and the age, sex, and race composition is similar to that of the city as a whole. Roughly four-fifths of the population in both the clinic area and the city are white; the clinic area has, however, a higher proportion of foreign-born individuals, among whom Italians predominate. Approximately two-thirds of the white residents and practically all the nonwhite residents are financially eligible for the service of the clinic. Eligibility for clinic services is restricted to persons whose annual income is \$3,500, or less.

This part of the city is generally recognized as one of the worst problem areas in Philadelphia. It is characterized by poverty, lack of education, inadequate housing and sanitation, as well as by high morbidity and mortality rates (2-4).

The First Clinic Visit

This report is based on a study of the first 1,500 consecutive patients who made their initial visits to the clinic between September 1948 and February 1953. These patients included 207 white men, 1,050 white women, 29 nonwhite men, and 214 nonwhite women, representing respectively 0.8, 4.1, 0.4, and 2.7 percent of the financially eligible population in each group.

Women predominated in every age group, with highest representation among white women 20 to 49 years old and nonwhite women 12 to 19. In general, individuals 50 years and older were poorly represented in the clinic census.

The individual's motivation for clinic attendance was either asked specifically of each patient or deduced from his history. Despite the admitted unreliability of this method, patients were considered subjectively "ill" if they knew of the existence of a specific illness or sought aid because of definite complaints. They were considered subjectively "well" if no specific complaint was volunteered.

If the individuals' statements can be trusted, almost half believed themselves "well" and actually came for health maintenance. The percentage who considered themselves "well" was slightly higher for white men than for white women and considerably higher for the younger than for the older persons in both racial groups.

The higher proportion of younger individuals in the clinic census who thought they were in good health may be attributed either to health consciousness indoctrinated recently in school or to the fact that young persons are really more healthy. Despite the poor representation of nonwhite persons, nonwhite women, 12 to 19 years of age, had a relatively high representation in the clinic census. A large proportion of this group came to the clinic presumably in good health.

It is not particularly surprising that 97 percent of those who considered themselves ill on the first visit really required medical attention. However, it is highly significant that three-fourths of the presumably well white men and practically all the presumably well women, particularly those 20 years of age and over, were found also to need medical care.

In all, 93 percent of the allegedly well really required treatment. Of all 1,500 patients, only 75, or 5 percent, were found to be free of medical, dental, or mental conditions. But 127 individuals, or 8 percent, could be considered in this category if caries of the teeth and pregnancy were not included as conditions warranting treatment. As was expected, the percentage of persons requiring medical attention was lower for the young than for the old, lower for men than for women, and lower for white than for nonwhite persons.

While the clinic was able to inform 23 persons that they were laboring under a misapprehension in believing themselves to be ill, 655 who thought they were well actually required medical guidance. Hence, there is no question as to whether the health maintenance clinic is fulfilling its purpose in the early detection of disease.

Number of Diseases Per Patient

Commonly a patient requiring medical help suffered from more than a single disorder.

The Health Maintenance Clinic Program of the Fife-Hamill Memorial Health Center.

By GULDEN MACKMULL, M.D., HYMAN MENDUKE, Ph.D., and JOSEPH J. CAVÀ, M.D.

A HEALTH maintenance clinic was established in 1948 at the Fife-Hamill Memorial Health Center by the department of preventive medicine of the Jefferson Medical College of Philadelphia.

Persons presumed to be healthy were to be registered at the clinic for periodic physical examination and instruction in health habits and proper hygiene as well as advice on environmental, economic, and personal problems relating to the early detection of health hazards or prodromes of disease.

The existence of the clinic was publicized by local South Philadelphia newspapers, parent-teacher associations, handbills taken home by school children, and by public health nurses.

A comprehensive history and environmental

details were obtained for each individual on his first visit to the clinic. This was followed routinely (1) by a complete physical examination, including pelvic examination in women, a complete blood count, urinalysis, serology for syphilis, stool examination for parasites, and X-ray of the chest. Special laboratory tests were made when indicated. As far as practicable, home visits were made by public health nurses accompanied by senior medical students of the medical college. These contacts permitted a personal appraisal of pertinent environmental factors which influenced the final disposition of cases.

After the initial examination, recommendations concerning the patient were given. If no disorders were discovered, the person was offered advice calculated to help maintain health, and he was urged to return for reexamination, usually within a year. When some disorder was discovered, pertinent suggestions were made, and the individual was referred to his personal physician, hospital clinic, or to an appropriate agency best suited for handling the particular problem.

The time elapsing between the initial and the return visit depended on the individual situation. At most it was a year. At this second examination, recommendations were reiterated, or new advice was offered if necessary. All persons were notified by mail several weeks before the date of the reexamination; notification was frequently repeated by a telephone call the day before the appointment date.

Drs. Mackmull, Menduke, and Cava are closely associated with the Jefferson Medical College of Philadelphia and with the college's health maintenance clinic program at the Fife-Hamill Memorial Health Center. Dr. Mackmull, assistant professor of preventive medicine, is chief of clinic and director of the division of clinical preventive medicine at the center. The associate director, Dr. Cava, is instructor in medicine and clinical assistant in preventive medicine. Dr. Menduke, assistant professor of biostatistics, serves the health maintenance clinic as statistical consultant. The center is located at Seventh and Delancey Streets, Philadelphia.

Area Served by the Clinic

Most of the patients included in this study lived in the section of Philadelphia between Chestnut and Mifflin Streets on the north and south and between the Delaware River and Broad Street on the east and west. This area in southeast Philadelphia has a total population of about 110,000, and the age, sex, and race composition is similar to that of the city as a whole. Roughly four-fifths of the population in both the clinic area and the city are white; the clinic area has, however, a higher proportion of foreign-born individuals, among whom Italians predominate. Approximately two-thirds of the white residents and practically all the nonwhite residents are financially eligible for the service of the clinic. Eligibility for clinic services is restricted to persons whose annual income is \$3,500, or less.

This part of the city is generally recognized as one of the worst problem areas in Philadelphia. It is characterized by poverty, lack of education, inadequate housing and sanitation, as well as by high morbidity and mortality rates (2-4).

The First Clinic Visit

This report is based on a study of the first 1,500 consecutive patients who made their initial visits to the clinic between September 1948 and February 1953. These patients included 207 white men, 1,050 white women, 29 nonwhite men, and 214 nonwhite women, representing respectively 0.8, 4.1, 0.4, and 2.7 percent of the financially eligible population in each group.

Women predominated in every age group, with highest representation among white women 20 to 49 years old and nonwhite women 12 to 19. In general, individuals 50 years and older were poorly represented in the clinic census.

The individual's motivation for clinic attendance was either asked specifically of each patient or deduced from his history. Despite the admitted unreliability of this method, patients were considered subjectively "ill" if they knew of the existence of a specific illness or sought aid because of definite complaints. They were considered subjectively "well" if no specific complaint was volunteered.

If the individuals' statements can be trusted, almost half believed themselves "well" and actually came for health maintenance. The percentage who considered themselves "well" was slightly higher for white men than for white women and considerably higher for the younger than for the older persons in both racial groups.

The higher proportion of younger individuals in the clinic census who thought they were in good health may be attributed either to health consciousness indoctrinated recently in school or to the fact that young persons are really more healthy. Despite the poor representation of nonwhite persons, nonwhite women, 12 to 19 years of age, had a relatively high representation in the clinic census. A large proportion of this group came to the clinic presumably in good health.

It is not particularly surprising that 97 percent of those who considered themselves ill on the first visit really required medical attention. However, it is highly significant that three-fourths of the presumably well white men and practically all the presumably well women, particularly those 20 years of age and over, were found also to need medical care.

In all, 93 percent of the allegedly well really required treatment. Of all 1,500 patients, only 75, or 5 percent, were found to be free of medical, dental, or mental conditions. But 127 individuals, or 8 percent, could be considered in this category if caries of the teeth and pregnancy were not included as conditions warranting treatment. As was expected, the percentage of persons requiring medical attention was lower for the young than for the old, lower for men than for women, and lower for white than for nonwhite persons.

While the clinic was able to inform 23 persons that they were laboring under a misapprehension in believing themselves to be ill, 655 who thought they were well actually required medical guidance. Hence, there is no question as to whether the health maintenance clinic is fulfilling its purpose in the early detection of disease.

Number of Diseases Per Patient

Commonly a patient requiring medical help suffered from more than a single disorder.

Some had as many as 7. The modal and median number was 2. This was true whether or not dental caries and pregnancy were included. There were only 52 individuals for whom the sole finding was caries or pregnancy, or both. In most cases, caries or pregnancy or both conditions were found in conjunction with other complaints. Including caries and pregnancy, the 1,500 patients reported here accounted for 3,288 medical conditions. If dental caries and pregnancy are excluded from the computation, the number is reduced to 2,906.

Table 1 shows no striking differences either between races or sexes in the incidence of multi-

² Percentages not computed when there were fewer than 20 patients.

ple illnesses. There was, however, a disparity between the sexes with respect to the presence or absence of disease: A higher proportion of the men were found healthy. As was anticipated, the incidence of multiple disease increased with the age of the patient. Boys and girls in the 12- to 19-year-old age group tended to have no illness or only one. Adults in the 20- to 49-age group tended to have 1 or 2 disorders and in the 50 and over category 2, 3, or more diseases.

Medical conditions found in the 1,500 individuals are tabulated in table 2. Obviously not all conditions could be itemized separately. Frequency of incidence constituted the main criterion for the compilation of this table, which follows a topographic classification (5).

A wide variety of medical conditions was observed, a substantial number of which were discovered in patients who were unaware of their medical problems.

For example, all cases of cervical erosion, cervical polyps, ovarian cysts (4 patients), cancer (3 patients), hypochromic anemia, intestinal parasites, gastric ulcer, and cholecystitis were diagnosed as a direct result of the efforts of the clinic. In addition, between three-tenths and nine-tenths of all uterine tumors, chronic cystic mastitis, dental conditions, malnutrition, diabetes mellitus, syphilis, hypertension, valvular heart disease, and goiter were presumably unknown to the patient before his first clinic visit.

Although such subdivision into conditions known and unknown to the patient is admittedly subject to error, there is little doubt that without the clinic examination a substantial number of illnesses would have been discovered only at a more advanced stage.

Referrals After First Visit

Although 1,500 persons accounted for 3,288 medical conditions, the number of individual referrals, 2,842, was smaller, since the hospital or family physician, could in many instances take care of more than one complaint (see table 3). The number of referrals ranged from none in the 75 healthy clients to as many as 5 for the patients needing treatment.

For the healthy person a variety of advice

was given. He was admonished, for example, to restrict or omit smoking or alcoholic beverages. Suggestions were offered, or actual arrangements were made with various agencies for a more appropriate job. Interviews with schools or special vocational training classes were arranged, and appointments were made

with officials of the Philadelphia Department of Public Assistance for conferences on increased financial aid.

The mode was 2 referrals per patient. The most frequent referrals were those made for services available in hospitals and for consultation with the nutritionist and gynecologist at the health center.

Return Visits

For a health maintenance clinic to be of greatest benefit, it is essential that return visits be made periodically. Therefore, it is of great interest to examine the record of the appointments which were kept or broken during the study period. It is equally important to compare the return attendance of those, the apparently healthy, who were told they did not need treatment with those, found to be ill, who were actually referred to some agency for therapy.

The 75 healthy individuals were given a total of 160 appointments for return visits. Thirty-three of these appointments, 21 percent, were kept, and 23 persons returned at least once.

The 1,425 ill patients received 3,857 appointments and actually kept 1,255, or 32 percent.

These return visits were tabulated through 1953.

It would appear that although neither group was particularly conscientious about keeping appointments for reexamination, the ill patients were somewhat more regular than the healthy. Records often showed that clients

Table 3. Disposition of 1,500 cases

¹ Includes 30 individuals who had never worn eyeglasses before. ² Primarily clinic referrals but includes 24 referred to psychiatrist.

would miss one appointment but would keep the next appointment. Therefore, an individual who kept an appointment within 2 years of this tabulation (1952 and 1953) was considered as still being served by the clinic. By the same reasoning, anyone failing to keep an appointment for 2 years was presumed to be separated from the clinic.

Obviously, the health maintenance clinic was able to do little for those who never returned for periodic examinations. A total of 37 percent of the healthy and 33 percent of the ill fell into this category. These figures exclude individuals who made their initial visit within 2 years of the termination of this study.

It is encouraging that more than half of the 1,500 individuals are still currently associated with the clinic. The record is somewhat better for the healthy than for the ill—57 percent for the former and 51 percent for the latter.

Of the 23 healthy individuals who were re-examined, only 6, or 26 percent, were found to have remained healthy on every return visit. It is impossible to say from present data whether this is a high or a low percentage. The figure is higher than the 5 percent who were found healthy on the first visit, but the comparison is not a fair one.

Evaluation of Results

Despite the convenient location of the Fife-Hamill Memorial Health Center in a problem area, only a small percentage of the financially eligible population availed itself of the services of the health maintenance clinic. A number of probable reasons for the low attendance can be advanced.

Known, or suspected, presence of illness is a powerful stimulus for an individual to seek medical attention. He accepts, usually without question, the therapeutic measures offered by a hospital outpatient department or by his private physician. On the other hand, a health maintenance clinic offers only a combination of health education, assurance, and personal interest on the part of the staff. Thus, such a program does not sell itself as readily as that of a conventional clinic.

The dental profession has been rather successful with its slogan "See Your Dentist Twice a Year." Well-baby clinics are now firmly estab-

lished. However, a similar program with respect to a "well-adult" clinic has not yet won wide acceptance among the general population or the medical profession. Therefore, before it can hope to succeed, the program offered by an adult health maintenance clinic must be sold and resold to the public over a number of years. One way is to have the public health nurse visit frequently the homes of actual or potential clients in order to explain the importance of periodic physical check-ups. When such contact is reduced or discontinued, the attendance of a health maintenance clinic suffers.

A professionally organized and properly executed health education program is essential for the operation of a health center. Such a program in full operation would enlist more clientele and assure a larger percentage of return visits. Lack of funds alone has prevented the Fife-Hamill Memorial Health Center, in general, and its health maintenance clinic, in particular, from enjoying such a program.

Periodic examinations are essential for a program of health maintenance. The overall number of return visits at the clinic was discouragingly low. Only 1 out of 5 appointments was kept by those healthy on the first visit and 1 out of 3 for those classed as ill on the first visit. Encouraging is the fact that half of all patients returned at least once. An additional 16 percent may yet return since their initial visit was made within the last 2 years.

Such a clinic may attract patients initially through publicity and maintain attendance to some extent through the efforts of the public health nurse. In the long run, however, clinic growth depends on word-of-mouth referrals by satisfied clients. The number of new patients should increase each year. Our program fell short in this respect. During the period covered, the number of new patients each year remained quite constant with an average of approximately 340.

The low attendance of men is difficult to explain. Only 8 of each 1,000 eligible white men came to the clinic, but the rate for white women was 5 times as high. Among nonwhite persons, where preventive medicine is most needed, men were even more poorly represented. Perhaps of importance is the inconvenience of attending the clinic during working hours, despite the fact

that many employers allow employees to attend clinics without loss of pay.

It is quite probable that 26 percent (6 out of 23) is a biased estimate of the proportion of the clinic census who remained healthy on every return visit. An individual who continues to feel well would be no doubt less likely to return than one who becomes aware of symptoms. No control group is currently available for comparison, and we are unaware of available figures for similar programs. In order to draw a proper conclusion, it would be necessary to trace the history of a similar group of healthy people to whom no health maintenance advice was given. In any event, the period covered by this study is quite short.

Early detection of disease, while ordinarily thought of as a correction rather than prevention, is preventive medicine in the sense that more serious developments are forestalled, or their effects are minimized. Medical conditions were discovered in 93 percent of the individuals who thought of themselves as well before examination showed they were not. The clinic seems, therefore, to have fulfilled its secondary role quite satisfactorily since without examination most conditions probably would not have been discovered until a more advanced stage.

Patients requiring treatment were referred to various agencies (table 3) since no therapy was given at the health maintenance clinic. Because financial eligibility for clinic attendance precluded accepting patients whose annual income exceeded \$3,500, it is not surprising that only 30 (1 percent) were referred to private physicians. Utilization of readily available facilities in nearby hospitals has become habitual with many of these families. Individuals requiring nutrition services were referred to the health center nutritionist since practical dietary guidance programs are not usually available in hospitals. The exceptionally large number of gynecologic consultations can be explained by the predominance of women in the child-bearing age (68 percent of the clinic census) and by the routine inclusion of pelvic examinations.

Occasionally, criticism has been made of a health maintenance clinic in that a false sense of security may be given to those not found to be ill. Periodic health examinations are essential if disease is to be discovered in the presymp-

tomatic stage. A false sense of security on the part of the patient is avoidable by including in the recommendations an explanation of the limitations of predictive diagnosis.

Summary and Conclusions

A health maintenance clinic for adults was established at the Fife-Hamill Memorial Health Center, Philadelphia, by the department of preventive medicine of the Jefferson Medical College of Philadelphia. The primary and secondary purposes of the clinic were the maintenance of health and the early detection of disease by means of periodic examinations of presumably healthy adults in the lower income population of the area served. Considered a health problem area, the geographic site served by the clinic is characterized by low levels of education and income, by substandard housing, and by high morbidity and mortality rates.

This study represents an analysis of the first 1,500 consecutive patients who consulted the clinic initially between September 1948 and February 1953. Return visits were tabulated through 1953. These patients represent only a small proportion of the financially eligible population of the area (annual income below \$3,500). White women 20 to 49 years of age predominated in the clinic census.

On the first visit to the clinic, although half of the patients thought of themselves as being well, almost every patient required treatment of some kind.

These 1,500 persons accounted for more than 3,000 conditions with mode and median of 2 per person. Multiplicity of conditions increased with age.

Only 75 persons (5 percent) appeared in good health and required no specific medical treatment.

Roughly half of all patients actually returned at least once for reexamination. An additional 16 percent visited the clinic initially within the past 2 years.

Of 23 healthy patients who were examined 1 or more times, only 6 were found to have remained healthy.

Because of insufficient data and lack of a control group, the role played by this clinic in

the prevention of disease remains equivocal. The success in early detection of disease appears established.

There is need for more concerted effort toward education in health maintenance through cooperation with private practitioners, school and public health agencies, hospitals and clinics, churches, social agencies, employers and other persons interested in public health.

Legal Note on Procedural Due Process

In *L. A. Darling v. Water Resources Commission*, 67 NW 2d 890, decided January 12, 1955, by the Supreme Court of Michigan, an order of the State commission was held invalid on the ground that the alleged polluters had not been afforded procedural due process.

The record of the "hearing" before the commission covering pollution of underground water disclosed that witnesses were not sworn, that no exhibits were identified, and that the commission relied on materials and data which were not introduced at the hearing and made no findings of fact.

The court said:

"The legislature's right under the police power to regulate the contamination of waters of this State is not in question, but the exercise of such power does not obviate the necessity to recognize the due process clauses of our State and Federal Constitutions. When the legislature created a 7-man commission, composed of 4 State officials and 3 citizens, it undoubtedly expected it to conduct a proper and legal hearing before issuing an order, such as was issued in this case, that appellant change its method of doing business at an expenditure of a large sum of money.

"The legislature provided for an appeal from the decision and order of the commission to the circuit court and that said appeal would be determined in chancery as a trial *de novo*. This provision did not obviate the necessity of a proper legal hearing before the commission. It did not contemplate that the failure of the commission to hold a proper hearing should be corrected by appeal. The legislature gave to the court the right and duty to pass judgment upon the decision and order of the commission based on the record of such proceedings before said commission."

When exposed to running sea water, the clam uses its own filtering system to cleanse itself of sewage bacteria ingested in polluted waters. How this is accomplished was demonstrated in a series of experiments conducted by the Shellfish Sanitation Laboratory.

Self-Purification of the Soft Clam *Mya arenaria*

By WILLIAM ARCISZ and C. B. KELLY

DURING the past decade the supplies of the soft clam, *Mya arenaria*, have become seriously depleted. Attempts made by biologists (1) to increase clam populations to their former abundance by establishing clam farms and reseeding depleted areas have met with little or no success. However, large supplies of clams in areas which are polluted with domestic sewage are available.

The possibility of ridding shellfish of undesirable bacteria has been given some attention ever since epidemiological evidence indicated that shellfish from waters subject to fecal pollution were responsible for enteric disease (2). That polluted shellfish can be made safe for human consumption by the process of purification has been adequately demonstrated by Fabre-Domergue (3), Wells (4), and Dodgson (5).

Purification is a mechanical process effected

by the physiological functioning of the shellfish in clean water. When shellfish are feeding, the gills act as a filter to strain out some of the material that may be brought in by the water which passes through them. If this water contains sewage, some of the micro-organisms in it are entrapped in the mucus on the body of the shellfish and transferred to the alimentary tract. Some of these are perhaps utilized as food (6) and the others discharged from the body in the form of feces and pseudofeces. When shellfish from polluted water are placed in clean water, the sewage bacteria are eliminated from the shellfish, and, since no more are ingested, purification is accomplished.

Two purification processes, based on the ability of shellfish to cleanse themselves, have been evolved:

Natural purification or relaying. Shellfish from polluted areas are transplanted into clean waters and allowed to purify themselves. This method of natural purification is widely used in the oyster industry. However, many biological factors combine to make it generally infeasible for use with soft clams.

Artificial purification or cleansing. Shellfish from polluted areas are placed in tanks which are filled with water that has been sterilized by filtration, chlorination, or by ozone. The water

Mr. Arcisz is bacteriologist at the Public Health Service Shellfish Sanitation Laboratory, Pensacola, Fla., and Mr. Kelly is chief of the laboratory. Other studies in this series of reports on shellfish experiments conducted by the laboratory have appeared in Public Health Reports, August 1954 (p. 716) and December 1954 (p. 1205).

may be drawn and replaced or recirculated after sterilization. The shellfish are kept in these tanks until purified. Cleansing of polluted clams has been practiced in Massachusetts for a number of years (2, 7).

Investigations by Galtsoff (8), Sandholzer (9), Dodgson (5), and others (10) have shown that shellfish are extremely sensitive to chlorine, slight amounts slowing down or completely inhibiting molluscan physiological processes. The Public Health Service Shellfish Sanitation Laboratory at its Woods Hole, Mass., location therefore undertook the investigation of purification rates of soft clams, using clean sea water obtained from a normally pollution-free source. The source of this water was Great Harbor, a sheltered continuation of Vineyard Sound, in Woods Hole, Mass.

Biological Activity of the Clam

The biological activities of the clam are of particular importance in considering pollution and purification of this species of shellfish.

The clam lives in burrows on the marine bottom between the high-water mark and as far as the 40-fathom mark. Although a substantial quantity of clams are taken in 1 to 2 fathoms of water, the bulk of the commercially available supply is obtained from the intertidal zone, that is, between the high- and low-water marks.

The clam obtains its food from the overlying water. Buried in the soil, the clam extrudes its "neck" which contains two connected tubes, the inhalant and exhalant siphons. The water which enters the inhalant siphon flows into the mantle chamber, passes through the basketlike gills and thence out of the exhalant siphon.

In addition to the function of respiration, the gills of the clam are used for food collecting. The gill filaments are lined with microscopic cilia which strain out minute forms of animal and plant life which serve the clam as food. These minute forms, when caught by the cilia, are bound together with mucus and normally transported by ciliary action to the edge of the gills and thence to the mouth by way of the labial palps. After passing through the stomach and intestine, the fecal material is extruded near the inner opening of the exhalant siphon through which it is discharged into the water.

The clam can protect itself from taking extraneous or noxious matter into its stomach. It can either close its siphon, or, if the noxious matter has entered the siphon, expel it by forcibly ejecting the matter as pseudofeces out of the inhalant siphon; or it can transport noxious matter by ciliary action away from the palps and thrust it out of the mantle at the pedal opening.

In view of this, it is quite obvious that the bacterial content of a clam is dependent on the bacterial density of the water in which the clam is resident and to a large degree on the amount of water the clam passes through itself. No data are available as to the exact amounts of water a clam filters in 24 hours. However, the work of Galtsoff (11), Loosanoff (12), and others indicates that, although there are individual differences in animals, an oyster may pass a maximum of 3.9 liters to a maximum of 20 liters per hour under normal conditions.

Temperature of the surrounding water plays an important role as to the amount of water an oyster or quahog will filter. Observations of Galtsoff (13) and Loosanoff (14) indicate that oysters become almost inactive at 6° C., or below. In contrast, the work of Belding (15) and Marston (16) demonstrates that clams are active and will "drink" for considerable periods at a water temperature below 39° F. (3.9° C.).

An important aid to sanitation is the fact that, just as the clam ingests bacteria, so, if placed in pure water, it will eventually free itself from bacteria. The question of primary interest is: How long does this take?

In order to answer this question, two series of experiments were conducted. The first of these experiments was made to determine the role of water pumping activity of the clam on purification. The second series of experiments was made to determine whether temperature of the water had any effect on the purification rate of clams.

Water Pumping Activity

The amount of water pumped through a shellfish is a factor in how rapidly an animal can be polluted and, conversely, how rapidly it can be purified. Unfortunately, no adequate methods are available for measuring the amount

of water which the clam can pump through itself. Insertion of tubes into the inhalant and exhalant siphons by surgical means for the purpose of measuring water flow, although feasible, is not satisfactory, since the ciliary action of these apertures is disturbed.

The carmine cone method of Galtsoff (17) and the corneal method used by Dodgson (5) and by Marston (16), which can be used to indicate pumping, were not considered suitable for use in our experiments. Since it is not feasible to measure quantitatively the amounts of water pumped through a clam, the most practical index of pumping activity appeared to be "openness" or "closedness" of the inhalant and exhalant siphons. For our purposes, an animal was considered to be pumping when its inhalant and exhalant siphons were open, and not pumping when both these orifices were closed.

It can be pointed out that this method may not be an accurate measure of pumping activity, if an analogy with measurement of pumping activity of oysters by the use of shell movement is made. Kymograph records, using "shell movement" as a measure of pumping activity, would indicate the passage of large volumes of water through an animal. However, observations of Loosanoff and Engle (18) on feeding of oysters, indicated that, under unfavorable conditions (heavy concentrations of organisms in the water), there was no correlation between the amount of water pumped and the kymograph record of shell movement. In their studies, they used the rubber dam technique of Nelson (19) by which the amount of water passed through an oyster can be accurately measured.

In our experiments, clams of 2½ to 3 inches in length were obtained from a commercial source and placed in an upright position in numbered, gridded trays, containing 98 to 144 animals. After being exposed to polluted water for 3 to 6 days, the clams in the trays were brought into the laboratory and washed with clean sea water. The trays were then placed into a wooden aquarium containing flowing sea water which was kept at all times 3 inches higher than the uppermost portion of the clam shells.

At 15-minute intervals the clams were ob-

served for activity, which was noted as active or inactive. Owing to the sporadic activity of individual clams, it was difficult to obtain "lots" of shellfish which were 100 percent "active" and 100 percent "inactive" for any protracted length of time. Therefore, for sampling purposes, it was found necessary to class clams showing the least activity as inactive and clams which showed the least inactivity as active samples.

The average results of two clam purification runs conducted at temperatures from 17.5° C. (63.5° F.) to 18° C. (66° F.) are illustrated in figure 1.

It can be seen that coliform content of the more active animals is reduced more rapidly than that of the less active animals for the first 5 hours. However, it can be noted that after the 5th hour the "active" clams became progressively less active and the "inactive" clams conversely became more active, so that at the end of 14 hours the "active" group was inactive for 2½ hours and the "inactive" group had been active for 3 hours. This probably explains the fluctuations in the coliform content of the "active" and "inactive" clams from the 5th to the 14th hour. In the 14 hours of observation, there was enough activity even among the less active animals to effect a significant reduction of bacteria.

Temperature Effect on Purification

Marston (16) has shown that *Mya arenaria* can actively feed at water temperatures below 39° F. (3.9° C.) and even at 35° F. (1.7° C.), and that it can ingest bacteria as readily at 37° F. (2.8° C.) as at 73° F. (22.8° C.).

Studies soon to be published, conducted by the Shellfish Sanitation Laboratory, in which the rates of accumulation of pollution in oysters (*Crassostrea virginica*), quahogs (*Venus mercenaria*), and clams (*Mya arenaria*) were studied, show that there is a correlation between the amount of pollution accumulated and the temperature.

In view of these observations, a series of six experiments was conducted at Woods Hole during 1952 and 1953 to determine whether temperature had the same effect on the purification rate of clams as it did on their pollution.

Escherichia coli was chosen as the representa-

tive coliform organism. Since no data are available on the rates of cleansing of enteric pathogens from clams, *Salmonella schottmuel-leri* was chosen as a representative of this group. *S. schottmuel-leri* proved to be an excellent indicator organism for these studies, since our purification waters, usually of excellent bacterial quality, were occasionally subject to coliform pollution.

These studies were conducted in a small-scale purification plant (fig. 2). Clams from a commercial source, measuring between 2½ to 3 inches in length, were placed in heavy wire trays supported by 2-inch metal legs. Fifty clams were placed in each tray. Four trays were then placed in a wooden aquarium containing a wooden dam. The capacity of the aquarium was 200 liters of sea water, maintained at a height of 3 inches over the uppermost portions of the clam shells. The clams were held in this aquarium for a 48-hour acclimatization period

during which they were continuously bathed with flowing sea water. Dead and weak animals were removed and replaced with healthy ones during this period of time.

At the beginning of each experiment the aquarium was drained and accumulated detritus on the clams and in the aquarium flushed out by a gentle hosing with sea water. The trays of clams were removed, and the aquarium was refilled with 200 liters of sea water. Bacterial suspensions of *E. coli* and *S. schottmuel-leri*, calculated to give the overlying water a density of 10,000 *E. coli* and 1,000 *S. schottmuel-leri* per 100 milliliters, were added. After a thorough mixing of the water, the 4 trays containing a total of 200 animals were placed in the aquarium. The animals were allowed to "drink" the polluted water for a period of 6 to 10 hours. The aquarium was drained and the shellfish placed in enamelware buckets and stored overnight. The aquarium and trays used in the

Figure 1. Effect of activity on reduction of coliforms in active and inactive clams. Numbers in parentheses indicate time in hours active or inactive.

Figure 2. Pilot clam purification plant.

pollution were sterilized for 1 hour with chlorinated water maintained at 100 p.p.m. residual. The sterilized material was then rinsed by flowing sea water for a period of 18 hours.

After overnight storage at room temperature, the clams were replaced in the wire trays and immersed in the aquarium. The rate of flow of sea water was adjusted to 200 liters per hour, or 1 liter per animal per hour. This flow of water was maintained for the duration of the experiment.

To insure that no viable salmonella would be discharged into the receiving harbor, the effluent water from the purification tank was chlorinated by a solution-feed hypochlorinator. Sufficient chlorine was applied to produce a residual of at least 10 parts per million after a detention time of 2 hours in a series of 2 baffled, effluent treatment tanks.

With the exception of a few minor modifications, the bacteriological methods used for the examination of clams and water were those recommended by the American Public Health Association (20). Quantitative estimation of bacterial densities was conducted by the dilution method in which at least 4 decimal dilutions—5 tubes for each dilution—were used.

The method for enumerating *S. schottmuel-leri* involved enrichment in Galton's (21) modification of Kauffman's brilliant green tetrathionate broth, with isolation of typical colonies from brilliant green agar. The test was completed by confirmation on Russell's double sugar agar, with occasional confirmation serologically, using salmonella group B antiserum.

The test for enumerating coliforms consisted

of preliminary plantings in lactose broth, with confirmation in brilliant green lactose bile broth.

Results of tests for both organisms were expressed as most probable numbers (MPN) per 100 milliliters, according to Hoskin's tables (22).

Samples of clams and overlying waters were

Figure 3. Purification of soft clams—Experiment 1. Water temperature range 2.5–4° C.

taken at designated intervals and examined for the presence of coliforms and salmonellae. Sampling was terminated when two consecutive samples showed the absence of salmonellae in the lowest dilution planted.

Results of Experiments

The results of these experiments are presented in a series of six figures.

Figures 3 and 4 show the results of experiments conducted at water temperature ranges of 2.5°–4.0° C. (36.5°–39.2° F.) and 3.5°–4.5° C. (38.3°–40.1° F.).

Figures 5, 6, 7, and 8 give the results at temperatures of 13° C. (54.5° F.), 15° C. (59.0° F.), 18° C. (64.4° F.), and 20° C. (68.0° F.), respectively.

Figure 4. Purification of soft clams—Experiment 2. Water temperature range 3.5–4.5° C.

Figures 3 and 4, illustrating the reaction of clams to purification at low temperatures, indicate that the reduction of coliforms in both experiments is similar. There is a similarity in

the rapid initial drop and the subsequent leveling off. Although the initial concentration of *S. schottmuelleri* is roughly 10 times less in experiment 1 than in experiment 2, the time required for complete purging of this organism is 3 and 4 days, respectively.

Figure 5. Purification of soft clams—Experiment 3. Water temperature 13° C.

Figure 5 shows that at 13° C. clams containing an initial concentration of 17,000 coliforms and 3,300 *S. schottmuelleri* were purged of the latter in 2 days. No explanation for the indeterminate level of less than 18 coliforms per 100 milliliters which was effected in 3 days can be made, in view of other experiments in which the coliform content of the water was generally low, other than perhaps the clams were more active during this experiment.

Figure 6 shows the results of an experiment in which there were no apparent differences in the physical or biological quality of the water from that illustrated in figure 5, other than a 2-degree rise in temperature. Animals containing an initial concentration of 7,900 coliforms

Figure 6. Purification of soft clams—Experiment 4. Water temperature 15° C.

and 4,600 salmonellae per 100 milliliters showed a rapid decrease of both organisms. However, the clams showed presence of salmonellae for 5 days. Complete purging occurred between the 5th and 7th days.

Figure 7 shows that clams having an initial concentration of 22,500 coliforms and 3,300 salmonellae were purged of salmonellae in 48 hours. The coliform content decreased but fluctuated with the water coliform content.

Figure 8 illustrates the effect of occasional pollution of an otherwise satisfactory water supply. Clams containing an initial concentration of 33,000 coliforms and 6.1 salmonellae per 100 milliliters were rid of the salmonellae in 24 hours. Although a reduction of coliforms in the clams did occur, it is not as rapid or as great in magnitude as that occurring in experiments in which the coliform-load of the purifying water was lower.

Discussion

The data which have been presented in this report demonstrate that contaminated clams can be purified by exposure to a continuous flow of clean sea water. There is a suggestion that the activity of the clams may play a part in the length of time required for purification. However, even the least active animals studied showed significant decreases in bacterial loads within the purification time employed in the usual clam treatment processes. It is also apparent that the clam can purify itself as effectively at 2.5° C. (34.5° F.) as it can at 20° C. (68° F.). The initial concentrations of polluting organisms used appear to have no influence so far as the length of time necessary for purification is concerned. That enteric pathogens, as represented by *S. schottmuelleri*, can be purged from contaminated clams has been adequately demonstrated. However, although these

Figure 7. Purification of soft clams—Experiment 5. Water temperature 18° C.

data indicate that purification is feasible, a discussion of certain regulatory, economic, and esthetic aspects of clam purification is indicated.

The use of water containing a chlorine residual of 0.05 p.p.m., or more, for purification of shellfish (23) is not supported by the findings of Dodgson (5), Galtsoff (8), Sandholzer (9), nor of the Massachusetts Special Commission Investigating Shellfish Purification (10), which demonstrated that chlorine, even in small amounts, can interfere with or inhibit molluscan physiological processes.

During our experiments, the coliform content of polluted clams usually was reduced to, or below, the recommended limiting coliform MPN of 2,400 per 100 milliliters (23) in 24 hours or less. Because this level of purification was accomplished with water of low coliform content, there is little doubt that using a water of drinking water quality, as recommended in the Public Health Service manual (23), a coliform MPN considerably less than 2,400 could be at-

tained. *S. schottmuelleri* was usually present in the clams in substantial numbers at the time the limiting coliform value was attained. However, at 24 hours and thereafter, *S. schottmuelleri* was irregularly present and only in small numbers at low and medium temperature purifications. Whether the demonstration of these salmonellae at irregular times after 24 hours' purification was due to recontamination of the clams with organisms retained in the experimental apparatus or whether the salmonellae were continuously resident in the animals cannot be determined at this time, and therefore the sanitary significance of their presence is in question.

The economic aspects of shellfish purification are a limiting factor. Finding a source of pollution-free water near areas where polluted clams are found is somewhat of a problem. In most instances, natural waters close to areas where polluted clams are found are not suitable for purification purposes without preliminary

Figure 8. Purification of soft clams—Experiment 6. Water temperature 20° C.

sterilization. This is true in Massachusetts, where clam purification is being practiced at this time. Even if pollution-free waters are found, sporadic pollution of these waters makes the use of naturally clean waters unfeasible for purification purposes. Data gathered at Woods Hole have shown that waters of excellent bacterial quality are on occasion subject to sporadic pollution which can only be related to aquatic birds or runoff from terrestrial sources. However, the problem of finding a pollution-free source of water has been remedied at Conway, England, where water sterilized by chlorine and then dechlorinated has been used with considerable success for purifying mussels.

The efficacy of purification has been questioned from an esthetic viewpoint. It has been compared with dirty milk, containing large numbers of bacteria, which has been pasteurized.

Referring to mussel purification, Dodgson (5) states:

"The analogy between purification of polluted shellfish with the pasteurization of dirty milk would appear to be unsound. In the case of dirty milk, although pathogenic bacteria are, or should be killed by the process of pasteurization, nothing is actually abstracted from the milk, the 'dirt,' of whatever nature, e. g., faecal matter, and so forth—remaining therein. In other words, the milk remains a dirty food. In the case of mussels, however, the whole of the solid matter which they may contain in the intestines or elsewhere, e. g., faecal matter of sewage origin, etc., is eliminated by the shellfish, and got rid of by hosing."

Summary and Conclusions

Polluted clams can be purified by exposure to running sea water of low coliform content, according to experiments conducted at the Public Health Service Shellfish Sanitation Laboratory, when it was located at Woods Hole, Mass.

Activity of the clam may play a part in the length of time required for purification. However, even the least active animals studied showed significant decreases in bacterial loads within the purification time employed in the usual clam treatment processes.

The clam is able to function and purify itself at water temperatures of 2.5° C. (34.5° F.) to 20° C. (68° F.).

The recommended coliform MPN of 2,400 per 100 milliliters for cleansed clams can usually be attained in 24 hours or less.

It has not been determined whether the few *Salmonella schottmuelleri* irregularly observed after 24 hours' purification were derived from organisms in the experimental apparatus and water or from those retained in the animal bodies.

Purification time was not materially influenced by the initial pollution loads in the clams used in these studies.

PHS films

Fundamentals of the Human Blood Groups

35 mm. filmstrip, sound, color, 15 minutes, 70 frames. 1954.

Audience: Pathologists, laboratory technicians, nurses, medical students, and physicians.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

The fundamentals of blood typing are explained by symbols and stylized drawings in this filmstrip

The genetics of blood groups and the incompatibility of the various groups together with a description of "sensi-

tization" are features depicted. Precautions in giving transfusions are emphasized.

All these blood group systems are inherited in a simple Mendelian manner.

The serum of the B group individual always contains anti-A antibodies.

technical publications

Comprehensive Dental Care in a Group Practice

Public Health Service Publication No. 395. 1954. 48 pages. 25 cents.

Presented is a study of time and service requirements for giving complete dental care on a fee-for-service basis to patients who were members of Group Health Association, Inc., a prepayment medical care program in Washington, D. C.

In the study group were 1,925 persons of all age groups, including approximately equal numbers of males and females. Participation of individual patients during the 5-year period of the study averaged approximately 25 months. Initially each participant received treatment for all accrued needs and was subsequently sustained in a state of good dental health by periodic maintenance care.

United States Participation in International Health

Public Health Service Publication No. 416. 1954. 24 pages; illustrated.

Through charts and explanatory notes, this pamphlet illustrates the role of the United States in the improvement of world health conditions. The United States has been concerned with health problems in other countries since 1902, when it participated in the development of the Pan American Sanitary Bureau. In 1942, the United States embarked upon its first bilateral technical assistance programs through the Institute of Inter-American Affairs. These programs are now conducted by the Foreign Operations Administration with the Public Health Service, through its Division of International Health, providing active support to the health components of the program.

The FOA-PHS health program is active in 38 countries in underde-

veloped areas, and its activities cover a wide spectrum. Primary emphasis is placed on training nationals and on controlling malaria, smallpox, yaws, and gastroenteric and parasitic diseases.

The pamphlet also describes the activities of the World Health Organization and the relationship of the Public Health Service to the participation of the United States in this international organization.

State Mental Health Programs Planned for Fiscal 1954 and 1955

Public Health Service Publication No. 374. 1954. 37 pages. 30 cents.

Presented is a cross-section view of how the national health program is being advanced in the States. In addition to abstracts of State mental health program plans, it summarizes major needs and administrative problems pertinent to such programs. Included is a State by State listing which identifies the responsible administrative unit designated by each State as its mental health authority. The text is based on information supplied by the States.

It's Good Business to Know Your Men

Public Health Service Publication No. 379. 1954. 12 pages; illustrated. 10 cents.

Mental health in industry is the subject of this new publication, which suggests how the foreman or supervisor can help to foster a healthy job environment for his workmen by understanding and applying basic mental health principles. It also suggests that he, as a key person, can best help the worker who has emotional problems by using tact and understanding rather than play-

ing the role of "amateur psychiatrist." Since the mental health of a person depends to a great extent on how he gets along in the work situation, the booklet is designed for both management and labor.

An Industrial Waste Guide to the Meat Industry

Public Health Service Publication No. 386. 1954. Prepared by the Committee on Meat Packing Plant Waste Disposal of the American Meat Institute in cooperation with the National Technical Task Committee on Industrial Wastes and the Public Health Service. 12 pages. 15 cents.

Industrial wastes which cannot be eliminated must be disposed of in a suitable manner to protect the Nation's water resources. This pamphlet discusses the sources, quantity, and character of meat industry wastes, the water pollution these wastes can cause, and remedial measures for the control of meat industry pollutants. It is designed primarily as a practical guide for operating and design personnel within the industry itself.

This publication is a revision of the original guide prepared in 1943 by the Public Health Service and published in supplement D of the report, Ohio River Pollution Control. It is the second of a series of industrial waste guides prepared by the National Technical Task Committee in cooperation with the Public Health Service, as a part of the joint government-industry program to reduce water pollution through control of industrial wastes.

How to Study Nursing Activities in a Patient Unit

Public Health Service Publication No. 370. 1954. 48 pages. 25 cents.

How much nurses' time is being diverted from patients to details that other personnel can do? This manual gives a method hospitals can use to study the time distribution of all nursing personnel assigned

technical publications

to inpatient units. The method is similar to that described in the published manual dealing with the head nurse, entitled "The Head Nurse Looks at Her Job." The new manual is intended to help hospital administrators with the next logical step—gathering the information needed to plan better staffing of inpatient units—with the hope that it will save them the time required to devise their own study methods.

The method provides for a sampling of the activities of personnel every 15 minutes. It will provide reliable information on the activities that take the most time and a general picture of the kinds of activities performed by each category of personnel.

Prenatal Health Examination Legislation—Analysis and Compilation of State Laws

Public Health Service Publication No. 369, 1954. 55 pages. 25 cents.

The Venereal Disease Program of the Public Health Service has compiled the laws requiring prenatal blood tests for syphilis which are now in effect in 42 States and 3 Territories. This publication reproduces these laws from the various legal reference sources of the States and Territories and includes citations for these sources.

In addition, the pamphlet contains a table showing the approval and effective dates of prenatal laws for each of the included States and Territories. It also reprints a paper entitled "Prenatal Health Examination Legislation—History and Analysis," by Laura M. Halse and Dominic V. Liberti. The original of the paper appeared in the February 1954 issue of *Public Health Reports*, pp. 105-110.

At the time the publication went to press, Alabama, the District of

Columbia, Maryland, Minnesota, Mississippi, Tennessee, Wisconsin, and Puerto Rico did not have prenatal laws requiring blood tests for syphilis.

Handbook on Sanitation of Vessel Construction

Public Health Service Publication No. 393, 1954. 70 pages; illustrated. 30 cents.

Superseding "Principles of Sanitation Applicable to the Construction of New Vessels" dated June 1949, this handbook contains the minimum public health standards relating to the general sanitation and ratproofing of new vessels and vessels undergoing major reconstruction.

Included in the text are standards for the construction of potable water systems, wash water systems, overboard water systems, pressure water connections, food service spaces, plumbing, swimming pools, and crew and passenger accommodations.

The publication is prepared especially for the use of naval architects, shipbuilders, vessel-operating companies, the industries supplying materials and equipment for vessels, and others interested in sanitation aboard ship.

Occupational Health and Safety Legislation

Public Health Service Publication No. 357. 315 pages. \$1.25.

Intended as a source of legislative reference, this compilation consists of citations and excerpts or digests of laws and regulations dealing with occupational health and safety. It represents a comprehensive revision of a multilithed publication entitled, "Industrial Health Legislation—a

Compilation of State Laws and Regulations," which was issued in limited quantity in 1950.

The present publication includes laws enacted up to and during the first half of 1953. Information on safety inspection and prevention of accidents has been included because lack of uniformity in the usage, coverage, and interpretation of such general terms as "health," "safety," and "sanitation" made it impossible to draw a sharp line of demarcation. No attempt has been made to evaluate the adequacy or effectiveness of the various provisions.

Pertinent information is given for all 48 States, the District of Columbia, Alaska, and Hawaii.

Laws dealing with selected aspects of worker health and safety were examined for the following State agencies: departments of health, labor, industrial relations, agriculture, and education; industrial accident commissions; bureaus and inspectors of mines; public utilities commissions; and a few others, such as State fire marshals for laws regulating health and safety in dry-cleaning establishments.

Selected subjects covered in the provisions include the following: authority and functions of agencies, general provisions relating to occupational health and safety, employment of women and minors, mines and mining, reporting of occupational diseases and injuries, workmen's compensation, vocational rehabilitation, and air pollution and nuisance control.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

The lessons learned from an environmental study of a radium therapy clinic and a medical study of its staff may be applicable to any institution using radioactive materials.

Radioactive Contamination *in a radium therapy clinic*

By ROBERT G. GALLAGHAR, MITCHELL R. ZAVON, M.D.,
and HENRY N. DOYLE

THE PROPOSED REMOVAL of a radium therapy clinic in Baltimore, Md., to new quarters in 1952 presented the city's health department with an unusual and interesting public health problem: the need for assessing the radioactive contamination about the premises occupied by the clinic. Consequently, at the request of the health department's bureau of industrial hygiene, the Occupational Health Program, Public Health Service, assisted in making an environmental study of the clinic building and a medical study of its staff. Although radium therapy clinics are relatively

uncommon in the United States, the lessons learned from this experience seem to warrant a brief report.

Historical Note

The clinic was organized in 1904 and made its first purchase of radium in December of that year. At one time, it possessed 5 grams of radium, then the world's largest single, privately owned supply. In 1914, the clinic started a radon emanation and purification plant to prepare radon applicators for therapeutic use. At that time the health hazards associated with radium were not fully appreciated, and practices that now would be considered extremely dangerous were then the normal procedure. It was not until 1918 that a radiochemist was employed to supervise the radon plant and chemical laboratory.

During the early years, the lack of more than minimal safety precautions may have been responsible for the death from aplastic anemia of 1 and possibly 2 radon pumpers. The radio-

Mr. Gallagher, now with the Liberty Mutual Insurance Co., Boston, was formerly a health physicist with the Occupational Health Program, Occupational Health Field Headquarters, Public Health Service, Cincinnati, Ohio. Dr. Zavon is with the Occupational Health Program in Cincinnati, and Mr. Doyle is chief of the Occupational Health Program, at the headquarters office in Washington, D. C.

chemist had a nearly fatal attack of the same disease at about the same time, and soon thereafter additional safety precautions were instituted. Since that time no health damage has been reported.

Over the years, radon applicators were collected and given to various research laboratories for investigative purposes. Lord Rutherford and Sir James Chadwick, noted British physicists, used material from the clinic in their early work, which led to the discovery of the neutron (1). Thus, indirectly, the institution played an important role in the development of atomic energy.

The Physical Plant

The clinic had been continuously located in a converted three-story brick, duplex residence. At one time, an adjacent building was used as a hospital for inpatient care. One-half of the clinic's duplex building was used primarily as offices and service rooms, and the other half housed laboratories and treatment rooms. Immediately behind and connected to the duplex was an added wooden structure which, on the second floor, contained a radiochemical laboratory and preparation, surgical, and treatment rooms. The radon emanation plant was contained in an elevated brick vault in the rear of an adjacent garden and was connected to the wooden structure by a walkway.

Two fires in recent years had gutted the wooden structure, and the latter of the fires had severely damaged the main building as well. Radiochemical equipment was involved in the second fire.

Basic Physics

To insure that the reader understands the physical basis of the report, the pattern of radium decay is shown in table 1. Commencing with uranium and proceeding by natural radioactive decay processes to stable lead, the radioactive elements produce various radiations. Each of the elements has its own characteristic half-life, that is, the time in which one-half the material originally present will have decayed to the next lower substance in the series.

Radon, the seventh radioisotope in the series,

Table 1. The radium decay series

Radio-element	Historical name	Symbol	Half-life
Uranium--	Uranium I--	${}_{92}\text{U}^{238}(\text{UI})$	4.51×10^9 years.
Thorium--	Uranium X ₁ --	${}_{90}\text{Th}^{234}(\text{UX}_1)$	24.1 days.
Protactinium--	Uranium X ₂ --	${}_{91}\text{Pa}^{234}(\text{UX}_2)$	1.14 minutes.
Uranium--	Uranium II--	${}_{92}\text{U}^{234}(\text{UII})$	2.32×10^5 years.
Thorium--	Ionium-----	${}_{90}\text{Th}^{230}(\text{Io})$	8.3×10^4 years.
Radium---	Radium-----	${}_{88}\text{Ra}^{226}$	1,600 years.
Radon---	Radon-----	${}_{86}\text{Rn}^{222}$	3.825 days.
Polonium--	Radium A--	${}_{84}\text{Po}^{218}(\text{RaA})$	3.05 minutes.
Lead-----	Radium B--	${}_{82}\text{Pb}^{214}(\text{RaB})$	26.8 minutes.
Bismuth---	Radium C--	${}_{83}\text{Bi}^{214}(\text{RaC})$	19.7 minutes.
Polonium--	Radium C'--	${}_{84}\text{Po}^{214}(\text{RaC}')$	1.5×10^{-4} seconds.
Thallium--	Radium C''--	${}_{81}\text{Tl}^{210}(\text{RaC}'')$	1.32 minutes.
Lead-----	Radium D--	${}_{82}\text{Pb}^{210}(\text{RaD})$	22.2 years.
Bismuth---	Radium E--	${}_{83}\text{Bi}^{210}(\text{RaE})$	4.97 days.
Polonium--	Radium F--	${}_{84}\text{Po}^{210}(\text{RaF})$	139 days.
Lead-----	Radium G--	${}_{82}\text{Pb}^{206}(\text{RaG})$	Stable 23.6% abundance.

is a gas; all others are solid. The possibility of this gas spreading beyond its intended confines is ever present. It can then, on decay, settle out as a particulate in areas far removed from contaminated areas or be tracked from contaminated areas to places still farther removed. Sealed containers of radium prevent the escape of radon gas, and within a month after encapsulation the radon will reach equilibrium with were taken, positive identification of loose sur-
sion of penetrating gamma radiation.

Gamma radiation is very penetrating in contradistinction to alpha radiation which can be stopped by a sheet of paper. Beta radiation is only slightly more penetrating than alpha, but the latter, because of its great ionizing power, is a serious hazard once introduced into the body as a contaminant. As may be seen from the table, radon quickly decays to produce radium C. So, in the absence of radium to replenish it, a given concentration of radon is soon depleted.

The clinic used both radium and radon sources for external and interstitial therapy. Multicurie amounts of radium in the form of

liquid radium bromide were used in the radon emanation plant for the production of radon seeds and needles. The radon was purified by freezing the impurities in liquid nitrogen and thence drawing it into glass bulbs or platinum needles. The seeds or needles were then delivered to the calibration room for activity determinations and thence to the treatment room or to a storage vault.

At the time of the survey, the number of patients treated at the clinic had been reduced; therefore, the radiation exposures received by personnel were proportionately reduced. It was possible, however, to observe some of the standard operating procedures, including the operation of the emanation plant, which was in limited production.

Radiation Contamination Survey

A radiation contamination survey of the main building and of the adjacent building was made using instruments sensitive to alpha as well as beta and gamma radiation (a Samson alpha survey meter (SIC-49A) with a useful range corresponding to 200-25,000 alpha disintegrations per minute, an alpha-beta-gamma ion chamber (AN/PDR-T-34) with 5-50,000 mr./hr. scale, and a Geiger counter (SGM-2C) with maximum scale range of 20 mr./hr. beta-gamma). Simultaneously, wipe samples were taken in various areas throughout the clinic. These wipe samples, made by smearing 1¼-inch disks of Whatman No. 41 filter paper over approximately 100 square centimeters of surface, were used to estimate the extent of removable surface contamination. Each disk was numbered and kept carefully separated from the other disks until it was counted in a gas flow alpha proportional counter (NICC scaler with NHC PCC-10 converter).

No attempt was made in the survey to evaluate contamination on the surfaces of known sources of radiation, such as radium capsules. Only fixtures, floors, and other exposed surfaces were monitored and wiped.

Air samples were taken at the filtration and capsule preparation operations. The samples were collected with calibrated, portable Hudson and Willson pumps. Both membrane and Whatman No. 41 filter papers were used.

Survey Findings

Materials containing removable alpha-emitting radiation were found throughout the clinic. In several areas the alpha contamination, resulting from the use of radioelements for almost half a century, was truly astounding. Counts as high as 30 million disintegrations per minute were recorded. This figure is in marked contrast to the 0-500 disintegrations per minute at present regarded as the maximum permissible level. Of the 30 million disintegrations per minute, removable contamination constituted 25,000 disintegrations per minute, considerably less than 30 million but certainly more significant than the fixed contamination because of the possibility of its being inhaled or ingested. A summary of the results of alpha counting on the first floor of the clinic is recorded in figures 1 and 2.

Furniture, carpets, floors, stairs, offices, and medical equipment were all found to be contaminated with radioactive materials. Although it was difficult to survey the burned areas of the building, wherever wipe samples were taken, positive identification of loose surface radioactivity was made. Radium contamination appeared to have been spread by water during the fire fighting and as a result of the subsequent traffic. The drains of several sinks, including that in the dining room, contained radioactivity.

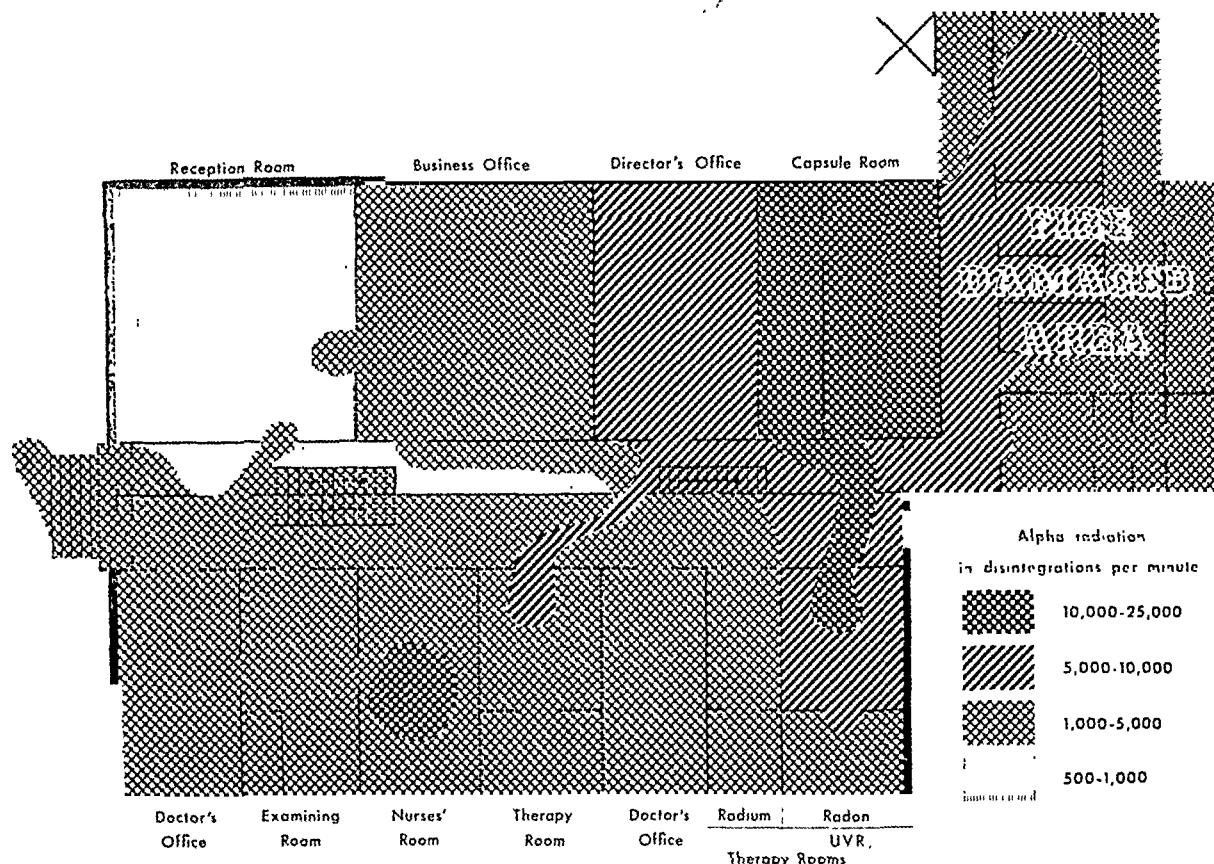

The adjacent building, which had been used as a hospital 15 years earlier, was also found to be contaminated with radioactive materials.

In the course of the survey, a misplaced radium source of approximately 40 millicuries was found in an office safe. In the same safe were several other sources in a strong box whose key had been misplaced years before. One of these sources contained 16 millicuries of radium. In another office, 6 "empty" radium capsules, each containing approximately 10 millicuries of activity, were found. A flask containing radium solution with 21 millicuries of activity was also located.

Personnel Monitoring

Because of the cumulative nature of radiation exposures, occupational radiation dosages are a function of the length of employment as

Figure 1. First floor: Fixed radioactive contamination on floor surfaces.

well as the amount and manner in which the radioactive materials are handled by an individual. Personnel radiation monitoring was provided for staff members at the clinic by means of pocket chambers and film badges. Because alpha radiation is easily stopped, neither film badges nor pocket chambers are of value in estimating exposure to this type of radiation. They are of value for estimating exposure to beta and gamma radiation if they are not contaminated by radioactive particulate matter, but prevention of such contamination was impracticable for persons working in the radon emanation plant.

To evaluate radiation dosages received by the clinic personnel, special film badge monitoring of employees not working in the radon plant was conducted for two short periods during the environmental radiation study. The film badges of two employees, a radium nurse and a physician, indicated that appreciable amounts of radiation were received during daily therapy procedures. This exposure may account, in

part, for the medical findings among the radium nurses and the one physician whose employment periods were relatively brief.

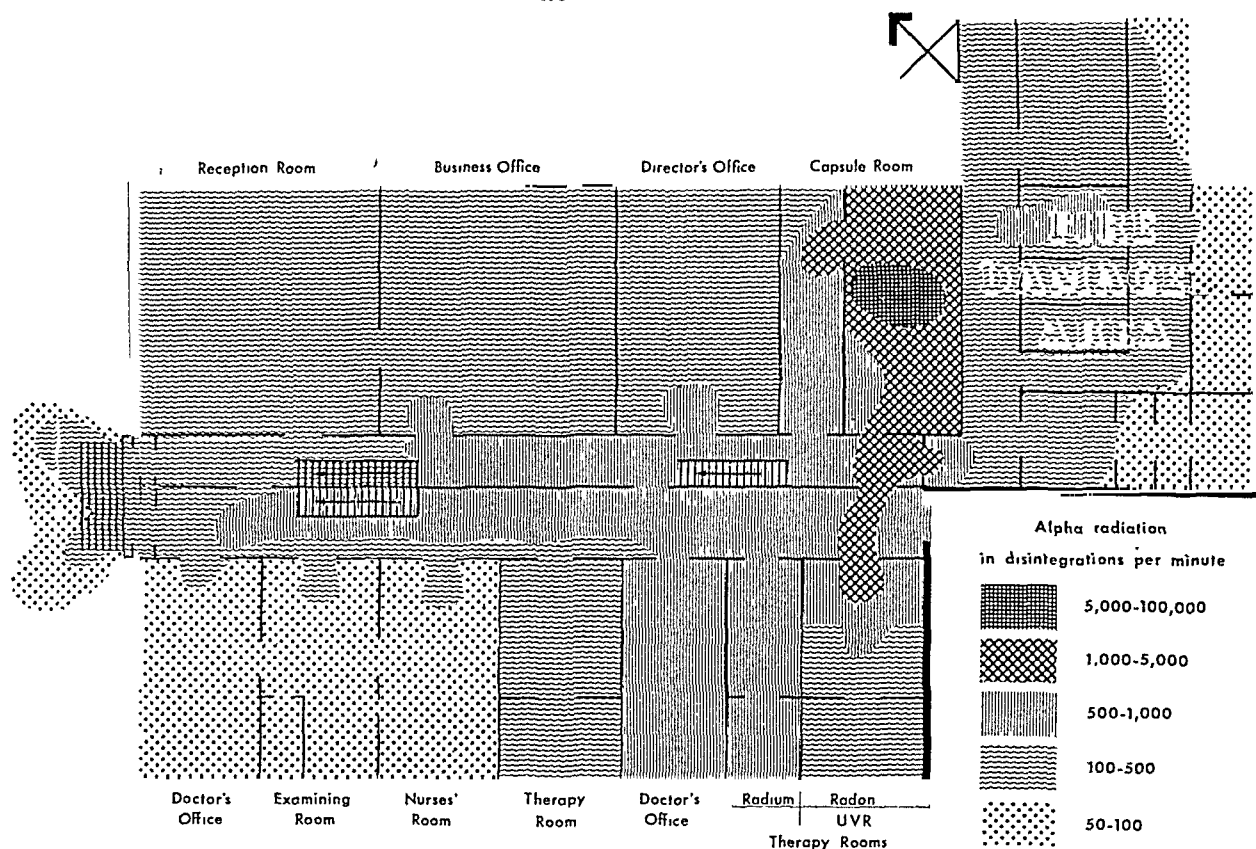

Medical Study

At the time of the study, 11 people were employed by the clinic full or part time. Six of these appeared voluntarily for examination upon request of the city health department and the present owner of the clinic. Four former employees of very recent date also appeared for examination on request of the clinic owner and former colleagues.

The length of employment of the 10 persons examined varied from 1 to 39 years and totaled 195 years. However, duration of employment is not necessarily synonymous with length of exposure as will be noted from the following job descriptions for clinic employees.

Radium nurse. Provides general care for clinic patients and assists in the administration of radiation treatment. (Generally, workers remain only 3 months of the year at this job.

Figure 2. First floor: Loose radioactive contamination as estimated from wipe samples taken from floor surfaces.

It is known that adequate protection is difficult to achieve in this type of work.)

Nurse. Provides general patient care but is not exposed to radiation except from material implanted in patients.

Physician. Plans and administers radiation treatment. (No rotation of personnel is stipulated.)

Radon pumper. Pumps radon off the radium after cleaning the vacuum system, requiring approximately 1 hour of work per day. (The usual rotation is 2 weeks on this duty and 6 weeks off, but periods of rotation have varied over the years.)

Medical History of Personnel

Since 1921 periodic blood counts have been done by the clinic on many of those employees exposed to radiation. In all, 310 employees had blood counts done on one or more occasions during this time. No findings of clinical significance could be discovered from inspection of these counts, and there were too few counts

per person to warrant subjecting the figures to statistical analysis.

The supervising radiochemist had been employed for more than 35 years. Early in his career at the clinic, he did considerable radium chemical research and radon pumping. He reported that he had had a nearly fatal attack of aplastic anemia in 1920 and his blood counts have been low ever since. The others examined had a number of ailments of medical significance but not any of a nature that is likely to be confused with radiation damage except for one person in whom epidermophytosis of the hands had been treated with X-ray in 1937 and another who had had three series of nasal radon applications for "prevention of colds."

Examinations

On the basis of previous experience, it was believed that any external radiation effects were most likely to be observed in the skin, nails, and hair (2). Routine hematological and urine examinations were performed on all those exam-

tion exposure history should be obtained and evaluated prior to allowing additional radiation work.

8. Personnel radiation monitoring should be maintained and evaluated. Whenever excessive exposure (greater than currently accepted maximum permissible limits) is detected, proper medical examination should be performed, and techniques devised to reduce exposure to permissible levels.

• • •

On February 13, 1954, the 2-gram supply of radium remaining at the former clinic was transported to the new location. The transfer took place without incident and was done in private vehicles. At this writing, nothing definite is known about the final disposition of the old buildings.

At the present time, most of the recommendations contained in this paper have been put into effect in the new building.

Applications for Grants in Cancer Research

Acting for the American Cancer Society, the Committee on Growth of the National Academy of Sciences-National Research Council is accepting applications for grants-in-aid for cancer research in the United States. Applications received before October 1, 1955, will be considered during the winter and grants recommended at that time become effective July 1, 1956. Investigators now receiving support will be notified regarding application for renewal.

The committee feels that an understanding of cancer depends upon a deeper insight into the nature of the growth process, normal and malignant. Therefore, the scope of the re-

search program is broad and includes, in addition to clinical investigations on cancer, fundamental studies in the fields of cellular physiology, morphogenesis, genetics, virology, biochemistry, metabolism, nutrition, cytochemistry, physics, radiobiology, chemotherapy, endocrinology, and carcinogenesis. The committee is particularly interested in encouraging research in the epidemiology of cancer.

Application blanks may be obtained from the Executive Secretary, Committee on Growth, National Research Council, 2101 Constitution Avenue NW., Washington 25, D. C.

Emphasizing the importance of knowing the "anatomy" of our communities, a health officer illustrates with two examples how epidemiological data and techniques can be used in program planning and suggests where more information is needed.

Epidemiological Techniques and Data in Planning Public Health Programs

By BERWYN F. MATTISON, M.D., M.P.H.

IT WOULD seem unnecessary to stress the reasons for the importance of program planning in public health. We have heard a great deal about program planning during the past few years, and we have learned that it, as well as program analysis, is a responsibility of a health department director that he must not shirk.

In order to plan new programs, we need an occasional glimpse of the health problems that lie ahead and of the techniques now being developed that may be applied to control them. We also need estimates of the current effectiveness of existing programs, for often new programs can be added only if obsolete activities are discarded. In both instances the data and techniques of epidemiology can be used to good advantage.

As long ago as 1927, that dean of American epidemiologists, Wade Hampton Frost, who

was talking about the relating of disease frequency to population characteristics, said that we needed many "facts collected especially because of their epidemiological significance. These, which are, perhaps, the most distinctive data of epidemiology, include systematic collective observations on the incidence of different diseases in relation to such details of local environment, personal habits, past history, and individual traits as may be supposed to have a probable relation to the occurrence of the disease." This goes far beyond the usual morbidity and mortality rates according to age, sex, and race. In view of the developments during the past quarter of a century, we might translate for local environment: level of housing sanitation or fluorine content of the municipal drinking water; for personal habits: the number of packs of cigarettes smoked each week; for past history: frequency of prior accidents; and for individual traits: the state of the individual's nutrition in terms of percentage overweight or underweight. Then we have striking reminders of the acuity of Dr. Frost's statement.

Such data are the natural domain of public health. They form a basis for the determination of a particular community's peculiar anatomy. Here I should like to digress for a mo-

Dr. Mattison, formerly commissioner of health of the Erie County Health Department, Buffalo, N. Y., is now secretary of health, Pennsylvania Department of Health. This paper is a condensation of the Delta Omega Lecture presented by Dr. Mattison at the University of Michigan School of Public Health in May 1954.

ment to stress the importance of the concept of community anatomy.

Both the practicing clinician in medicine and his patients accept the ill individual as the clinician's proper field of operations. His knowledge of normal histology and anatomy and his training and experience in the pathogenesis and etiology of disease form the foundations of his value to the individual in curing or ameliorating illness. Also, it should now be firmly established that the public health physician has the additional responsibility of knowing the characteristics of the groups of individuals which make up his community and the disease patterns of the community as a whole and of its various population groups.

There is a parallelism here that cannot be ignored: Just as the private physician examines the various parts of the human body in order to understand what is going on in his individual patient, so must the public health physician examine a group of communitywide factors in order to understand disease patterns as they affect masses of people. But there is also a strict dichotomy: The kinds of information necessary to analyze and correlate community factors with disease prevalence are such that they are not readily available to the individual clinician, based as they must be on reports of disease, deaths, and births and involving, as they do, not characteristics of the individual but group patterns of these characteristics. Thus, only a community agency, such as the health department, is in a position to perform this function.

What are the factors involved in determining community anatomy? The following list, though by no means all inclusive, gives examples of the principal kinds of factors, a knowledge of which will add considerably to the understanding of community disease patterns.

Internal factors:

1. Age.
2. Sex.
3. Race.
4. Inherited tendencies.

External factors not controlled by public health programs:

5. Type of work and working environment.
6. Economic status, as reflected by housing and nutrition.

7. Climate and seasons.

8. Chronologic location on the long-term disease incidence cycle.

External factors controllable by public health programs:

9. Sanitation.
10. Physiological resistance to disease.
11. Isolation, quarantine, and hospitalization.
12. Health education.

Now let us turn to some illustrations of the use of epidemiological data and techniques in program planning and analysis.

Diabetes Case Finding

During the past 5 years in Erie County, N. Y., the health department has been cooperating with the medical society and the public health laboratory in a program of diabetes case finding, using mass survey techniques. Because the collection of capillary blood samples was found to be much more acceptable to large groups of people than the collection of urine samples, fairly extensive use has been made of the Wilkerson-Heftmann blood glucose test. At first, voluntary laboratory technicians carried out the examinations, but during the past year, the clinitron has been used.

In this program, we have tried to tie in the operation of detection centers with public education on diabetes, particularly stressing the population groups that we believe most likely to have undiscovered clinical diabetes. It was decided early to direct our message toward people who are over 40 years old and overweight and who have a family history of diabetes. Also, it was decided to emphasize the danger among women in these categories.

During the first 4 years, detection centers were operated for less than 1 week each year in a few of the large department stores in downtown Buffalo and for exactly 1 week in the health building at the county fair. Since the county fair is traditionally in August, the city survey was conducted in the wintertime. During the past year, two major changes were made in the distribution of case-finding services: First, detection centers were set up in four different locations in the city at 2-month intervals. Second, the Wilkerson-Heftmann clini-

tron test was made a part of the health department chest clinic routine.

Let us now consider questions which should be asked about this kind of operation, some of which can be answered by application of epidemiological data and techniques. Does the nature of our appeal to the public and the location of the centers give us the kind of test groups we think we should be reaching? And, of course, does the yield of positive tests confirm or disprove the validity of our basic assumptions as to which groups should be reached?

Clinical verification of positive tests has not been considered in evaluating the program. It is assumed that persons with blood glucose values above the screening levels used deserved further medical consultation and that the clinical diabetes yield in these groups would be greater than in otherwise similar groups with lower blood glucose levels. Few, if any, persons with known diabetes are included in the test groups. Each person reporting for a test was asked twice whether or not he had diabetes, first by the volunteer worker who filled out the history sheet and again by a public health nurse just before the test was made. If the answer was yes, the person was either not tested or his record was excluded from the subsequent tabulations.

Characteristics of 1950 and 1951 Test Groups

As shown in table 1, between 27 and 33 percent of the population in Erie County in 1950 was 45 years of age or over, but more than 50 percent of the 1950 and 1951 diabetes test

groups were in this age group. Thus, we succeeded in testing considerably more people past the age of 45 years than were normally distributed within the community. We also tested considerably more women than men. In the age groups 15 to 44 years and over 45 years there were 3 women to every man. It might be noted that there was no significant difference in age distribution in the population between males and females.

There are certain other internal factors about which we have information for the test groups but none for the population as a whole. For instance, the data concerning history of diabetes in the family showed that 27 percent of the 1950 group and 25 percent of the 1951 group had such a history. Incidentally, over 70 percent of the known prior cases were among lineal relatives rather than collateral relatives. It would seem unlikely that 1 out of 4 people in the general population has diabetes in the family, but at present there are simply no adequate data for comparison.

Furthermore, we were interested in testing people who were overweight and particularly women who were overweight. Forty-four percent of all women in the 1950 and 1951 test groups admitted to weights of over 150 pounds, and 37 percent of those under 5 feet and 4 inches in height still admitted to weights of over 150 pounds. Here again, there are no good communitywide data for comparison, but it would seem that the test groups were really weighted in the direction in which we had hoped they would be.

Table 1. Age distribution of population in Buffalo and Erie County, N. Y., in 1950 and of the 1950 and 1951 diabetes test groups

¹ Screening level of 130 mg. percent after eating.

² Screening level of 180 mg. percent after eating.

Yield of Positive Tests in 1950 and 1951

As shown in table 2, there was indeed a tremendous difference in percentage of positive tests between the younger age groups and the age group 45 years and over. Even among the young adults, those aged 15 to 44 years, the yield of positive tests was only about half the yield among the oldest group. This was true for the 1951 group, for whom the blood-sugar screening level of 180 mg. percent was used, as well as for the 1950 group, for whom the very low screening level of 130 mg. percent was used.

From table 3, we see that there was, as expected, a considerably higher yield of positive tests among overweight people, if we accept two broad weight groups—over 150 pounds and under 150 pounds. The yield in the group over 150 pounds was from 30 to 55 percent greater than the yield in the group under 150 pounds.

With respect to the yields according to sex

Table 3. Yield of positive tests in 1950¹ and 1951,² according to weight

and history of diabetes in the family, however, the data did not confirm our original hypotheses. For 1950, when the lower screening level was used, 15.4 percent of the males and 15.7 percent of the females had positive tests—not a significant difference. For 1951, when the higher screening level was used, there was still no real difference in yields according to sex—1.5 percent positives among males and 1.4 percent positives among females.

As shown in table 4, neither in 1950 nor in 1951 did we observe any excessive yields associated with prior diabetes among relatives. This finding cannot be fully explained, but it may be that cases in which heredity is a factor are discovered early in life and would therefore

Table 4. Yield of positive tests in 1950¹ and 1951,² according to history of familial diabetes

² Screening level of 180 mg. percent after eating.

not be reflected in these test groups, which are made up largely of older adults.

A Group Tested in 1954

Finally, let us consider a group tested for diabetes during the first quarter of 1954 as part of the routine of the health department chest clinic. Table 5 shows some of the characteristics of this group. The numbers of males and females were practically equal. It is still predominantly a group of older persons, but only 52 percent were over 40 years of age whereas this percentage were over 45 years in the 1950 and 1951 groups. Again, we did not find an excess of positive tests among females; in fact, we found the percentage higher among males.

Table 5. Yield of positive tests among chest clinic patients, according to age, first quarter of 1954¹

¹ Screening level of 160 mg. percent after eating.

Because the screening level was again changed, this time to 160 mg. percent of glucose, direct comparisons between this group and the earlier ones is impossible, but it is interesting to note the continuing preponderance of yield in the older age group.

To recapitulate, we see how such factors as age, sex, body weight, and heredity can be considered in both the planning of a diabetes case-finding program and later in an analysis of the extent to which those plans have been carried out. The ultimate evaluation of the program must, of course, take into account clinical confirmation of cases referred on the basis of positive blood tests as well as the prevention of disability and death resulting from the early discovery of cases.

Housing and Health

One hundred and four years ago, Lemuel Shattuck, in his Report of the Sanitary Commission of Massachusetts, said, "The condition of dwelling houses has a most intimate and important relation to the health of the inmates." Since that time there has been general acceptance of this dictum, and many statements have been made sympathetic to the theory that better housing might produce better health. But the quantitative relating of housing to health is difficult and has been attempted infrequently. Obviously, the problem is a complicated one, with the whole picture of depressed economic status, rather than just the condition of housing, having an important bearing on health.

In approaching this problem, we must first try to find out whether the life expectancy for

people living in areas of crowding, poor sanitation, and lack of recreational facilities actually differs from that for people living in more fortunate circumstances and, if it does, just what the difference amounts to in a specific situation. Then, as one step in attempting to sort out the impact of crowding and improper sanitation in contrast to inadequate provision of medical care, we might try to determine the causes of excess mortality and see whether there is a preponderance among those diseases characterized as infective and parasitic. We might expect such a preponderance if crowding and improper sanitation are major factors in decreased life expectancy, since upper respiratory infections or hand-to-mouth and vector-transmitted infections are most likely to occur under these conditions. We might also get a rough check on some of the related factors by making nutrition surveys on a sampling basis in areas with varying economic status. Such surveys might indicate whether or not nutritional inadequacies are contributing to the morbidity and mortality pattern.

During the past year, we have attempted to do various of these things in the city of Buffalo. First, all the census tracts were grouped into three economic categories: above average, average, and below average. United States Bureau of the Census data on housing for 1950 were used, and three characteristics were considered—density of population, adequacy of water supply, and presence or absence of toilet facilities. Then, life tables were prepared for the population in each of those three groups of

Table 6. Life expectancy at birth, according to socioeconomic areas, Buffalo, 1950

Socioeconomic areas ¹	Life expectancy (in years)		
	All persons	Males	Fe-males
Above average.....	68. 5	67. 0	69. 9
Average.....	66. 9	64. 8	68. 9
Below average.....	61. 8	59. 9	64. 5

¹ Census tracts grouped according to density of population, adequacy of water supply, and toilet facilities, from United States Bureau of the Census data on housing.

have no generally acceptable index of change in people's attitudes that would enable us to measure the effectiveness of different techniques.

In conclusion, may I urge that we accept and utilize the concept of community anatomy. To do this effectively, we must develop adequate

epidemiological data, in the broadest sense of the term, to describe our communities, their people, their health problems, and their health protective resources. In this way, we can help our community improve the health and happiness of its people.

Poliomyelitis Vaccine Advisory Committees

Appointments were made in May 1955 to three key advisory groups to aid the Department of Health, Education, and Welfare and the Public Health Service in the formulation of policies concerning safeguards for the production, continued research, and the distribution of Salk poliomyelitis vaccine.

Named to the permanent advisory group, called the Technical Committee on Poliomyelitis Vaccine, are the following: David Bodian, poliomyelitis laboratory, Johns Hopkins University School of Hygiene and Public Health; Thomas F. Francis, Jr., School of Public Health, University of Michigan; Jonas E. Salk, virus research laboratory, University of Pittsburgh; Richard E. Shope, Rockefeller Institute for Medical Research; Joseph E. Smadel, department of virus and rickettsial diseases of the Army Medical Services Graduate School; John F. Enders, department of bacteriology and immunology, Harvard University Medical School; William McD. Hammon, department of epidemiology and microbiology, University of Pittsburgh Graduate School of Public Health:

Arthur C. Hollister, Jr., bureau of acute communicable diseases, California State Department of Public Health; Robert F. Korns, poliomyelitis vaccine evaluation center, University of Michigan, and bureau of epidemiology and communicable disease control, New York State Department of Health; Edward H. Lennette, viral and rickettsial disease laboratory, California State Department of Public Health:

G. Foard McGinnes, National Foundation for Infantile Paralysis; John R. Paul, Yale University Medical School; Albert B. Sabin, Children's Hospital Research Foundation, University of Cincinnati College of Medicine; Howard J. Shaughnessy, Illinois Department of Public Health; and Herdis von Magnus, State Serum Institute, Denmark.

Surgeon General Leonard A. Scheele named Bodian, Francis, Salk, Shope, and Smadel to a Standing Expert Committee. James A. Shannon, associate director of the National Institutes of Health, Public Health Service, was named chairman of this group.

Health, Education, and Welfare Secretary Oveta Culp Hobby named the following to serve on the National Advisory Committee on Poliomyelitis Vaccine:

Chester S. Keefer, committee chairman, and special assistant (for health and medical affairs) to the Secretary of Health, Education, and Welfare; Philip S. Barba, American Academy of Pediatrics; Daniel Bergsma, New Jersey State commissioner of health; Robert Fischelis, American Pharmaceutical Association; Malcolm Phelps, American Academy of General Practice; Julian P. Price, American Medical Association; George M. Uhl, Los Angeles city health officer;

Basil O'Connor, National Foundation for Infantile Paralysis; Mrs. Newton P. Leonard, National Congress of Parents and Teachers; Mrs. Charles L. Williams, National Congress of Colored Parents and Teachers; and Frank W. Moudry, National Association of Retail Druggists.

AIR POLLUTION CONTROL

A NEW FRONTIER

Twenty papers are presented in brief from the First International Congress on Air Pollution, March 1-2, 1955, New York City. Attended by scientists and engineers from seven countries, the congress was organized by the American Society of Mechanical Engineers in observance of its 75th anniversary. It is the outgrowth of early and continuous air pollution research by ASME, which published a model smoke law widely used as the basis of most municipal ordinances aimed at air pollution control in the United States.

Biological Effects

PHR One reason why air pollution has been the subject of so much rumor is the lack of precise understanding of what ills result from the contaminants in the air around us.

Beyond question in several well-publicized disasters, serious illness and death resulted from polluted air. Yet in ordinary industrial cities the life span and general state of health continue to improve.

We have every reason to suspect that in the middle ground between these two extremes some health impairment must be resulting, but of an extent unknown.

In some cases, the needed information is not so much new biological research as a better description of the environment. In most instances, however, our information on the biological effects of air pollutants is meager or nonexistent.

Before we can estimate the magnitude of the problem, we must define the nature of the biological effects in which we are interested. These could be listed as systemic diseases, skin, eye, and respiratory irritation, and lung cancer.

Skin and Eye Irritation

With some reservations, we can say that our major attention should be directed to the biological effects of air pollutants acting on the body surfaces, for systemic poisoning arising from air pollutants appears to be rare. Nevertheless we should be alerted to the possible difficulties arising from carbon monoxide and lead, which are normal byproducts of the use of anti-knock gasoline.

To continue with our listing, skin irritation no doubt occurs in unusual situations. However, the skin is not readily troubled by the mild level of irritants ordinarily found in the

By Norton Nelson, Ph.D., director, Institute of Industrial Medicine, New York University-Bellevue Medical Center, New York.

air of even heavily contaminated areas. Very possibly some specific allergic skin sensitivities can be developed from air contaminants.

Eye irritation is one of the most prevalent of the biological effects attributed to air pollutants and one about which it may be possible to achieve a moderately objective judgment as to its presence or absence.

Although a substantial amount of investigative work has been done on eye irritation, we have neither a reliable estimate of the variability of susceptibilities to irritants in different individuals, nor a well-authenticated table of comparative irritancy of various substances.

Filling in these two gaps would help systematize our understanding of the importance of eye irritation and aid in setting standards for control. Eye irritation possibly could be used as an indicator for generally assessing the irritancy of materials. Such a scale might aid in predicting irritancy for tissues where measurement is more difficult.

As the eye is more sensitive to corrosive and irritant materials than the skin, so are the pulmonary tissues more sensitive than the eye. Hence, the effects of irritating materials on the respiratory tract are perhaps the most significant biological effects of airborne contaminants.

Respiratory Irritation

Most of the deaths and the many instances of illness occurring in the Meuse Valley in 1930, at Donora in 1948, and at London in 1952 stemmed from respiratory involvement. Except possibly for Donora, the nonfatal events remain unknown in extent. Deaths that occur in such episodes are perhaps chiefly those that are in some degree imminent in that those stricken are elderly, ill, or are otherwise poised precariously. During the London smog, sulfur dioxide concentration rose to a peak of 1.34 p.p.m. This level is, however, much below the concentration of 10 p.p.m. considered tolerable for industrial work places.

To understand better how such deaths may arise, let us discuss the effects of irritants on the pulmonary tract.

The lining of the upper part of the tract, the nasal passages, and the conducting airways are perhaps less sensitive than the alveoli. Cer-

tantly, damage to these delicate tissues is more serious than is irritation of the upper tract. When the chief reaction occurs in the upper tract, there will be coughing, sneezing, and a sense of nose or throat irritation. When the reaction occurs in the alveoli, a series of changes set in which may have far-reaching consequences.

The functional state of the lungs depends on a finely balanced interplay of factors which contrive to maintain efficient performance with a substantial margin of safety in the healthy individual.

In a person with pre-existing lung or circulatory disease, this usual safety factor has disappeared. The congestion and increased permeability of the capillary walls arising from the irritant effect of inhaled material can lead to progressive fluid accumulation. This interferes with oxygen uptake, which then adds its part to the vicious circle, since oxygen lack favors increased fluid effusion. These changes further impede ready circulation through the lungs.

Although inhaled irritants will influence both upper and lower respiratory tissues, certain factors tend to determine the major locus of uptake and accordingly control the nature and severity of symptoms. Thus gases of high water solubility are largely absorbed in the upper tract. Conversely, low solubility leads to deep penetration with generally graver consequences. Also, transportation of irritants on small particles of 1 micron or less probably favors deep penetration.

Can we infer from our findings in Donora and London a direct and systematic relationship leading to real but lower levels of difficulty at lesser intensities of irritants? An analysis of the incidence of deaths from bronchitis in various parts of Britain shows a definite correlation between the death rate from this disease and the average sulfur dioxide concentration. But it would be hasty to conclude that a cause and effect relationship has been established.

We cannot simply extrapolate downward from such experience to an estimate of the incidence of illness caused by air pollutants as found in our larger cities so long as we are lacking in assurance as to the relative impor-

tance of the various irritants, as well as a systematic understanding of the relationship of level to effect, and, especially, in complete comprehension of the pattern of changes that occur and how they are modified by already present disorders.

Sulfur Dioxide

The classical methods of animal toxicology are generally inefficient for the demonstration of functional impairment. These methods have real limitations in detecting the effect of very low levels of materials which simply modify the balance of physiological events without producing overt tissue damage.

Amdur and Drinker have found that sulfur dioxide and sulfuric acid taken by human subjects at subsensory concentrations produced increased pulse and respiratory rate and decreased tidal volume and that these effects were involuntary physiological responses.

More extensive research work of this type would help us understand the physiological malfunction resulting from the inhalation of irritants, the physiological events leading to these observed changes in pattern, and how response is altered in elderly or diseased individuals.

We are still confronted with the epidemiological problem of measuring the frequency of occurrence of pulmonary and cardiac disorders attributable to air contaminants. An important distinction can be made here between the measurement of mortality and the measurement of morbidity. There is no uncertainty about the presence or absence of death, but there is about the presence or absence of disease when the concern is with a vague group of disorders which are present whether we have air pollutants or not.

Some systematic measurement of the frequency of occurrence of nonfatal respiratory difficulties was obtained at Donora and from the British experience also. However, we lack authoritative information on the contribution of air pollutants to respiratory disorders for the ordinary situation. Perhaps the most useful attack would be in the direction of devising simpler procedures to obtain this information.

Other than sulfur dioxide, what are the sig-

Biological Effects

PHR One reason why air pollution has been the subject of so much rumor is the lack of precise understanding of what ills result from the contaminants in the air around us.

Beyond question in several well-publicized disasters, serious illness and death resulted from polluted air. Yet in ordinary industrial cities the life span and general state of health continue to improve.

We have every reason to suspect that in the middle ground between these two extremes some health impairment must be resulting, but of an extent unknown.

In some cases, the needed information is not so much new biological research as a better description of the environment. In most instances, however, our information on the biological effects of air pollutants is meager or nonexistent.

Before we can estimate the magnitude of the problem, we must define the nature of the biological effects in which we are interested. These could be listed as systemic diseases, skin, eye, and respiratory irritation, and lung cancer.

Skin and Eye Irritation

With some reservations, we can say that our major attention should be directed to the biological effects of air pollutants acting on the body surfaces, for systemic poisoning arising from air pollutants appears to be rare. Nevertheless we should be alerted to the possible difficulties arising from carbon monoxide and lead, which are normal byproducts of the use of anti-knock gasoline.

air of even heavily contaminated areas. Very possibly some specific allergic skin sensitivities can be developed from air contaminants.

Eye irritation is one of the most prevalent of the biological effects attributed to air pollutants and one about which it may be possible to achieve a moderately objective judgment as to its presence or absence.

Although a substantial amount of investigative work has been done on eye irritation, we have neither a reliable estimate of the variability of susceptibilities to irritants in different individuals, nor a well-authenticated table of comparative irritancy of various substances.

Filling in these two gaps would help systematize our understanding of the importance of eye irritation and aid in setting standards for control. Eye irritation possibly could be used as an indicator for generally assessing the irritancy of materials. Such a scale might aid in predicting irritancy for tissues where measurement is more difficult.

As the eye is more sensitive to corrosive and irritant materials than the skin, so are the pulmonary tissues more sensitive than the eye. Hence, the effects of irritating materials on the respiratory tract are perhaps the most significant biological effects of airborne contaminants.

Respiratory Irritation

Most of the deaths and the many instances of illness occurring in the Meuse Valley in 1930, at Donora in 1948, and at London in 1952 stemmed from respiratory involvement. Except possibly for Donora, the nonfatal events remain unknown in extent. Deaths that occur in such episodes are perhaps chiefly those that are in some degree imminent in that those stricken are elderly, ill, or are otherwise poised precariously. During the London smog, sulfur dioxide concentration rose to a peak of 1.34 p.p.m. This level is, however, much below the concentration of 10 p.p.m. considered tolerable for industrial work places.

To understand better how such deaths may arise, let us discuss the effects of irritants on the pulmonary tract.

The lining of the upper part of the tract, the nasal passages, and the conducting airways are perhaps less sensitive than the alveoli. Cer-

quickly died down, but from time to time the matter was revived, and pressure continued steadily.

The committee of inquiry, over which I presided, was appointed in July 1953. We thought that it was desirable to issue an interim report, in order that the final report should not be cluttered with descriptive material which would distract attention from our findings and recommendations. The interim report appeared early in November and was received with a howl of derision by most of the popular press.

So much the better. Anything was better than absence of interest.

The Final Report

We published our final report in November 1954, at the beginning of our serious fog season. It was received with the most remarkable chorus of approval and a general call for action. The atmosphere of public opinion was at the moment peculiarly suitable and receptive for the right kind of report.

We particularly aimed at being clear and emphatic in the expression of our views and in the definition of our recommendations. We wrote so that the general newspaper reader could easily understand what was proposed and why. We certainly had enough material to produce a detailed, scientific study, and indeed we had to consider and weigh this vast volume of material, but we finally produced our conclusions in some 12,000 words.

For those who do not know England, Scotland, and Wales, I must explain that most of the population lives in an area about 60,000 miles square, not more than 100 miles wide—say about the area of Michigan and 8 times its population. There are in this area some 14 million houses, nearly all with open fireplaces and some hundred thousand factory chimneys. If one included all the small furnaces, which between them may consume some 10 to 15 million tons of fuel a year, the total number of chimneys would be at least twice as great and possibly more. Add that pollution from factory chimneys and domestic grates has been measured 60 and more miles from its source, and you have some idea of the problem in one single permanently polluted area.

My committee estimated that more than half the population lived in highly industrialized and heavily populated areas that were by geographic situation subject to frequent and persistent natural fog throughout the autumn months and consequently subject to frequent concentrated severe smog. We called these the "black areas," and we decided that attention must be first directed to these plague spots.

These conditions are so different from those in the United States that it may not be easy to realize how such a position both required and permitted that the problem be treated as a whole, and as a national problem. We had no doubt that this was so, though leaving generally with the local authorities the responsibility for enforcing the great part of the legislation.

We took no formal evidence. We started with the premise that all persons were agreed as to the objective, namely, the cure of air pollution, and that the only questions for discussion, therefore, were the practicability and the means. We invited all interests to a round-table discussion, and we broke up our committee into a number of small subcommittees to carry on the subsequent discussions quite informally. We believed, and the event confirmed the belief, that circumstances justified such an approach.

We started our report with a clear statement of the two counts against air pollution—health and cost. We expressly avoided basing our arguments on the danger to health of particular incidents, such as the London smog. We felt that undue emphasis on it would distract attention from the sad bill of unhappiness and ill health and earlier death that the whole country was paying. And then we gave our considered estimate of the economic cost to the nation.

Over and above the burden of ill health, the country was spending each year something like \$15 per head of the population, as we believe, a conservative estimate. It was against this background that we then proceeded to make our recommendations.

Proposals for Action

First, we proposed that all previous legislation, national and local, should be swept up into a new all-embracing act applicable to the whole

country. We proposed that this should be called the clean air act, a simple but brilliant and pregnant suggestion.

We proposed that legislation regarding industry should be nationwide and that there should be no question of pushing or removing potential industrial nuisances out of one local boundary into another. This is, of course, a much easier line to take in our small and more or less homogeneous country than it would be in the United States, but the differing attitudes and fears and jealousies of neighboring local authorities, of which there are over 1,000, had in the past seriously militated against action in regard to serious and avoidable nuisances.

We proposed to prohibit dark smoke from all ordinary furnaces and that it should no longer be necessary to prove nuisance.

We proposed that there should be no "protected" or sheltered industries or processes, that all without exception should be subject to challenge by really qualified national inspectors.

We proposed to create a simple way of establishing smokeless zones, instead of each local authority having to secure parliamentary power for itself.

We invented a new type of semismokeless zone in which smoke was to be reduced by 80 percent and which could therefore include industrial areas not fitting into any smokeless zone.

We proposed that part of the costs that would fall on individuals and businesses should properly be defrayed from the national purse.

We proposed that every local authority would have to publish annually an account of its activities in the past year in dealing with air pollution.

Finally, we proposed that there should be a clean air council to watch, encourage, coordinate all activities, and to report annually to Parliament.

I cannot say what action will eventuate. But I can say that I do not believe recommendations of this nature would have had the slightest chance of being accepted either by government or by industry or by the ordinary householder or by the public press. 20 years ago, perhaps even 5.

Now, the odds are, I believe, quite strong that action will follow. I think so because it seems

to me quite evident that this is now the public wish, because at last there has been that growth of public opinion on which everything in the end rests.

Administrative Patterns

PHR So far as is known, New York State is the only State to make any organized effort to assess "grass roots" problem areas and combine the findings in an integrated picture of the problems in air pollution control. Extrapolation of the data collected in New York State would indicate that at least 10,000 communities in the United States have a local air pollution problem.

Large areas of the United States are without effective governmental regulation of air pollution. It is of real interest, therefore, to examine the needs of various areas for such regulation and the form that it should take. We tend to think that all we must do is check the map for large population and industrial centers. But we overlook a wide variety of problems. Thus, in what might be termed wasteland uninhabited by humans, a need for control arises if the flora and fauna of the area are being adversely affected to the extent that a natural resource is being abridged. At the other end of the scale, a need for control arises as soon as the finish on a single parked car is damaged by the effluent from a nearby stack.

The 1954 New York State survey definitely points to the need for State level legislation and organization for air pollution control.

In that study, town, village, city, and county clerks were questioned as to their personal

By Arthur C. Stern, formerly chief, engineering unit, division of industrial hygiene, New York State Department of Labor, and now chief, Air Pollution Control Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati.

knowledge of the severity of the local air pollution problem and the nature and location of the principal sources of contamination. Particular note was made of the limits of legal jurisdiction of the affected community and the interest of the local government in the problem. In addition, information as to applicable local ordinances and enforcement organization was obtained.

Although the sample of communities reporting is only 34 percent (530) of a total of 1,555, it includes 88 percent of all communities of over 3,000 population in New York State.

Analysis of the Findings

Since air pollution problems frequently crop up in rural communities where they are least expected to occur, they can best be uncovered by persons having close familiarity with the scene. However, it was obvious that the use of one local official's response to categorize a community lacks objectivity. Statement by a respondent that specific air pollution sources exist were accepted as true even though the sources may not have been causing trouble at the time of the investigator's visit to the community.

It was characteristic of the study that in small communities, officials thought of the problem in terms of a few specific offenders, whereas in larger ones they thought in terms of processes causing pollution, such as incineration. Obviously, a major nuisance in a small community is deemed a minor one in a city of several thousand blocks.

The survey revealed the following:

Four hundred fifty-five communities in the State of New York are recognized as having local air pollution problems.

About half the urban and a third of the rural communities have problems they think need correction.

As expected, air pollution is of significance in a greater percentage of urban than of rural communities, but it also exists to a significant extent in even the smallest of the rural communities.

Seventeen percent of the urban and 20 percent of the rural jurisdictions report one or more important air pollution sources outside their jurisdiction.

There are no local air pollution or smoke control ordinances in 55 percent of the urban communities and 83 percent of the rural communities which have air pollution problems.

Personnel are employed full time to cope with air pollution problems in only 8 of the 455 communities.

Estimates of part-time responsibility of personnel are rather meaningless since every community has some individual or agency to receive and hear citizens' complaints of all types, regardless of their ability to act effectively. Therefore, it may be assumed that in 447 communities having an air pollution problem effective local attention is available only in those instances where there are sanitary engineers in the municipal or county health department. There are about a dozen such jurisdictions in the State; 4 are in county health departments and thus embrace a number of communities.

State and Regional Control

New York has two State departments, health and labor, to which local agencies can turn for assistance in solving air pollution problems, but a number of other States have no State agencies with personnel trained and available for such matters.

Over the past two decades there has been an expansion of the concept of the air pollution control area. During this period a number of county control organizations have been created, some including or excluding the city forming the heart of the county.

In the San Francisco Bay area, counties are presently authorized to declare themselves individually to be countywide air pollution control districts. Some now feel that, in a region where populous counties are contiguous, the county is too small an administrative unit. They are exploring the development of multicounty or regional administrative units as best fitting the needs of metropolitan areas.

Exploration of the regional concept reveals several major metropolitan areas embracing more than one State and indicating a possible need for interstate compacts for their legal creation and implementation. Fortunately, similar situations requiring interstate compacts have been solved in the water supply, water

country. We proposed that this should be called the clean air act, a simple but brilliant and pregnant suggestion.

We proposed that legislation regarding industry should be nationwide and that there should be no question of pushing or removing potential industrial nuisances out of one local boundary into another. This is, of course, a much easier line to take in our small and more or less homogeneous country than it would be in the United States, but the differing attitudes and fears and jealousies of neighboring local authorities, of which there are over 1,000, had in the past seriously militated against action in regard to serious and avoidable nuisances.

We proposed to prohibit dark smoke from all ordinary furnaces and that it should no longer be necessary to prove nuisance.

We proposed that there should be no "protected" or sheltered industries or processes, that all without exception should be subject to challenge by really qualified national inspectors.

We proposed to create a simple way of establishing smokeless zones, instead of each local authority having to secure parliamentary power for itself.

We invented a new type of semismokeless zone in which smoke was to be reduced by 80 percent and which could therefore include industrial areas not fitting into any smokeless zone.

We proposed that part of the costs that would fall on individuals and businesses should properly be defrayed from the national purse.

We proposed that every local authority would have to publish annually an account of its activities in the past year in dealing with air pollution.

Finally, we proposed that there should be a clean air council to watch, encourage, coordinate all activities, and to report annually to Parliament.

I cannot say what action will eventuate. But I can say that I do not believe recommendations of this nature would have had the slightest chance of being accepted either by government or by industry or by the ordinary householder or by the public press. 20 years ago, perhaps even 5.

Now, the odds are. I believe, quite strong that action will follow. I think so because it seems

to me quite evident that this is now the public wish, because at last there has been that growth of public opinion on which everything in the end rests.

Administrative Patterns

PHR So far as is known, New York State is the only State to make any organized effort to assess "grass roots" problem areas and combine the findings in an integrated picture of the problems in air pollution control. Extrapolation of the data collected in New York State would indicate that at least 10,000 communities in the United States have a local air pollution problem.

Large areas of the United States are without effective governmental regulation of air pollution. It is of real interest, therefore, to examine the needs of various areas for such regulation and the form that it should take. We tend to think that all we must do is check the map for large population and industrial centers. But we overlook a wide variety of problems. Thus, in what might be termed wasteland uninhabited by humans, a need for control arises if the flora and fauna of the area are being adversely affected to the extent that a natural resource is being abridged. At the other end of the scale, a need for control arises as soon as the finish on a single parked car is damaged by the effluent from a nearby stack.

The 1954 New York State survey definitely points to the need for State level legislation and organization for air pollution control.

In that study, town, village, city, and county clerks were questioned as to their personal

By Arthur C. Stern, formerly chief, engineering unit, division of industrial hygiene, New York State Department of Labor, and now chief, Air Pollution Control Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati.

cessive cost and under conditions which do not suspend or interfere with operations for any protracted period.

The most important approach toward solving the problem is that which involves the recovery of a byproduct which is salable or can be returned to the manufacturing process. This has been demonstrated many times in steel production, as in the recovery of material from a blast furnace and the recovery of sulfur and of noble metals from smelter waste gases. Recovery of this kind has not been done without a long-range consideration of the initial cost of the equipment. Amortizing this cost against the recovery of the material has made the application reasonable, but a definite time factor and capital expenditure are involved.

Unfortunately not all economic aspects of air pollution control on which needed development is desired can be handled as simply. Many waste gases contain materials of insignificant value in offsetting the cost of control equipment. The burden of this assessment can be called the price of good community relations. Much equipment is installed on this basis to the credit of industry. When its cost becomes so disproportionate in relation to the cost of the operation that it cannot be amortized or justified on a basis of buying time in the community then we must seek less expensive methods for control of the contaminant. This emphasizes the need for less costly air-cleaning devices from both the capitalization and operating aspects.

We are fast approaching the time when atmospheric dilution and dispersion of contaminants no longer can be done when communities lie close to facilities. Few locations are now available for heavy industry where ideal transportation, raw material, power, and other economic factors justify moving a plant into an undeveloped area where the community does not encroach rapidly. There is a limit as to the height and cost of a stack, which must be balanced against the cost of the air-cleaning equipment.

Education Needed

Education can push the frontier of engineering control methods farther ahead. A significant

body of literature on aerosol technology can now be presented to young engineers and chemists who will encounter in their future careers the problems of contaminants dispersed in gases.

Problems of air and gas cleaning should be a part of the curriculum of graduate mechanical and chemical engineering courses in more institutions than at present. Engineers at college level should be provided with basic information on techniques of air pollution control and performance of equipment. The engineer in training should be made aware of the differences in aerosol-collection mechanisms and their relation to particle technology.

We need some education of design and sales engineers now working in the air-cleaning and gas-cleaning equipment field in order that misapplications are avoided.

We need education of engineering and development personnel working in process design departments of many industries on aerosol technology.

We need education of individuals in regard to appraisal and evaluation of air pollution problems.

We need education of citizens as to what constitutes an air pollution problem and the degree of control which can be obtained within economic reason.

Fundamental Research

Fundamental research in air pollution control by engineering methods is largely a problem of application of theory and empirical data already developed. A considerable amount of knowledge in fine particle technology has already been developed, however, and many fundamental filtration and other separation methods have been well defined.

More work is desired to yield data on new aerosols and their inherent properties. Particularly is this true of fundamental particle dynamics, electrostatic charge, and wetting. Removal of particles by aggregation, flocculation, and agglomeration remains a void, at least as to practical application in recovery of aerosols.

Unfortunately, research knowledge is not in the hands of imaginative engineers who can

apply it to practice. A restraining force is the fact that a fair amount of inertia exists in the air-cleaning and gas-cleaning industry, just as in other industries. A company which produces equipment to handle certain process effluents on a large scale may be reluctant to make major design changes without extended pilot plant experience.

Application of bag filters to air streams containing both particulates and corrosive gases is a good example of how control equipment is sometimes put to work before a thorough evaluation is made of the nature of the contaminant. Although the particulate might be removed effectively, the gas damages the fabric media in a short time. Immediately, an intensive search is made for a fabric to withstand the gas and still permit the particulate to be removed satisfactorily. Just how to remedy this condition rapidly is a difficult problem, although there has been already a tremendous advance in fiber technology.

Applied laboratory research on effective simulation of the actual problem based on reliable field evaluation may often prevent this kind of situation. On the other hand, the time factor is often ignored, and fatiguing of materials will develop in practice. This, therefore, involves able research forecasting to anticipate possible ramifications which may develop in operation.

Technical Aspects

Technical areas still needing further investigation include:

New methods for handling fine metallurgical-process fumes at high temperatures.

Methods for controlling acid mists and complex high vapor-pressure organic suspensoids.

New methods for recovering chemical effluents which are difficult to adsorb or remove by contact washing.

New devices for combustion of low levels of gases which create odor problems and yet are too concentrated to adsorb on odor canisters but not concentrated enough for a major recovery system.

Continued studies on fundamental particle dynamics as applied to inertial separation,

filtration, and electrostatic properties of particulates.

Continued investigations of the photochemical stability and physical chemistry of aerosols.

Fundamental studies on fixed and dynamic filters with particular reference to life studies with a wide variety of aerosols.

Further studies on graded filter media for low loadings of air contaminants.

Development of temperature-resistant fabrics able to withstand 500° to 1,000° F. and still perform effectively as filter media.

Development of relationships from particle and equipment parameters which will enable the reliable prediction of performance from primary dimensions and rapidly evaluated properties of the particulate material.

Meteorological Problems

PHR To many people, air pollution brings to mind products of combustion and of industrial processes which are released into the air. These products may be referred to as artificial air pollutants. A listing would include industrial gases, fumes, and particulates; exhausts from cars, buses, trucks, locomotives, and aircraft; products from incinerators, both private and public; and radioactive debris from atom and hydrogen bomb testing.

Natural contaminants are substances which would be in the atmosphere even without man's activities. Examples are volcanic gases and dust; salt particles from the oceans; pollens, spores, rusts, and smuts; small insects in various stages of development; sand raised in sand storms; forest and brush fire smoke; and bacteria and viruses.

Natural air pollution also may be augmented

By E. Wendell Hewson, professor of meteorology, department of civil engineering, University of Michigan, Ann Arbor.

artificially by man's activities. Land-use practices may promote the carrying of soil particles and airborne pollens into the atmosphere. Many forest fires are started as a result of carelessness.

Applied meteorology has a substantial contribution to make in the campaign for clean air. The nature of the meteorological problem depends on whether dispersal near the source or at great distances is of primary concern.

Wind direction, wind speed, and wind turbulence are the three meteorological variables governing the behavior of a contaminant near its source. When dispersal near the source is being studied, the variables may be taken as approximately constant during the travel of the contaminant from its source to a specified point downwind.

Wind direction specifies the general area into which a pollutant will move. Other things being equal, the concentration downwind from a source varies inversely with the wind speed. The degree of turbulence of the wind determines the rate of diffusion. In addition, small-scale turbulence may promote coagulation of particles in a plume. The vertical temperature gradient influences the turbulence field but has no basic significance.

The meteorological problem becomes much more complex when dispersal far downwind is to be assessed. Thus, diurnal and other variations of meteorological variables must be considered along with wind direction, wind speed, and wind turbulence.

The plume may be subject to additional influences, such as slight diffusion at night followed by great diffusion by day or vice versa; deformation and attenuation by large-scale variations of wind speed, direction, and turbulence with height; major convection currents in an unstable air mass; and large-scale uplift or subsidence in pressure systems or near frontal surfaces.

Washout of gases and particulates by precipitation falling through the plume may also be a factor in dispersal. Photochemical changes in contaminants by solar radiation may increase their toxicity, as the studies of Los Angeles smog strongly suggest. Features of the terrain influence dispersal. In valleys, for example,

the meteorological analysis is much more complex than over level country.

Single Source Pollution

Advances in our understanding of pollution near a single source have been made, but much more must be learned about this complex subject before it can be asserted with confidence that the meteorology of air pollution control has reached a satisfactory state of development.

Future research in this field may develop through the individual or the integrated approach. It is necessary and proper in the early stages when the outlines of the problem are still indistinct and ill-defined to take one or more small segments of the problem for investigation. However, our knowledge of the meteorological aspects of the air pollution control problem near a single source is now sufficient to warrant a more integrated approach.

I propose that a research unit be established for the purpose of attacking the various unsolved problems in this area on an integrated basis. We need more studies of the variations in diffusion with the stability of the air, with the nature of the terrain, the nearness of the source of pollution to buildings, the height of the source, and the differences in time intervals used for sampling periods.

Adequate funds, facilities, and personnel would be needed for these coordinated studies, and the main outlines of the research would be delineated by a planning committee of the most competent scientists in the areas of theory, instrumentation, and analysis.

It is admittedly difficult to carry out satisfactorily such a large-scale research undertaking, but the rewards in increased knowledge are great, and the difficulties can be surmounted. With such a project, it would be possible to evaluate most of the unknowns and thus to place the meteorological aspects on a satisfactory design basis.

Dispersal Far From the Source

Dispersal far from the source may be influenced by the meteorology of the entire troposphere, which in middle latitudes extends up to 6 miles on the average.

The rapid increase of industrialization throughout the world, and especially in the United States, suggests that a knowledge of diffusion over great distances will be increasingly important. New methods must be devised for measuring the meteorological quantities needed to specify this large-scale diffusion.

Very little is yet known about the influence of diurnal variations on dispersion. Present theory neglects the variations of wind speed and direction with height, which is a permissible simplification near the source. Dispersal by convection currents should be the subject of a full investigation. In particular, instrumentation is needed for rapid and precise measurements of the structure and diffusion action of large eddies.

Since so little is known about dispersal over great distances, I recommend that several studies by different research groups be undertaken, in order that the limits of the problem may be more closely defined.

Pollution From a Multiple Source

Although a number of studies of city pollution have been made, these have not produced precise information on meteorological influences. Little is known about the concentration of contaminants at large distances from a multiple source. Here again, I recommend several investigations by different research groups, using a variety of techniques and instruments developed for the purpose.

The Los Angeles studies may yield much new information on the meteorology of multiple source pollution and on the role of solar radiation in producing photochemical changes of contaminants. The pollution survey of Leicester, England, is an outstanding example of a general investigation, but comprehensive investigations are needed to verify or modify the tentative statement of large-scale dispersal formulated by that study.

Detailed studies are required in which representative values of turbulence, lapse rate, and associated concentration as well as wind speed and direction are measured both in the city and at various distances downwind. Investigations for several cities would be desirable, starting with one in flat, open terrain, and then studying

in succession several others in different terrain and under different climatic regimes.

The ultimate object is the development of a climatic classification based on the diffusing capabilities of the atmosphere. City planning commissions would then be in a position to specify tolerable limits of contaminant emission for any area and season.

With industrialization growing, the rate of accumulation of industrial contaminants, both gases and small particles, in the atmosphere should be studied on a continuing basis. It is not clear how an increasing accumulation of gases and particulates in the atmosphere might affect human life and activities, but the question is of sufficient importance to warrant much more research.

Health Implications

PHR. Perhaps it would be sound to recognize that the London episode of December 1952, as contrasted with the other now famous air pollution disasters, represents a distinct type of pollution situation which we may call "typically urban."

In our opinion, the problem presented by a number of major cities is this relatively featureless type of pollution. Of course, it is known that the oxides of sulfur and the particulate products of the combustion of coal and other fuels contributed substantially to the load of atmospheric pollutants in London, but at the same time sulfur dioxide and the particulates of themselves in the concentrations found do not seem to account completely for the effects observed.

Probably there are more instances of typically urban situations than there are of the special

By E. A. Watkinson, M.D., D.P.H., chief, occupational health division, Canadian Department of National Health and Welfare, Ottawa, and member, Canadian Section, Technical Advisory Board on Air Pollution, International Joint Commission.

types. If this is true, it follows that many more people are exposed to these typically urban atmospheres.

It is helpful to recognize that the irritant or toxic actions of air pollutants may be classified on an intensity scale which is related to their concentration.

Fairly well-defined damage to the human body can be associated with the acute effects following exposure to high concentrations of many toxicants; and correlations of this type have been provided by acute gassing incidents. Unfortunately this information is of little value in efforts to determine the results of long exposure to toxicants which lie above the body threshold and below the acute level, in the region where chronic effects may occur. Post-mortem findings may reveal that damage is present, but such evidence is usually nonspecific and not pathognomonic of the nature of the causative agent.

Detroit-Windsor Study

Possibly more definitive correlations between low pollution levels and resulting chronic effects might be obtained from appropriate exploitation of data from properly designed surveys.

One purpose of the current Detroit-Windsor study is to determine the effects on health of long exposure to common pollutants in a heavily polluted area. We are obtaining detailed records of the sickness of each individual over a considerable period of time in order to compare the amount of chronic disease and other kinds of sickness in areas of different pollution level. The relative amounts of chronic sickness, as measured by such indexes as number of days sickness per person and proportion of medically attended illnesses and of hospitalized illnesses, may also be used for comparison.

We are also collecting information on symptoms associated with chronic disease and on symptoms which represent responses to short-term changes in air pollution levels.

Three Hypotheses

While surveys of this type represent one approach toward solving some of the air pollu-

tion problems, there is no lack of hypotheses to explain the unaccountable high irritant and toxic properties of urban smogs.

Among these hypotheses, that of synergism has been frequently discussed. Evidence has been provided to show that synergistic effects arise out of the actions of certain toxic mixtures, but in general such evidence either deals with systems which are of little importance in our problem of urban air pollution or does not meet the requirements of a statistical demonstration of true synergism. It is necessary that this whole field be examined in detail, with particular attention being paid to the design of the experiments.

Two other hypotheses, which we may call the solubility and adsorption hypotheses, have been put forward.

If we imagine that some mechanism exists whereby relatively enormous absolute amounts of irritants can be abstracted from an atmosphere and transported to the lung during respiration and there undergo some interfacial phenomenon which permits the release of these large amounts of irritants or toxicants, then the existence of such a mechanism would afford an explanation of the enhanced effect of smog atmospheres containing only small concentrations of irritants per unit volume. Since smog contains droplets of water and aqueous solutions, it might be that these could dissolve large amounts of irritants, such as sulfur dioxide, carry them into the lung, and liberate the gas in contact with the alveolar epithelium.

Similarly, particles of carbon or fly ash might adsorb sulfur dioxide, transport it to the lung, and again release it locally.

Existing data relating to the solubility and to the adsorption isotherms of common air pollutant gases in the usual droplet and particulate constituents of smog are far from complete and in general do not extend down to the region of the low partial pressures of gases which are present in smog in, at most, a few parts per million.

Work is now in progress in Canadian laboratories which is designed to provide evidence relating to these three hypotheses. Ultimately it may develop that a full explanation of the high biological activity of urban smogs will re-

quire a recognition of the contributions from these three mechanisms and possibly others, acting simultaneously and also interacting with each other.

Our interest in submicron particles has led to reports on problems relating to the use of microchemical and electron microscopic techniques in connection with the analysis of these fine particles.

Owing to the lack of basic experimental data, our knowledge of the health implications of these concepts is still beyond our present reach, and the final answer is dependent, in part, on work yet to be performed.

The Sarnia Survey

PHR An example of how industry is fighting a front guard action against air and water pollution may be seen in the cooperative investigation undertaken by foresighted industrial companies in the Sarnia basin, Ontario, Canada.

Sarnia faces Port Huron in the United States. About 60 miles northeast from Detroit, it lies in the heart of Chemical Valley, on the east bank of the St. Clair River, where the river waters leave Lake Huron. The terrain is flat. Heavy industries lie along the waterfront. The river is the highway for many obsolete vessels.

Much of the pollution at present results from the poor firing techniques used by these older vessels. When the St. Lawrence Seaway Project is completed, new vessels, designed for the seaway conditions, will be commissioned.

The Industry Committee

Begun in October 1952, the Sarnia survey is being conducted with the approval of the Research Council of Ontario, and in cooperation with the Ontario Research Foundation. Can-

ada is seeking to prevent conditions in Sarnia from becoming as acute as those in some of the world's major industrial areas.

The companies participating include several oil refineries, plastics, synthetic rubber, and carbon black plants. Oil companies and these other heavy industries are especially alert to the danger of loss and pollution.

Half the cost is paid by the Provincial Government of Ontario and half by the participating industries. This latter amount is allocated by agreement among the companies.

Industry representatives meet monthly to discuss progress with the foundation's air pollution staff. Committee members have the confidence of top management in their ability to make sound recommendations.

The group does not attempt to regulate. Its function is to discover the constituents and concentration of pollutants and to devise methods of suppression. It does not encroach on the rights of the International Joint Commission from whom it receives technical assistance in the application of the same techniques now used in the Detroit-Windsor survey.

A subcommittee of the research council watches the progress of the survey.

The success of the enterprise is not to be measured by physical means. From the original gesture made to the public by the member companies, a chain reaction was started.

The industries have already observed a surge of interest in air pollution. They are experiencing a spontaneous interchange of data. Other companies have asked to join in the project. A continuous study of present and future pollution problems is under way in each plant. Public appreciation of the problem and community public relations have improved noticeably. The city council and the city's air pollution committee are more than cooperative.

The industry committee is convinced that enlightened manufacturers who fearlessly and publicly gather the facts about avoidable pollution, and then act on their findings, are realizing that enforcement legislation need be reserved for nonconformers only.

The Survey Design

Sarnia has been divided into three zones of pollution: medium heavy (65-100 tons per

By B. C. Newbury, B.Sc., research fellow, department of chemistry, Ontario Research Foundation, Toronto.

square mile per month), medium (50-65 tons), and low (35-50 tons). The low pollution zone includes most of the residential area. Ships and the associated docking activities may be responsible for a dust fall of the order of 20 tons/sq. mile/month.

The research foundation is responsible for the correlation of all data collected. Its air pollution laboratory has set up a master recording station in one of the more heavily polluted parts of the residential area.

The station is in an open space about 2 miles from the major industries and approximately in line with the direction of the prevailing wind. It houses a Thomas autometer, Bendix-Frieze anemometer, Hemeon and high-volume samplers, and a dust can.

Meteorological data are compiled at the station, and a continuous record of sulfur dioxide concentrations have been kept since the start. Data are needed on vertical temperature distribution, but there is no local television transmitter to which thermometers could be attached.

Nine dust cans are serviced by the foundation in the residential area. Ten in the industrial area are owned and serviced by the industries themselves. Each company is responsible for taking and analyzing stack samples and dust samples deposited on its own site and for financing these tests. The results are given to the foundation.

Every test made is duplicated by a similar test at the master station, so that data for simultaneous conditions can be compared.

Each can location is associated with a sampler location, usually within 50 yards. The sampling filters can be mounted on hydroelectric poles and plugged into the public electricity system.

Two high-volume aerosol runs have already been conducted, but the samples were not sufficiently large to give long-term averages.

In order to monitor the sulfur dioxide and other gases at locations other than at the master station, a mobile trailer laboratory was designed. The towing unit is a standard station wagon.

The trailer is a self-contained unit, carrying its own water, heat, and power supply, but it has proved more practicable for the laboratory to take its power from the public system. Fu-

ture units will be built to tap the public supply for heating and power.

This traveling laboratory has made it possible to carry out runs with a Thomas autometer at varying locations much more cheaply than at a series of fixed stations. The unit has been of great value in measuring the level of sulfur dioxide and in indicating the relative contributions of the various sources to the total pollution recorded at the master station.

Water samples are taken in duplicate at the head of the river, at the inlet to each plant, and at a location well below the industrial area. Each sample is analyzed in two different laboratories before the results are forwarded to the foundation.

Further water testing is the responsibility of the Ontario Department of Health, which has been monitoring the river for many years.

Code of Good Practice

The pollution of the air by dust particles and gases leaving the stacks has taken serious aspects in several districts of the Netherlands. Although deposits of solid matter may cause considerable inconvenience and nuisance in residential districts, complaints will generally be raised only by people living within a few miles around the plant. Analyses of such deposits shows that the percentage of coarse dust particles is predominant whereas the amount of very fine particles with a diameter less than 10 microns ($d < 10\mu$) is generally minimal.

Recent investigations made near a large power station, where people were complaining bitterly of deposited dust, showed, for example, that 75-80 percent of the dust collected in the exposed region consisted of particles larger than 50μ , whereas dust leaving the stacks contained only 10-15 percent particles with $d > 50\mu$.

By A. J. ter Linden, professor of mechanical engineering, Technical University, Delft, Netherlands.

quire a recognition of the contributions from these three mechanisms and possibly others, acting simultaneously and also interacting with each other.

Our interest in submicron particles has led to reports on problems relating to the use of microchemical and electron microscopic techniques in connection with the analysis of these fine particles.

Owing to the lack of basic experimental data, our knowledge of the health implications of these concepts is still beyond our present reach, and the final answer is dependent, in part, on work yet to be performed.

The Sarnia Survey

PHR An example of how industry is fighting a front guard action against air and water pollution may be seen in the cooperative investigation undertaken by foresighted industrial companies in the Sarnia basin, Ontario, Canada.

Sarnia faces Port Huron in the United States. About 60 miles northeast from Detroit, it lies in the heart of Chemical Valley, on the east bank of the St. Clair River, where the river waters leave Lake Huron. The terrain is flat. Heavy industries lie along the waterfront. The river is the highway for many obsolete vessels.

Much of the pollution at present results from the poor firing techniques used by these older vessels. When the St. Lawrence Seaway Project is completed, new vessels, designed for the seaway conditions, will be commissioned.

The Industry Committee

The city council and the city's air pollution committee are more than cooperative.

The industry committee is convinced that enlightened manufacturers who fearlessly and publicly gather the facts about avoidable pollution, and then act on their findings, are realizing that enforcement legislation need be reserved for nonconformers only.

The Survey Design

Sarnia has been divided into three zones of pollution: medium heavy (65-100 tons per

By B. C. Newbury, B.Sc., research fellow, department of chemistry, Ontario Research Foundation, Toronto.

Immediately a number of patients showed an increase of the subjective symptomatology of their diseases. This matter amused the technicians and contributed to creating the conviction that the complaints had a speculative origin. However, we doctors know, through our research into physiology, and particularly of conditioned reflexes, that complaints of ill people find adequate enough an explanation in physiology.

Yes, Italy, too, suffers from injury to man and animals, and damage to property from atmospheric pollution. We must admit that complaints against industry are fairly frequent and that many cases reach the courts.

We have had many cases of mass toxicity, some sensational, from atmospheric pollution within plants, caused either by faulty construction or erroneous placement of rooms. We have another frequent collective toxicity caused by Carbon monoxide in factories.

In comparison with Italy's well-known cases of toxicity taking place within the factory, many cases resulting from industrial atmospheric pollution escape the diagnostic judgment of the physician. Furthermore, the distillation of industrial effluents in the atmosphere for not such as to bring about well-defined toxic factors to be attributed with certainty to any given product. Our diagnostic means do not yet permit us to establish a definite diagnosis of functional or organic symptoms caused by a long exposure to low concentrations.

We often do not take into consideration the injuries suffered by persons as a result of atmospheric pollution. We do not include in our calculations those people who are either ill or physically unfit, and especially children, pregnant women, hypersensitive individuals, for whom small doses of dust, gas, vapors, or odors may not be only harmful, but toxic, and even fatal. In my opinion many cases of diffuse eczema, asthma, rhinitis, and allergic conjunctivitis are brought about by sources of industrial pollution often escaping the patient's and the physician's attention.

I close with the suggestion that the maximum publicity be given to all devices discovered or invented which may contribute to the purification of the atmosphere. This dissemination of information is necessary so that all countries

may take advantage of technical improvements. Such information also will make it possible for health authorities to require the installation of those new devices in order to safeguard the health of their citizens.

The Air Pollution Syndrome

On the industrial front it is most often the local plant manager or the small local industrialist, and not the big industrial statesman back at company headquarters, who has to deal with the problems of air pollution in his community, and who so often makes such heavy weather of it.

The local industrial manager often finds himself in a curious, frustrating situation. He is successfully running a plant to produce goods that people need and want. He is constrained by the hard laws of economics to produce these goods at lowest possible cost and to sell them at a profit.

He finds himself in a community that should, in his opinion, appreciate the job he is doing to provide work for its citizens and a market for some of its local products and services. Yet, unaccountably he finds himself under fire because now and then his plant has been emitting a little smoke or fly ash, or possibly some bad odors. It is even possible that the local newspapers have assailed him with editorials. Lawsuits, threatened or actual, may be hanging over him.

Under these circumstances, the industrialist is likely to react according to what we recognize as the industrial "air pollution syndrome."

Local managers of industrial plants are often of the old tradition still, when it comes to public and community relations, especially in air pollution matters. When complaints are first

By G. Edward Pendray, senior partner, Pendray & Company, New York City.

made about smoke, fly ash, fumes, or whatnot, often communicated by friends, two sorts of self-contradictory replies are commonly made.

The first is generally to the effect that it isn't so. I have known instances where this kind of retort was made even though, at the very moment, visible clouds of smoke were pouring from the stacks and fly ash particles were falling like gentle rain. Obviously this answer satisfies nobody. But it convinces both the friends and opponents of the management that the plant will not take a hint.

When agitation increases, the manager's next retort is likely to the effect that—well, it's an industrial area. The plant was there long before the town grew to its present size. If people want to move into an industrial community, they must take the consequences.

The net effect is to make everybody mad. An antiplant movement is likely to take organized form. There will presently be meetings, speeches, and letters to the editor. Before long, a vocal opposition develops—an opposition that has become convinced that political or legal action is necessary to make the plant take the steps required.

The Start of Fireworks

At this point, the manager asks the advice of legal counsel. The lawyer generally advises that any kind of statement, other than denial, may constitute an admission of fault and therefore be costly.

So the management, which up to now may have handled the matter only blunderingly, takes a worse step. It begins to act guilty. It refuses to discuss the pollution problem, perhaps even maintaining there is none.

A delegation of citizens comes to discuss the question, hoping to find a meeting of minds, or to be able to report progress. The management may refuse to see them, or may have a lawyer do the talking. The local paper may send a reporter out, with a view to helping the management off the spot. The reporter gets barred at the gates, or is told that the company has no statement for the press, or is handed a brief denial of all guilt, patently written by an attorney.

By this time the stage is set for real fire-

works. What started out to be a simple problem of dealing with a natural community desire for better living has by now been blow up into a crusade. Employees find themselves in disfavor with their neighbors. The company now has an employee morale problem added to its other difficulties.

Presently a pollution ordinance is passed, or if the community already has one, it is given teeth. A policeman, under one title or another, is appointed to deal with the plant. Regulations as to the amount of smoke, fumes, pollutants, and the like are adopted—often without any idea of their effect either on the nuisance or on the economics of the community.

The plant is at last forced to yield or to take the remedial measures which, had they been undertaken voluntarily, would have gained the company credit for public spirit. But now, though the cost is the same, or maybe greater, the company comes out of the quarrel with a black eye. Its employees are confused and alienated. All private industry has received another setback in the community.

Unfortunately, it is not possible to tell how widespread situations of this kind are today. But there are a great many more of them than most industrial managements know about or will admit.

I know of one city where the local manufacturers association has a fine-sounding air pollution control committee. Its members include representatives of the city's leading industries. There are several plants in this city that have done nothing, except to make promises, to solve a shockingly bad smoke and fume pollution situation. The committee doesn't even meet. Some of its members have said that the committee is afraid to acknowledge the existence of the pollution problem because then the community will demand too drastic a cleanup.

In the meantime, the community is demanding a cleanup anyway. A citizens committee on air pollution has also been organized, and it meets. In this city it is not just one plant that is going through the syndrome. All industries seem to be following the same foolish course collectively.

On the other hand, there are many communities where the investment of major companies in research, air pollution control, and intelli-

gent community relations practices has really begun to bear fruit. Some are even reaching the point where the citizens can actually bring themselves to believe that some factors other than industry are adding to air pollution—communities where apartment houses, private homes, municipal plants of various kinds, garbage dumps, and even autos and buses are coming in for their share of critical examination and efforts at control.

Many a company has discovered that air pollution problems can also be community relations opportunities. I know of several that have gone through the air pollution syndrome, and, as a means of clearing up its aftermath, have organized complete and effective community relations programs, only to discover with delight that these activities have brought them great and unexpected gains in better employee morale, better community and supplier cooperation, and have even enhanced their reputation far beyond the communities immediately concerned.

I think all industry will ultimately make this kind of discovery. It is a good thing, too, for in my opinion the necessity to control air pollution will grow—rather than diminish in the future—because air pollution is one of the diseases of increasing population, and population both in the United States and all over the world will continue to increase, at least throughout the balance of this century.

Not Instruments Alone

Periods of aggravated air pollution are usually recognized because of reduced visibility, effects on health, and damage to plants. Damage to vegetation annually causes great economic loss. Typical of the sources of the several pollutants

By J. T. Middleton, Ph.D., plant pathologist, department of plant pathology, University of California, Riverside, Calif.

contributing to this loss are the processes associated with chemical manufacture, ceramic production, and combustion effluents.

Not only is the effect of pollution on the plant of economic importance, but the response of the plant to the pollutant is useful in estimating the severity of the problem. By their response as a biological system, plants provide a convenient method for recognizing the presence of airborne contaminants, determining the distribution of the pollutants, assisting in an estimate of the level of pollution, and providing a passive collection system for subsequent chemical analysis.

The use of plant material has certain limitations. Among the more important is the non-specific response of plants to some chemically different airborne constituents.

Use of Instruments

The development of instruments for monitoring and recording toxicant levels has made an assay of local pollution more effective. The Thomas autometer is used for accurate and continuous determination of levels of sulfur dioxide and, by the addition of a combustion chamber, for recording the total sulfur in the atmosphere.

This machine has obviated the need of a biological system for noting sulfur dioxide. However, when it is used to record sulfur dioxide and total sulfur concentrations, discrimination between hydrogen sulfide, other sulfurous materials, and sulfur dioxide cannot be completely assessed, and further interpretation is made possible by the response of test plants.

Recording devices are becoming available for the measurement of halogens and halides. The automatic recording of atmospheric fluoride through an apparatus developed by the Stanford Research Institute should aid greatly in monitoring this effluent in areas adjacent to sources of fluorides. Until such equipment is available, noting the response of plants remains a useful method.

Levels of airborne fluoride can be detected by using a variety of plant materials and noting the species affected. The gladiolus has proved satisfactory for measuring concentration, gra-

dient, and geographic distribution of the toxicant. Plants resistant to injury from fluoride can be used as passive collectors, and the level of pollution can be determined subsequently by chemical analysis.

A new Beckman instrument provides a continuous record of oxidant level based on the colorimetric measurement of iodine released from neutral buffered potassium iodine. During periods of aggravated pollution in the south coastal basin of California, elevated oxidant levels have been recorded. Investigations by Haagen-Smit have shown that oxidants resulting from ozonation of unsaturated hydrocarbons produce reaction products which are responsible for the smog injury common to California's urban areas.

Nature's System

Research at the University of California at Riverside has corroborated the findings of Haagen-Smit. The specific response of pinto beans, grown under controlled conditions, to the reaction products of oxidation of hydrocarbons and ozone has provided a ready means of determining the presence in the atmosphere both of oxidized material and of ozone.

Exposure of test plants to oxidized hydrocarbons has shown that silvering and bronzing is limited to the lower leaf surface. Controlled fumigations in which ozone is introduced into the fumigation space have shown that the upper leaf surface is bleached and mottled with no injury to the lower. When both oxidized hydrocarbons and surplus ozone were present, bleaching of the upper leaf surface and silvering of the lower resulted.

A 1954 survey was conducted with the Air Pollution Foundation to determine the relation between plant damage and oxidant level as measured with the Beckman oxidant recorder. Exposed pinto bean plants were evaluated on a subjective basis for the presence of damage caused by oxidized hydrocarbons and that due to ozone only. Test plants were found to be regularly injured by oxidized hydrocarbons. Only twice was there a suggestion of some ozone damage. Yet pinto beans are much more sensitive to ozone. Analyses thus far completed support the view that the reaction prod-

uct of oxidized hydrocarbons rather than ozone is the principal phytotoxicant present in the southern California coastal basin.

This evaluation could not have been made with instrumentation alone and well illustrates the need and value of analytical biological systems since the machine apparently cannot distinguish between the two toxicants.

Measuring Particle Size

PHR There has long been a desire for a rapid method to determine the particle size and size distribution in an aerosol of nonuniform particle size. This desire ranges from a vain wish for an instrument that will automatically plot a size distribution curve from a sample in situ to an approximate method of measurement of the average size.

Continuous and automatic measurement of predominant particle size by light-scattering is one method of rapid approximation. It provides measurements on the aerosol in situ with a minimum of disturbance.

Other methods of illumination have been used, but the one I propose appears to be the simplest feasible optical system. It partly overcomes the multivalues of most light-scattering functions, such as scattering cross section, depolarization, and ratio of forward to back scattering. The method will tell nothing about the distribution of particle size, but it will tell the predominant size within a certain range.

Two light-scattering chambers and two phototubes are required to simultaneously record the forward and 90-degree scattering, either of which can be used as a measure of concentration. A constant source of white light is necessary for sufficient stability and intensity.

*By David Sinclair, Ph.D., senior research physicist,
Johns-Manville Research Center, Manville, N. J.*

The aerosol is drawn continuously through the two chambers in quick succession. One has darkfield illumination similar to that used in the Sinclair-Phoenix aerosol photometer, except that the cone of incident light is narrower. Illumination is provided by an annular ring at angles between 5° to $7\frac{1}{2}^{\circ}$ from the axis, allowing observation of scattering at angles from 2° to 10° .

The source, a coiled tungsten filament, is focused on the aerosol passing through the chamber in a narrow stream at right angles to the axis of illumination. The aerosol is collected on a filter to determine mass concentration and calibrate the instrument.

A wide angle cone of illumination is used in the second chamber. Observation is made at right angles to the axis of illumination. The scattering from each chamber may then be measured simultaneously with separate photomultiplier tubes and the photocurrent amplified and recorded continuously. The normalized relative value of the two readings is a measure of the particle size or sizes which produce the predominant light-scattering effect. The larger sizes greatly predominate over the smaller, a defect common to all light-scattering measurements, as well as other measurements made on the aerosol as a whole.

Performance calculations show that the ratio of small-angle forward scattering to right-angle scattering is single valued over a large and useful range of particle size. This ratio increases continuously, but not uniformly, from 2 in the very smallest region of sizes to about 500 at a diameter of 6 microns.

Measurements of this ratio in a nonuniform particle size aerosol could be used to determine an approximate average particle size or whether a change in scattered light intensity was caused by a change in the particle size or a change in concentration.

The change in size will be obtained only approximately, but the details are frequently not needed. A detailed size distribution curve may often be obtained with the electron microscope, but the labor involved is enormous. However attractive such a curve may look on paper, it is frequently more important to observe the integrated effect of the aerosol, such as the visibility and mass concentration. The photom-

eter will give a continuous record of such information with a minimum of effort and, with proper calibration, will give information about particle number concentration and size.

Efficiency of a Cyclone

PHR The separation of dust from a gas stream in a cyclone, the most important industrial type of centrifugal dust collector, is often hindered by air leaking into the dust bunker.

At the Mining Research Establishment of the Netherlands State Mines at Treebeek, Netherlands, experiments showed quantitatively the detrimental effect of this leakage.

Leakage may be the source of clogging or extreme wear of the cyclone, but most important is the low efficiency and high dust content of the cleaned gases caused by it.

Leakage of air into the bunker is only possible if there exists a pressure difference between the outside and the inside of the bunker. The bunker pressure is, of course, lower than the atmospheric pressure when the gas outlet of the cyclone is connected to the intake of a fan. But even in the case where the gas outlet opens directly into the atmosphere the pressure in the dust outlet and in the dust bunker may be lower than the atmospheric pressure and be the cause of leakage.

As a result of the tests it appears that the pressure in the dust bunker rises when the diameter of the dust outlet increases. This may be a means to diminish the pressure difference between dust bunker and atmosphere and to prevent, in this way, the leakage.

It is shown that, when there is no leakage, increasing the dust outlet size has sometimes the agreeable consequence of increasing the col-

By H. J. van Ebbenhorst Tengbergen, mechanical engineer, Mining Research Establishment, Staatsmijnen in Limburg (Netherlands State Mines), Treebeek, Netherlands.

lecting efficiency of the cyclone. The detrimental effect of air leakage on the collecting efficiency is smaller with a large dust outlet than with a small one.

In the investigations the dust outlet area was varied by more or less lengthening the cone of the cyclone within the bunker.

For the sake of simplicity, the tests were carried out with a single cyclone placed in a gas transport system, although the cyclone was not always of the same type. The same conditions would apply, however, to cyclones placed in parallel or to multicyclones. The dust—in all tests the same foundry dust was used—was introduced into an airstream, which by means of a fan was forced through the cyclone and then returned into the atmosphere through a filter bag. Tests were carried out with both large and small bunkers, but the capacity of the bunker had no appreciable influence.

In many cases the bunker pressure cannot be made equal to the atmospheric pressure. Then the valve or sluice under the dust bunker has the difficult task of preventing any leakage from outside to inside and, at the same time, of letting the dust flow freely in the other direction. In the paper several constructions are shown.

Injuries to Vegetation

PHR Portugal reports two cases of damage to forest stands of maritime pine (*Pinus pinaster* Sol. ex Ait) and blue gum (*Eucalyptus globulus* Labill.) which point to atmospheric pollution by sulfurous gases.

This conclusion was reached as a result of our observations in the field, the peculiar symptoms

By Natalina Ferreira dos Santos de Azevedo, forest pathologist of the Direction General of the Forest Services and of the National Agronomic Station, Lisbon, Portugal.

in evidence on the affected trees, the general aspect of the surrounding vegetation, the near-by presence of smoke emitters, and the microscopic and chemical analyses in the laboratory. There is no question of biotic disease.

But it was on the assumption that an unidentified and highly destructive disease was spreading among the pine and eucalypts in two forest conservations in the District of Aveiro that I was sent in 1953 to survey the damage.

The first case was that of a mixed stand of pine and eucalypts, where the latter was the dominant species, surrounding a small mine working a smelter for pyrites. On approaching the premises, I became aware of a strong irritation of the eyes and the mucosae of nose and mouth. I even had violent fits of coughing and a sense of suffocation, suggestive of a high sulfur dioxide concentration in the air.

The pines in this stand did not undergo such severe injuries as appeared on the leaves of the eucalyptus trees. In the early stage of damage, red and brown patches, outlined by a thickened rim, appeared on the leaves of the latter. In the more advanced stages of the attack, silver specks and patches developed, which ultimately would turn into large corroded areas. The whole leaf would then become dry and deciduous, leaving the trees completely bare.

The second case was that of two pine stands (with a few eucalypts in one stand) in the vicinity of a brickyard, where the wind spread the exhaust gases from an oil engine over most of the nearby trees, causing very severe damage.

The pines, especially, presented the aspect of a greatly lowered vitality, and their needles were very thin and small.

A great many were dry or even burnt. Secondary branches, the upper part of the trunks, and the twigs were soft—not “woody”—to the touch when pressed between the fingers. They could easily be bent without breaking. The trees were covered all over with black soot. The damage in these stands was considerable—a great number of trees had been killed.

The pines unquestionably had suffered most, but the eucalypts also presented nearly all the symptomatology described for the first case.

With the expansion and modernization of many small industrial enterprises throughout Portugal it is no longer rare to meet with forest

units in the vicinity of factories showing evident signs of greater or lesser degree of damage not caused by pathogenic agents.

The World Supply of Sulfur

Sulfur, one of the first chemical elements used by mankind, has maintained its position as an essential material through the ages of history.

The pattern of use by a nation is an accurate gauge of the extent and nature of the nation's industrial and agricultural activity.

As each new industrial or agricultural development has occurred, some new application of sulfur generally has resulted. In the atomic age of today, the versatility and indispensability of the element continue to be demonstrated.

Sulfur and the chief form in which it is used, sulfuric acid, are warp and woof of our own industrial economy. As a nation, we consume 3 times as much sulfur as aluminum, 4 times as much as copper, 5 times as much as lead, 5 times as much as zinc, about 50 times as much as nickel, and more than 90 times as much as tin.

Sources of Sulfur

The discovery of native sulfur in the United States and the invention of the Frasch hot-water process for mining the element changed the pattern of world supply and set the stage for the important role sulfur was to play in the industrial growth of the future.

Among the forms in which sulfur is commonly found are native sulfur, or brimstone, the principal source of which is the salt dome deposit; metallic sulfides, principally pyrites; sulfide gases associated with natural gas and petroleum; and natural sulfates. Although not an important source of supply at this time, the natural sulfates, principally anhydrite and

gypsum, occur so extensively as to be almost inexhaustible.

A second major source of supply is the limestone and gypsum formations in Sicily and on the mainland of Italy. A third source originates in volcanic activity. Important deposits are found in Japan and the Andes Mountains of South America.

Large deposits of the pyrites, the iron sulfide minerals containing from 25 to 50 percent sulfur, are located in the southern part of Spain and Portugal. Other major reserves are in Cyprus, Norway, Sweden, Finland, Japan, Italy, Germany, France, Canada, Australia, and elsewhere.

A secondary source of sulfur related to sulfide minerals is the sulfur dioxide in stack gases of smelters treating sulfide ores for the recovery of copper, lead, and zinc. Sulfur dioxide contained in these gases is usually converted to sulfuric acid in contact acid plants. Feed gases are first cleaned and dried before being fed to the catalyst. In other instances, the smelter gases are used in the manufacture of liquid sulfur dioxide or ammonium sulfate.

Another source of byproduct sulfur is the hydrogen sulfide in natural, refinery, and coke oven gases. In the recovery of sulfur from gases, hydrogen sulfide is first extracted from the source gas with selectively absorbent solutions. High-strength hydrogen sulfide gas is then stripped from the absorbent and fed to a furnace where combustion air is introduced to burn about one-third of the hydrogen sulfide to sulfur dioxide. The mixed gases are cooled and passed through a catalyst to form sulfur and water vapors. These vapors are cooled to condense the sulfur to a liquid state, while most of the moisture is discharged as vapor with the exhaust gases.

The amount of sulfur recovered from hydrogen sulfide in sour natural gas and in refinery gases in the United States alone has increased from 57,000 tons in 1949 to an estimated 350,000 in 1954. At the same time the number of recovery plants has increased from 4 to over 30.

A number of factors has stimulated the recovery of sulfur from these gases. The mounting demand for natural gas had led to the development of new natural-gas fields in the

By J. C. Carrington, vice president, Freeport Sulphur Company, New York City.

United States and Canada having a hydrogen sulfide content as high as 50 percent. Before this gas can be used, the hydrogen sulfide must be removed. In addition, the drive to reduce atmospheric pollution at refineries has exerted a strong influence.

A World Pool

The free world draws in varying degree upon all of the sources mentioned for its supply of sulfur. The supply may be considered as a huge pool, filled by production from some 40 different countries. The production of sulfur and sulfur-bearing materials has been growing steadily. Major changes have occurred since 1949 in connection with the production of Frasch sulfur.

In 1953, the estimated sulfur consumption of the free world was about 12.5 million long tons. Consuming nations took from the supply pool about the same amount that was put into it. The excess of production over consumption amounted to only 200,000 tons, or less than 2 percent of the total. The present supply-demand picture is one of ample production and productive capacity, and the history of sulfur consumption would indicate a continuing growth in the use of the element.

Powerplant Stack Gases

PHR So far as is known, the only power stations in the world in which flue gas is washed are in Great Britain. Although powerplants burn only about one-fifth of all coal consumed and mostly discharge stack gases into the atmosphere at a much higher level than other consumers, interest has continued for many years in the possibility of lowering the concentration of sulfur dioxide in powerplant stack gases.

By R. Llewellyn Rees, M.A., M.I.Chem.E., chief chemist, British Electricity Authority, London.

Interest has been intensified by the rate of growth of electricity generation, by the trend toward high concentrations of sulfur in the fuel above the normal average of 1.5 percent, and by the effects of the 1952 London fog, which led to the formation of the Committee on Air Pollution.

One of the committee's many recommendations is the removal of sulfur from flue gases at new power stations in populated areas. The British Electricity Authority has been studying the whole subject since its formation in 1948.

Gas-Washing Processes

The principal difficulty in the way of devising a satisfactory flue gas-washing process for a modern powerplant lies in the severe requirement that at least 90 percent of the sulfur dioxide must be removed from gases flowing at a rate of more than 1 million cubic feet per minute, when the original concentration of sulfur dioxide is 0.1 percent or less. The washed gas, unavoidably cooled in the washing process, comes to ground so much nearer the stack than hot unwashed gas that there might be no improvement in the maximum ground level pollution by sulfur dioxide if a lesser amount were removed.

This difficulty rules out a number of processes that are used effectively at smelters, where the initial concentration of sulfur dioxide is much higher, and where a higher residual concentration of sulfur dioxide is deemed satisfactory.

Other difficulties too are presented by the problem of coupling the process to the generation of electricity at a cost that is not prohibitive, by the presence in the gas of other constituents which may lead to unwanted and wasteful side reactions or to contamination of the end product of the process, and by the large-scale operation required for waste disposal or sale of an end product being produced in some instances at the rate of 20 to 40 tons an hour.

From the point of view of British authorities, there are only three gas-washing processes which show promise at present for active chemical engineering development. These are the Battersea effluent process, which is severely restricted in its application by site require-

ments; the cyclic lime process, which is extremely costly and presenting a huge waste disposal problem; and the ammoniacal liquor process, which is restricted in its application by the supply of ammoniacal liquor, and which has only just passed from the laboratory stage to that of the pilot plant. Only the last is productive in the sense that any value is derived from the sulfur dioxide in the flue gases. One advantage is that the ammonium sulfate market is not likely to be upset by its operation.

Value of Tall Stacks

There has been considerable debate over the real value of gas washing in alleviating air pollution, whether it is sufficient to discharge the gases from tall stacks or whether it is also necessary to wash the gas.

At first sight it seems that the removal of some tons of sulfur dioxide hourly from the gases leaving a powerplant is bound to improve the state of the atmosphere substantially. This is undoubtedly true when the gas is discharged from stub stacks in such a way that it is caught in the down eddies that form in the lee of the buildings, as happens at older plants.

All but one of the newer powerplants in Great Britain have stacks at least $2\frac{1}{2}$ times the height of the buildings and at least 300 feet high. Thorough surveys by the British Electricity Authority have showed that in no instance has it been possible to detect any changes in the monthly mean sulfation rates that can be related significantly to the amount of coal burned in the plant.

The implication is that either the technique of measuring the rates is inadequate for measuring the extent of pollution or that our method of discharging the gas hot and at speed from high stacks gets it sufficiently well dispersed into the atmosphere before it can reach ground level.

Conversely, gas washing cools and saturates the gas, which falls to the ground from time to time quite near the power station although discharged from tall stacks. The fall is most frequent and rapid when the wind is light and variable, an effect so far not taken into account by the equations describing dispersal of gases from tall stacks.

In practice, however, this effect is important to the London public. People complain about the emission from the city's power stations, when most of the sulfur dioxide has been removed, but make no complaints about the other powerplants with tall stacks where gas washing is not in use.

It is also worth noting that washed gas has no chance of escaping through the ceiling of an atmospheric inversion, whereas hot gas leaving high stacks has a good chance.

It may be concluded that the removal of sulfur dioxide from flue gas in its present state of development leads to loss of goodwill in the neighborhood of the powerplant. A lowering of the general level of air pollution, which would seem to be an obvious result, has not been disclosed by the methods of measurement that have been used to test the improvement. Whether the gain can be worth the extra cost in the price of electricity that the gas washing would necessarily entail has still to be decided.

Sulfur in the Steel Industry

PHR It is significant that classical and medieval literature has always associated the art of metalmaking with the lower regions—with torment, fire, and excessive labor—and that the flames of Hades were associated with evil-smelling, poisonous flames of sulfur.

So far as ironmaking and steelmaking are concerned, everlasting torment and sulfur have always been synonymous terms. The presence of sulfur in iron and in steel, except under certain conditions, is harmful, and rigid limits on the amount permissible are imposed by standard specifications.

No matter what the sulfur content of the raw materials used may be—and practically all iron

By T. P. Colclough, C.B.E., D.Sc., M.Met., technical adviser, British Iron and Steel Federation, London.

ore, limestone, and the fuel particularly, contain sulfur in varying but marked degree—the sulfur content of the finished iron or steel product cannot exceed a specified percentage, 0.05 percent or even less.

In the steelmaking operation, the sulfur content of the raw materials must be reduced to below the limits imposed by the specification for the finished steel. The whole of the sulfur removed from the metal is retained in the furnace slag, and it is imperative that no sulfur enter the metal or the slag from the fuel used. Its combustion must be complete, and the sulfur content must be converted to sulfur dioxide. Chimney gases from the furnaces carry away all the sulfur dioxide formed. The same conditions apply to the rolling and forging heating operations.

In the manufacture of the coke which is used in the blast furnaces, some 60 percent of the sulfur in the raw coal is retained in the coke; 40 percent is found in the tar and coke oven gas. This sulfur is removed when the gas is used for public utility purposes and under certain conditions can be removed economically when the gas is used for steelmaking or other industrial purposes. Some 14 percent of the total sulfur in the raw coal carbonized is contained in the stack gas from the ovens where unpurified gas is used for underfiring. The remaining 86 percent is retained in the coke and other byproducts.

In the smelting of pig iron, the whole of the sulfur present in the coke, ore, and other raw materials used is absorbed in the blast furnace slag with the exception of a small percentage in the iron itself. No sulfur-bearing gases are formed.

Fuel—The Problem

The iron and steel industry presents no unique problem so far as pollution of the atmosphere by sulfur is concerned. In fact the only sulfur emitted arises from the fuel which is used for the thermal requirements of the process, and the amount, measured as percentage of the sulfur entering the system, is far less than in many other industries.

The sulfur pollution of the atmosphere by the industry arises essentially from the combus-

tion of the fuels which it consumes. The elimination of this pollution is shared in common with all fuel users and can only be attained by a reduction of the sulfur content of the fuel supplied and the removal of the sulfur-bearing constituents of stack gases, or by both practices.

The steel industry in the United Kingdom may be regarded as removing some 48 percent of the total sulfur present in the various fuels which are consumed and, to this degree, makes a marked contribution to the problem of reducing the pollution. However, this statement does not in any sense minimize the importance of preventing the pollution which still exists.

A determined effort has recently been made in the United Kingdom to develop an economic wet absorption process which will eliminate or reduce the sulfur content of coke oven gas used internally as fuel. Considerable difficulties have been encountered, arising mainly from the extremely corrosive action of the solutions formed, but so far the process has been a success to the point that 80 percent of the sulfur can be removed and recovered in the form of sulfuric acid.

This means that the pollution of the atmosphere from this purified coke oven gas, when used, will be far below that of any other type of fuel available. If similar processes can be applied on a wide scale, a marked contribution can be made to the solution of air contamination.

A Scrubbing System

It is one thing to develop a method for the elimination of air pollution. It is something else to find a method that is economically sound, at least to the extent that it does not make the entire operation a cost burden. It is also important

By Clayton Lawler, B.S., technical director, Western Sulfur and Acids Division, Olin Mathieson Chemical Corporation, Little Rock, Ark.

that the method selected does not convert an air pollution problem into a water pollution problem which cannot be handled.

We believe these criteria have been met successfully in the sulfur dioxide removal system installed more than a year ago in the large sulfuric acid plant of the Olin Mathieson Chemical Corporation at Pasadena, Tex. We see tremendous possibilities for application of this extremely efficient system to the removal of sulfur dioxide from powerplant stack gases.

The process is a modification of the single-stage recovery system pioneered by the Consolidated Mining and Smelting Company of Canada. The modified design, which is in effect a 2-stage unit provided with automatic controls, yields an exit gas containing less than 0.03 percent sulfur dioxide, a very low level which will be more than satisfactory to any community. The system is so designed that a minimum of ammonium sulfate is formed and a maximum of sulfur dioxide is removed from the gas stream. It operates at low temperatures.

The system involves the use of an oversize scrubbing tower made of redwood and a stripper for recovering the sulfur dioxide from the ammonium sulfite-bisulfite solution. The upper section of the tower is separated from the lower section. Absorbing solution is circulated to the top section to remove all but traces of the sulfur dioxide. Anhydrous ammonia is continuously added to the scrubbing solution as makeup for that which is converted to ammonium sulfate. The addition of water to the system maintains the solids concentrations at the optimum value for effective operation. The inert gases are discharged to the atmosphere from the top of the tower.

Exit gases from the acid plant containing sulfur dioxide, which formerly was discharged to the atmosphere, now enter the base of the new tower through a vestibule. Solution is continuously bled from the scrubber to the stripper. Sulfuric acid is added to the stripper to convert the ammonium sulfite-bisulfite to ammonium sulfate and to assist in the evolution of sulfur dioxide. The exit gases from the stripper containing sulfur dioxide and air are returned to the acid plant drying tower for conversion to sulfuric acid. The solution from the stripper

is pumped to an adjacent fertilizer plant as a 40 percent solution of ammonium sulfate. Including handling losses, 97 percent of the ammonia is recovered as ammonium sulfate under normal operating conditions.

Refinery Sulfur Recovery

PHR The disposal of hydrogen sulfide released in some petroleum refining operations poses a problem to refiners. Many have found that easily operated plants which convert the hydrogen sulfide to elemental sulfur provide a practical and profitable means to handle these streams. Not only is the quantity of sulfur compounds emitted to the atmosphere reduced but also an additional supply of a valuable commodity is produced.

In the past, sour, or sulfur-containing, crude petroleum was not generally processed because it added corrosion problems and increased the processing facilities required to meet petroleum product specifications. With the decline of sweet crude reserves, however, it soon became apparent that more sour crudes must be processed.

The sulfur in sour crudes exists in many forms from elemental sulfur and hydrogen sulfide to a variety of complex organic compounds. As refinery facilities for handling sour crudes were installed, it became necessary to dispose of the hydrogen sulfide released from the crude petroleum.

Legal and safety restrictions based upon the odor and toxicity of hydrogen sulfide essentially forbid its being discharged to the atmosphere. To meet these restrictions, the hydrogen sulfide gas streams were burned to sulfur dioxide in a flare stack or boiler before being re-

By George E. Smalley, senior process engineer, and James W. Klohr, process engineer, the Ralph M. Parsons Company, Los Angeles.

leased to the atmosphere. Sometimes the hydrogen sulfide was converted directly to sulfuric acid.

As cracking and other refining processes increased the yield of useful petroleum products, other forms of sulfur in the crude were converted to hydrogen sulfide. Catalytic refining processes are particularly effective in converting sulfur to hydrogen sulfide.

As more catalytic refining processes are being installed, the amount of hydrogen sulfide released per barrel of crude petroleum is increasing. The quantities of hydrogen sulfide being produced in many refineries today are too large to permit flaring as sulfur dioxide.

Installation of recovery plants to convert the hydrogen sulfide to elemental sulfur is the best solution to the problem.

By the end of 1955 approximately 1,000 tons a day of sulfur will be recovered from sour gases at petroleum refineries throughout the United States. The recovered sulfur will represent a reduction of 2,000 tons a day of sulfur dioxide which otherwise would be released to the atmosphere.

There will soon be 17 refinery plants converting hydrogen sulfide gases to elemental sulfur.

In Los Angeles, such units are daily recovering almost 180 tons of sulfur which would otherwise be emitted to the atmosphere as 360 tons of sulfur dioxide.

The Los Angeles Ruling

Even though a sulfur recovery plant materially contributes to the reduction of sulfur compound emitted to the atmosphere, until recently regulations in Los Angeles County would not permit the operation of a sulfur recovery plant unless the operator obtained a variance from a special hearing board.

Strict application of the regulation relating to specific contaminants, known as rule 53a, was recognized as a deterrent to the installation and operation of plants that recover sulfur compounds. The regulation permitted no single source of emission to discharge sulfur dioxide exceeding 0.2 percent by volume. Yet, even with 3 or more reactors, incinerator effluent gases could not normally meet the limitation.

To correct this situation, a new rule (rule

53.1) was added in November 1954. The new rule is undoubtedly of interest to other air pollution agencies throughout the country and reads in part:

"Where a separate source of air pollution is a scavenger or recovery plant, recovering pollutants which would otherwise be emitted to the atmosphere, the Air Pollution Control Officer may grant a permit to operate where the total emission of pollutants is substantially less with the plant in operation than when closed, even though the concentration exceeds that permitted by Rule 53 (a) . . ."

A Gas-Washing Process

PHR In the Fulham-Simon-Carves ammonia process for the removal of sulfur dioxide from flue gas, sulfur is recovered in the form of ammonium sulfate and sulfur.

Flue gas is scrubbed with a concentrated solution of ammonium salts, ammonia being added at a rate corresponding to that of the absorption of oxides of sulfur. If pure ammonia is used, the scrubbing liquor contains ammonium sulfate, sulfite, and bisulfite, and oxidation of the solution converts the sulfites to sulfate. On the other hand, if crude ammonia (concentrated gasworks ammoniacal liquor) is used, ammonium thiosulfate is formed in addition to the salts mentioned.

The liquor obtained in the latter case is treated in an autoclave in the presence of a small amount of sulfuric acid, when the sulfite, bisulfite, and thiosulfate decompose to give sulfur and ammonium sulfate as the final products. About 90 percent of the product is ammonium sulfate suitable for use as fertilizer, and about 10 percent is sulfur.

The metropolitan borough of Fulham, London, and Simon-Carves, Ltd., sponsored pilot

By H. E. Newall, Ph.D., Sc.D., Department of Scientific and Industrial Research, Fuel Research Station, London, England.

plant experiments at the Fulham generating station in 1939 and were granted a patent in 1940. The work came to an end in 1940 owing to the war.

After the war, it was decided, in consultations between the British Electricity Authority, Simon-Carves, Ltd., and a working group set up by the Department of Scientific and Industrial Research, that experimental work on the process should be restarted and that it should be carried out at the Fuel Research Station of the department.

Pilot plant experiments at the Fuel Research Station showed that efficiencies of removal of sulfur dioxide of 80 to 95 percent, depending on the conditions, could be obtained.

Some of the conditions influencing the efficiency were the rate of gas flow, the depth of

the grid packing in the scrubber, the concentration of ammonium sulfite and bisulfite in the liquor, and whether the scrubbing was performed in one or two stages. The maximum efficiency was obtained by a 2-stage process in which the flue gases were scrubbed with a concentrated solution of ammonium salts in the first stage and with a dilute solution of ammonium salts in the second stage.

Copies of the full papers may be purchased from the Order Department, American Society of Mechanical Engineers, 29 West 39th Street, New York 18, N. Y. The complete proceedings of the congress will be available in book form after October 1, 1955.

Legal Note on Dual Inspection

In *Falfurrias Creamery Company v. City of Laredo*, 276 SW 2d 351 (Tex. 1955), the Court of Civil Appeals of Texas held unconstitutional the portion of a municipal milk ordinance providing that the city health officer of Laredo shall not accept inspections, examinations, or certificates of any health officer of another city in issuing permits to sell milk. The State Legislature of Texas had enacted as a statewide statute the Milk Ordinance and Code—1953 Recommendations of the Public Health Service.

The city of Laredo contended that in accordance with the provisions of its local ordinance it had the right and duty to inspect the facilities of a dairy at Falfurrias, Tex., 90 miles from Laredo, before issuing a permit to the Falfurrias dairy to sell its milk and dairy products within the city of Laredo. A milk inspection service is maintained by the city of Falfurrias which is fully approved and accredited by State authorities, and the dairy in question had been inspected and passed by the milk inspection authorities at Falfurrias.

The court in its decision indicated that while it was the legislative purpose in enacting the standard milk ordinance as a State statute to

insure the purity of milk supplied to the inhabitants of the State, it also was the legislative purpose to provide for the free flow of wholesome milk products from one city to another, unburdened by unnecessary duplication of adequate inspection and the erection of prohibitive trade barriers. The court indicated further that one of the purposes of the standard milk ordinance is to restrict the erection of trade barriers that would result from pyramiding of inspection fees and services.

The court pointed out that the record in the case indicated that the Falfurrias inspection was made in accordance with the regulations of the State health officer and is generally accepted by other cities in the State. Further, the Laredo health officer made no claim that he was dissatisfied with the standards or methods of the Falfurrias inspection. Therefore the court stated that since "Any ordinance or statute which prevents any person from engaging in a lawful business cannot be upheld unless protection of life, health or property make it reasonably necessary," the position of the Laredo health authorities, in the light of the record, was "wholly arbitrary."

leased to the atmosphere. Sometimes the hydrogen sulfide was converted directly to sulfuric acid.

As cracking and other refining processes increased the yield of useful petroleum products, other forms of sulfur in the crude were converted to hydrogen sulfide. Catalytic refining processes are particularly effective in converting sulfur to hydrogen sulfide.

research, many valuable immunizing agents have been produced.

Elimination of some diseases from our animal population has been so complete that many people have never known or have forgotten that such diseases ever existed; hence, too many of our citizens are somewhat unconcerned regarding veterinary education and research. This is the more regrettable because disease is not static. New problems arise frequently and solutions to these must be sought.

History of Veterinary Education

Formal veterinary education began in France with the founding of the veterinary college at Lyons in 1761. This important event was precipitated by outbreaks of rinderpest (cattle plague), a serious epizootic disease of ruminants prevalent in Africa and Asia and repeatedly spread to Europe, especially in times of war.

Emergencies created by wars were largely responsible for the founding of a second veterinary college in France in 1764, the renowned *Ecole Nationale Vétérinaire d'Alfort*.

In 1773, the Royal Veterinary College in Copenhagen, Denmark, was established for the purpose of providing protection for the health of the all-important animal industries of that country. Soon after the founding of these three veterinary colleges, others were established throughout Europe and elsewhere.

Veterinary Education in North America

The first veterinary college in the United States was established in Philadelphia in 1852; the second, in Boston, in 1855, and the third, in New York, in 1857. All these failed in a short time. From 1852 to 1947, 34 veterinary colleges were established and discontinued in the United States and Canada.

The Ontario Veterinary College, affiliated with the University of Toronto, was founded in 1862 and is the first one in North America to have survived to the present.

In 1908, there were 14 private and 7 State veterinary colleges in the United States. By 1918, the number had grown to 23, all offering complete courses in veterinary medicine; 12 of

these were private and 11 were State-supported and affiliated with State colleges and universities. The oldest of the State veterinary colleges in the United States was established at Ames, Iowa, in 1879 as a division of Iowa State College.

A move to raise veterinary educational standards by providing better instruction and more adequate equipment was made in 1908 by Dr. A. D. Melvin, chief of the Bureau of Animal Industry, United States Department of Agriculture, and representatives from 12 veterinary colleges. Strangely enough, the opposition to this effort came chiefly from State schools.

Effects of Higher Educational Standards

During World War I the Surgeon General of the United States Army contributed to the raising of standards of veterinary education. Up to that time veterinary education varied from 2 to 4 years of college and there were varying entrance requirements.

Thus, because of the demands of the Bureau of Animal Industry and the Medical Corps of the Army, to which the Veterinary Corps was attached, minimum standards for veterinary education were established, namely, high school graduation or its equivalent as qualification for veterinary college admission and 4 years of study in an accredited veterinary college for obtaining the D.V.M. or V.M.D. (University of Pennsylvania) degree.

Because of the elevation of educational standards, the private colleges closed during or soon after the war period. Only the 11 State-supported schools remained. During the decade from 1920 to 1930, enrollment in veterinary colleges in the United States fell to an all-time low. Since then, it has increased rapidly (see chart).

Following World War I a number of veterinarians in the United States became vitally interested in the public health aspects of veterinary medicine and, through teaching and research, contributed much to preventive medicine and public health. Among them were: William H. Feldman, Ward Giltner, William A. Hagan, I. F. Huddleson, K. F. Meyer, Nathan Sinai, and Jacob Traum.

Graduates from schools of veterinary medicine, 1930-54

Illustration from the *Journal of the American Veterinary Medical Association*

This graph is based on the schools in the United States only. "War years" refers to the effect of World War II on the number of graduates. In 1943, two classes were graduated in 1 year due to acceleration; in 1948, because of the decrease in demand for veterinarians, only five schools had graduates.

Increased Demands for Veterinary Education

Since 1945, six new veterinary schools have been established in the United States, partly to meet the demands of returned war veterans for veterinary education and partly because of obvious need for more veterinary services. One of the fields of veterinary service which began to attract more and more veterinarians was what, for want of a better designation, is now called veterinary public health. This field has to do with the maintenance of animal health for the specific purpose of protecting the public from animal diseases transmissible to man. There are now 17 veterinary schools and colleges in the United States and 2 in Canada. These are listed, in the order in which they were founded, on page 665.

In 1954, the veterinary colleges in the United States graduated 799 students with the doctor of veterinary medicine degree (V.M.D., University of Pennsylvania). Ontario Veterinary College graduated 74. The number of graduates from the School of Veterinary Medicine, Province of Quebec (affiliated with the University of Montreal) was 18. The total number of seniors in the 19 veterinary colleges was 904 in 1954. The total enrollment in 1952 was 3,836 and in 1954, 3,883.

Entrance Requirements and Curriculums

From the time they were founded, three of the older veterinary colleges—Kansas State College, Michigan State College, and Texas

A. & M. College—have offered a 4-year professional curriculum with graduation from an accredited high school as entrance requirements. Iowa State College changed from a 3-year to a 4-year curriculum in 1903. The State College of Washington added a fourth year in 1906. During the period 1913 to 1917, all the rest of the older schools in the United States went over to 4-year curriculums. All the schools established since 1945 began with 4-year professional curriculums.

Entrance requirements have been raised from time to time. In 1931, Iowa State College added 1 year of college work, and soon the other colleges did likewise. Since 1949, all veterinary colleges in the United States have required 2 years of college work of a prescribed nature as minimum preparation for admission. A considerable number enter with the bachelor of science, master of science, or even the doctor of philosophy degree.

The United States Army and the Congress helped to elevate standards of veterinary education to their present level. Shortly after World War II, the initial rank of commissioned veterinary officers in the Army was changed from first to second lieutenant. The principal reason for this was that only 5 years of college work were required for the attainment of the D.V.M. degree. Members of the professions and the veterinary colleges reacted promptly and vigorously by adding a sixth year to the veterinary curriculum. The Congress responded by reestablishing the first lieutenancy as the initial rank for commissioned veterinary officers in the United States Army.

The Canadian colleges offer 5-year professional curriculums, with graduation from high school (5 years) or its equivalent as a minimum entrance requirement.

The nature of present-day veterinary education is shown in the curriculum on page 666, taken from the catalog of an American college.

It will be noted that much time is devoted to subjects dealing with communicable diseases, infectious and parasitic, with emphasis on preventive medicine. This undoubtedly has been instrumental in the success the veterinary profession has achieved in controlling and eradicating communicable diseases of animals. Inasmuch as veterinarians are trained to approach

health problems particularly as they apply to the herd rather than to the individual, they are well prepared for work in public health.

Three of the American colleges offer little or no formal class work in the fourth professional year. All, or most, of the fourth year work is done in the clinics where the students are required to make use of what they have learned in their basic science courses, that is, they must apply bacteriology, pathology, parasitology, pharmacology, and so on, in veterinary practice under the supervision of a well-qualified

² Veterinary public health administration.

clinician. In the clinics they will encounter patients in the form of all sorts of livestock, including chickens, ducks, and turkeys, and also pets and wild birds and animals of a considerable variety. This is one of the several features of veterinary medicine which make it a broad and often a very difficult subject.

One veterinary college assigns students for periods of service in slaughterhouses, public health agencies, and on farms of State institutions for experience and training in veterinary public health and general veterinary practice.

The colleges that are not so fortunately situated attempt to provide similar training through field trips to such places under the direction of teachers in the respective fields. Visits to biological and pharmaceutical manufacturing plants are usually included. Some schools require, and all encourage, the students to spend at least one summer vacation with a veterinary practitioner. Others require that the students spend 3 months during the summer in the clinics of the college in lieu of experience with a private practitioner.

One college requires that students who have completed the junior year continue during the summer quarter. Thus, they will be able to complete all professional academic requirements by the end of the winter quarter of their senior year. Each student then is required to spend the spring quarter as an intern under an approved veterinary practitioner. This system may have special merit because students who have completed all their academic work will obviously be better prepared to gain more out of this practical experience than will those who have only 3 years of basic professional education.

Emphasis on social and professional responsibilities is an intrinsic and essential item in education of any sort. Veterinary students should be thoroughly indoctrinated in their various responsibilities to society. Because veterinary education has been made possible by public expense, the public demand on a veterinarian's service in any field in which he may have been trained, seems just. This applies to participation in community public health activities, as well as to any other phase of veterinary practice.

Every veterinary college should have on its staff a veterinarian with graduate training and field experience in public health. Only a person with such training and experience can interpret properly veterinary public health problems and portray adequate, public health practices to the student.

The veterinary research worker must be fully cognizant of the public health aspects of his problems, and, last but not least, the livestock regulatory official, Federal, State, or local, must always be mindful of his public health responsibilities.

What Is Next in Veterinary Education?

Veterinarians graduated from modern American colleges have received considerable education. The rapid increase in educational requirements makes one wonder what may be the next step in veterinary education. The increasing volume of scientific literature may make it seemingly necessary to lengthen college courses. But students would then spend so much time in school that little would be left for life beyond the university. The minimum total education period for a veterinarian is now 18 years. For those who have earned the B.S. degree before entering the veterinary college, it is 20 years, and for those who have taken graduate work before being admitted to the veterinary college or following graduation with the D.V.M. degree, it may be 26 to 28 or more years. No person can become a practicing veterinarian before he is 24 years old, assuming that he starts primary school at the age of 6.

For veterinarians who expect to become teachers or research workers or both, the Ph.D. degree is now almost a prerequisite. Therefore, these persons may be 28 to 30 years of age, or even older, before they can be considered to have arrived at a fully acceptable educational level. Thus, there will be relatively little time left for a professional career and for raising a family. Furthermore, the cost of such education, like the cost of medical education, has become so great that practicing veterinarians must have substantial resources, or the prospect of a substantial income, in order to enter the profession. This initial overhead has had its impact on the costs of veterinary services.

Much must be done before the best of which we are capable can be achieved in veterinary education. Our goal will not be reached by continuing to add years to the curriculum but rather by better use of the time now allotted to it. Students need a higher degree of motivation and a keener perception of the responsibilities and social implications of professional service. Careful attention to this aspect of education in the home, in the Sunday School, and in grade schools could provide a good foundation for further training in that direction in college.

Continuing Education

Continuing education is another means through which a solution to our educational problems may be sought. If professional schools can succeed in convincing professional students of the absolute necessity of lifelong study, and if adequate facilities can be established for continuous professional education, we will do better than by further lengthening undergraduate, preprofessional, and professional education.

True, we have postgraduate short courses

now; but, in my opinion, they are not very effective. The professional people who need them most do not bother to attend. Also, too often the courses are conducted in much the same manner as ordinary professional conventions. The first sessions in the morning and after lunch are generally very poorly attended; laboratory work is relatively seldom included, and the only lectures and demonstrations that are usually well attended are those which provide information that will lead to immediate financial returns.

It does not seem unreasonable to suggest that certificates of active and satisfactory participation in at least one refresher course periodically, perhaps even one a year, should be required for uninterrupted license to practice. By active and satisfactory participation is meant actual attendance at lectures and laboratory sessions. Some such system of continuing education, if developed, would go a long way toward assuring continuation of effective veterinary services in the United States.

Population studies may serve useful purposes not originally planned, as in this application of data collected on the sample population in the Arsenal health district in Pittsburgh.

Participation in the Allegheny County, Pa., Mass Chest X-ray Campaign, 1953

By DONOVAN J. THOMPSON, Ph.D., and SIDNEY PELL, M.B.A.

MASS chest X-ray campaigns have been conducted in many cities in recent years to screen large population groups for previously undetected cases of tuberculosis, neoplasms, cardiovascular disease, and other diseases. Many of these campaigns, owing to skillful organization and tremendous effort, have been able to induce a large proportion of the population to participate in the campaign. Participation rates as high as 75 percent have been reported for some communities (1). However, even in the most successful campaigns, a sizable proportion of the population fails to avail itself of the opportunity to have a chest X-ray.

Although those working directly in the promotion of attendance have impressions as to the differences between the groups that participate and fail to participate, very little quantitative information is currently available on these differences. A description of the existing differ-

ences, between the group which participates and the group which does not, would seem to be useful from several points of view.

First, such knowledge would permit a better judgment of the effectiveness of an X-ray campaign in eliminating undetected cases of tuberculosis and other diseases from the population group surveyed.

Second, pointing up the group differences should assist those responsible for increasing the proportion participating in future campaigns of this type by indicating subgroups requiring special promotional attention.

Finally, students of mass phenomena may find interesting the characteristics of the two groups considered here.

With these considerations in mind, the biostatistics department of the Graduate School of Public Health, University of Pittsburgh, and the Pittsburgh and Allegheny County X-ray Survey Foundation initiated a project designed to compare the participants with the nonparticipants in the Allegheny County X-ray survey. The survey was conducted during April to September 1953.

Procedures Followed

In connection with a series of community health studies (2, 3) being conducted by the Pittsburgh School of Public Health in the

Dr. Thompson, associate professor, department of biostatistics, University of Pittsburgh Graduate School of Public Health, was formerly associated with the statistical laboratory, Iowa State College. Mr. Pell is currently a fellowship student at the graduate school engaged in statistical research for the medical division of E. I. du Pont de Nemours & Co.

tion available, it may be estimated that these adjustments would reduce the county participation rate to 65-67 percent. Furthermore, the net effect of the possible errors of identification in our procedures is undoubtedly in the direction of an undercount of the persons attending. Thus, the apparent discrepancy between Allegheny County and the Arsenal health district in attendance performance, as indicated by the two rates quoted above, is sharply reduced.

All comparisons in the following sections will characterize the group of 3,500 persons X-rayed and the group of 2,474 persons who, although eligible, did not have a chest X-ray. The assumptions underlying the adjustments we have made appear to be reasonable. However, it is felt that considerable deviations from the assumptions would be necessary to vitiate the comparisons of the two groups which follow. Our findings will be presented in four broad categories:

Basic age, sex, and racial differences in the two groups.

Health differences.

Differences in various social characteristics.

A brief examination of the attendance pattern within families.

Age, Sex, and Racial Differences

Since age, sex, and racial differences in participation are expected a priori and since most of the other findings will be presented in terms of age-sex specific participation rates, we shall examine these characteristics first.

Estimates of the sampling variation of the participation rates quoted are not included in the tables or text to follow. However, the number of cases upon which the rates are based is generally shown, and the extent to which sampling variation may contribute to an observed difference in rates may therefore be assessed.

Table 1 and figure 1 show that the basic age pattern of response to the survey is common to both sexes. It is characterized by a peak among adolescents followed by a sharp drop in the early 20's, a rise to another peak in middle life, and then, after age 55, by a steady decline to a very low response among the elderly. This same pattern will be found in the 1946 Muscogee County, Ga., chest X-ray

survey (4) and the 1950 Los Angeles county-wide survey (5).

Among all the age-sex groups studied, the highest response came from girls between 15 and 19. Below the age of 35, women responded more than men, with the exception of those in the 25 to 29 age group. Their attendance forms an interesting contrast with the consistently higher response of men in all age groups beyond 65. Between 35 and 65, there are differences in response between the sexes, but the differences show no consistent pattern.

Small differences in participation rates were observed for white and nonwhite persons (58.8 and 54.2 percent, respectively), but the number of nonwhite participants in the sample was insufficient to permit age-race comparisons.

Health Status and Health Awareness

As measures of the current health status of the two groups, data on hospitalization during the year July 1951 to July 1952, for all admissions other than delivery, pregnancy complications, and physical checkups, data on a specific reported condition—heart disease—and data on chronic illness are available from the 1951 household survey for comparison.

A comparison of the participation of persons hospitalized during the year preceding the survey with those not hospitalized reveals a small difference in the overall participation rate between our two groups, 56 percent for X-ray respondents and 59 percent for those who did not respond.

All persons reported to have one or more of the following conditions were classified as chronically ill:

Rheumatism	Hardening of the arteries
Arthritis	Hernia
Heart disease	Loss of use of limbs
High blood pressure	Blindness
Diabetes	Deafness
Kidney trouble	

Persons of both sexes with chronic illness responded to the X-ray invitation at only a slightly lower rate than those not chronically ill, 57 and 59 percent, respectively.

For the single condition, heart disease, the corresponding figures are 55 and 59 percent. The data also indicated that participation of the chronically ill, as compared with those free

of chronic illness, varied with age, but not in a simply described pattern. For the age group 65 and over, the difference in participation was accentuated, 39 percent for the participants and 48 percent for the nonparticipants.

Two additional items related to health awareness were studied, X-ray of the chest during the year preceding the mass campaign and health insurance coverage. Our data indicated that X-ray of the chest in the year before the mass campaign was not a significant factor in relation to participation.

Turning to health insurance coverage, however, we find striking features in the data (fig. 2 and table 2). We see that those who do have health insurance coverage have a markedly higher participation rate than those not having such insurance and that this finding holds true for every age and sex category.

To summarize the findings in this section, we can say that—

Variation in participation by health status is clearly in evidence though, on the whole, not of a striking nature.

As age advances, persons with chronic conditions appear to participate in smaller numbers than those who are free of these illnesses.

Hospitalization in the year preceding the survey is associated with a lower participation rate.

By far the most interesting finding, and one worthy of speculation, is the higher response of persons who have some kind of health insurance.

Social Characteristics

Our findings on four social characteristics—education, marital status, type of occupation, type of industry in which employed—which may relate to a person's motivation to participate or ability to conveniently get to an X-ray unit, should be particularly interesting to those responsible for promoting mass health campaigns. The isolation and characterization of groups with a noticeably poor attendance record, as was done in the preceding section, also relate to the principal objective of the survey, the detection of unknown cases of tuberculosis.

Education

Our inquiry into the variation of attendance with years of formal education showed variation in participation by highest grade of school completed within the different age groups, but no systematic influence of education was discernible. The breakdown by age and educational attainment did reveal, however, the poor attendance among young men over 15 and under 24 who have completed high school (29 percent)

Table 1. Number and percent X-rayed in sample of persons eligible for X-ray, by age and sex, Arsenal health district, Pittsburgh, 1953

and the poor attendance of both men and women in the oldest age group who had completed less than the fifth grade (38 and 33 percent, respectively).

Marital Status

Our findings with respect to the relation between attendance and marital status are summarized in figure 3. Although the percentage of married persons who responded to the survey (61 percent) is somewhat greater than that of single persons (54 percent), interpretation of this difference is complicated by the relation between marital status and participation, as found in the age group 15 to 24. The relationship is the reverse of that observed in all the other age-sex categories. From figure 3 it can be seen that the single women in the 15- to 24-age group had the highest percent response of the 16 age-sex-marital status categories (65 percent) and that the married women showed the poorest response (29 percent). The difference between married and single men in this age

category, although similar, is not as striking. For the remaining age-sex categories, married persons consistently attended in greater proportion than single persons.

Type of Occupation

Participation is summarized in table 3 by type of occupation for all ages combined. The highest participation rate was achieved among women classified as students (72 percent). This is largely accounted for by the excellent response of the girls of high school age. If the age group 15-17 is considered, almost all of whose members are high school students, 77 percent of the girls and 69 percent of the boys are estimated to have participated. These percentages point up the success of the X-ray campaign in the secondary schools.

Table 3 also shows that sales workers of both sexes and male clerical workers responded well.

The poorest attendance was found among men and women having "no usual occupa-

Figure 3. By age, sex, and marital status.

tion." This category consists largely of persons 65 years and over and those who are retired or disabled. The attendance of housewives as a group was somewhat below the average of the entire sample, but an analysis by age indicates that the response was poor among housewives aged 15 to 24 years and over 64. In these age groups, 38 percent of the housewives in the sample were X-rayed, as compared with 62 percent of the housewives between 25 and 64. The comparison of attendance between the white collar and the labor groups indicates that the response was better among white collar workers for both sexes, 62 and 57 percent, respectively.

Employment Factors

If the 13 type-of-industry classifications used in this study are divided into 2 categories, one consisting of the 7 highest in percent of response to the X-ray survey, and the other consisting of the 6 lowest in response, we find the following division and ranking:

Highest

Students
Finance, insurance, real estate
Manufacturing—durable goods
Wholesale and retail trade
Manufacturing—nondurable goods
Transportation, communication, etc.
Mining and construction

Lowest

Housewives
Public administration
Personal, professional, entertainment services
Retired
Unemployed
Disabled

NOTE. These classifications are based, with some modifications, on the "category of industry" classification used by the Census Bureau. The modifications consist of (a) grouping together "personal services," "professional services," "entertainment services"; (b) separating "students" from "professional services" and "housewives" from "personal services" and (c) adding "retired," "unemployed," and "disabled."

An interesting pattern emerges from this kind of grouping. Each of the seven classifications found to be highest in X-ray attendance represents either a business, industrial, or educational organization; or, we might say that persons in these categories frequently are drawn from large aggregates of persons working under one roof or in a small area. On the other

hand, this is also descriptive of "public administration," which is among the six classifications lowest in response. The other five groups comprise the following: people who do not work (the retired, unemployed, and disabled), self-employed persons (personal, professional, and entertainment services), and housewives.

The higher response of the first category of persons may be explained by one or more of the following reasons:

The effectiveness of a group in stimulating an interest in the X-ray survey.

A planned campaign on the part of the organization, on its own or in cooperation with the Allegheny County X-ray Survey Foundation.

The convenience of the X-ray unit to persons working in these organizations.

The very high response of students (67 percent), discussed previously, is best explained by the effectiveness of the secondary schools in utilizing their resources and position to bring the students, in a sense a captive group, to the X-ray unit. At the other extreme are those who are retired, unemployed, and disabled (47-percent participation for all of these). The poor response of this group may be due to factors relating to age, inaccessibility of the X-ray unit, and the lack of a group stimulus.

By summing up the findings relating participation to the social characteristics of the individual, we can see that the data in this section indicate that participation of married persons was somewhat greater than that of unmarried persons, with the exception of the 15 to 24 age category, where the reverse was true. The response of married women was considerably lower than that of the unmarried women in this group. Apart from the poor response of persons with less than 5 years of schooling, there appeared to be little relationship between the highest grade of school completed and participation in the X-ray survey, so that this set of data would fail to support the hypothesis that people with higher educational attainment are more likely to volunteer for a chest X-ray.

These findings imply that, with the exception of age, the personal characteristics that were studied, such as sex, education, and marital status, are of minor importance in explaining differences in participation in the X-ray survey,

Table 2. Number and percent X-rayed in sample of persons eligible for X-ray, by age, sex, and health insurance coverage, Arsenal health district, Pittsburgh, 1953

and that the differences that do exist are more closely associated with occupational and employment characteristics. Among all of the occupational groups, the best response was obtained from persons of high school age. It was also noted that a better participation record was made by persons who performed their occupations in large organizations than by housewives, or by those who were self-employed, or unemployed for one reason or another. It appears, therefore, that we must look to the group rather than to the individual to understand the participation patterns observed in the survey.

Family Unit Characteristics

In the preceding sections our findings have been presented in terms of characteristics of the individual as they relate to his attendance performance. We now turn to a brief examination of X-ray attendance by members of the same household. Our definition of household is the same as that employed by the Bureau of the Census, which principally requires that the group of persons constituting a household live under a common roof and share common eating facilities.

A striking variation in household attendance patterns, according to whether or not the head of the household was X-rayed, may be observed in tables 4 and 5. Here is one of the most interesting findings of the study: There appears to be a marked tendency for persons of the same household to react in a similar fashion to the X-ray invitation.

For households composed of only two persons it can be seen that in 65 percent of the homes (table 4) when the household head had a chest X-ray so did the other member of his household; on the other hand, if he did not take part in the campaign, the other person attended in only 40 percent of the cases.

The manner in which this tendency manifests itself for the other three sizes of households covered may also be observed in the table.

There are many possible explanations for the observed relation, and it should be mentioned that our choice to present this finding in terms of the attendance of the head of the household was principally one of convenience.

It may also be observed that this comparison by size of household is a gross comparison: Age, sex, race, occupation, and similar characteristics of the household members are in no way

standardized. From some points of view, this makes this finding even more striking.

In table 5 we have a similar comparison where the household units have been standardized to the extent that they have been grouped by size as measured in terms of number of persons 15 years of age and older (the group eligible for X-ray). The attendance pattern of nonheads of households has changed from that observed in table 4. However, the positive association between the attendance of the head and the attendance of greater numbers of other members of his household is perhaps even more evident, now that the children have been removed from the comparison. It is noteworthy that evidence of intrafamily influence was also found in the Muscogee County, Ga., chest X-ray survey of 1946 (4).

Social Welfare Status

Finally, from a study (6) of the relation between health status and social welfare status we have a classification of our sample households as measured by whether or not the household is known to the Pittsburgh Social Service Agencies through requests by one or more members of the household for assistance from the agencies. The proportion X-rayed (55 percent) in households with active cases, as of

July-December 1951, is somewhat lower than the corresponding proportion (61 percent) in households not known to the agencies, particularly for women (53 and 61 percent). However, the response among the "needy and troubled" is not alarmingly low.

Discussion

The many factors that may be at work simultaneously to impel a person to volunteer for an X-ray pose a problem in interpreting the data. If the data indicate that a certain characteristic is associated with X-ray attendance, an interpretation of that relationship is difficult to make because the observed association may merely be a manifestation of one or more significant, but unknown, underlying factors. For this reason, the principal objective of the study has been largely restricted to a report of facts about the two groups.

However, several tentative conclusions concerning the factors that influence attendance seem warranted from an evaluation of all the findings. First, although a number of differences have been noted between the group that participated and the group that failed to respond, the differences generally are not large. Racial, sex, education, health and welfare status differences in the two groups, in general, are

not striking. Even with respect to age, for which the observed differences have been discussed earlier, the participation rate in the age category 65 and over is estimated to be 44 percent, as compared with 59 percent for all ages.

These facts would seem to indicate that the organizational and promotional activity of the Allegheny chest X-ray survey had a very broad base and motivated large numbers of persons in all walks and stations of life. The data presented here do not seem to indicate that the factors of training, education, and conditioning, which might be thought to stimulate awareness of the importance of periodic health examinations, were important in increasing X-ray attendance. There is little evidence that a greater amount of education is associated with a higher rate of participation. Rather than increased attendance with advancing age the data showed a decline in participation as age increases beyond the middle years. Furthermore, there is little evidence in the data to suggest that a chronic illness or a recent hospitalization was an important factor in influencing attendance.

Although the factors described in the preceding paragraph apparently are not strongly associated with the decision on the part of a per-

son to divert himself from his normal daily habits and step into an X-ray booth, there is evidence in this study of the effect of motivation of the individual through the group or groups of which he is a member. It was found that persons who were self-employed, or not employed, had a lower attendance than those associated with insurance and real estate firms, schools, and industrial and commercial establishments, where social pressures and concerted effort on the part of the organization might be easily applied.

A similar impetus may have been responsible for the observation that in households where the head participated in the X-ray campaign, larger numbers of other household members also participated than where the head failed to attend. Another piece of evidence that fits into this pattern is the finding that persons covered by health insurance participated in larger numbers than those not so covered. Since health insurance coverage is positively associated with working in large establishments, through the high prevalence of group plan insurance in these concerns, this finding is consistent with the hypothesis advanced.

The reasons for the positive association be-

tween participation and group membership cannot, of course, be determined from the data at hand. Another interpretation of the higher participation rates in the groups mentioned is that of accessibility of the X-ray unit to the person whose participation was sought. The higher rates in the groups of school children, industrial and commercial establishments, and other establishments where large numbers of persons assemble in pursuance of daily tasks may be simply a reflection of success in locating an X-ray unit in or near the premises so that difficulty in seeking the X-ray was minimized.

Although it seems doubtful that mass X-ray campaigns for the detection of tuberculosis, such as the type of campaign described here, will be undertaken in the future should the present downward trends in incidence of tuberculosis continue, this discussion cannot properly be ended without commenting briefly on what the findings indicate with respect to detecting new cases of tuberculosis in the community. Since the tuberculosis problem is becoming more and more a problem of an aging population, the falling off in participation after the middle years to low participation among elderly persons (table 1) would indicate that

the results would be poor in these age groups.

Several other groups with low participation rates were isolated in our study. Those that are particularly interesting in this connection are (a) married women in the age group 15 to 24 and (b) persons retired, disabled, or unemployed for other reasons. Both these groups merit special attention when survey groups are considering ways of detecting new cases of tuberculosis. The first group contains a high proportion of young mothers, and the second contains the elderly, both groups that should be important targets for case-finding activities.

Summary

At the end of a campaign designed to motivate a large population group to participate in a community venture, such as a chest X-ray survey, the question is always raised as to the characteristics that distinguish the group which responds from the group which fails to respond. During the Allegheny County X-ray survey conducted from April to September 1953 a unique opportunity for studying these group differences was available to the Graduate School of Public Health, University of Pitts-

burgh. An equiprobability sample of 5,974 persons, 15 years of age and older, representing a population group of some 80,000 persons residing in the Arsenal health district of Pittsburgh, provided information on many characteristics of both the group which participated in the survey and the group which failed to participate. We have presented the findings of the inquiry into the reasons for these differences.

From an overall point of view the differences between the two groups, while sizable for certain characteristics, are generally not extremely large. Some of the differences that do exist, however, suggest certain factors that may be related to participation in the X-ray survey. Comparisons between the participants yielded the following important findings:

In examining X-ray response according to age, it was found that comparatively high participation rates occurred among adolescents and middle-aged individuals. Relatively poor responses were noted among persons in their early 20's and those 65 years and older.

Among persons 25 years or older, the response of married persons in each age group studied was greater than that of the unmarried.

The participation rate of students of high school age was the highest among all occupational categories studied. The data also indicated a tendency of persons who worked as part of a group to have a higher response rate than those who were self-employed or not employed.

Persons who were covered by some form of health insurance showed a considerably higher rate of participation than those not covered. This finding was true of each age-sex category.

Evidence of forces within the family unit to

stimulate participation in the X-ray survey was demonstrated by a comparison of attendance in households according to whether or not the head of the household volunteered for an X-ray. The pattern of participation in households where the head did attend clearly indicated a greater response in these households than in those where the head did not participate.

Little or no association was found between response to the X-ray survey and health status, education, sex, race, or social welfare status.

Tuberculosis X-Ray Case-Finding Activities United States, 1953

STATE health departments reported that more than 15½ million persons were X-rayed in tuberculosis case-finding projects in the continental United States during the calendar year 1953. This number, which exceeds the number X-rayed in case-finding activities in 1952 by 2 million, is the largest ever reported. Reports were received from all States in 1953.

In Alaska, Hawaii, and Puerto Rico, a half million persons were X-rayed, according to the reports received from these Territories. The State and Territorial reports generally did not include the X-rays taken by Federal agencies, except those taken by the Public Health Service. When the number of X-rays taken by Federal agencies is added to the 16 million reported by the States and Territories, the total number of persons X-rayed in the United States and Territories during 1953 is more than 21 million.

Data on X-ray case-finding activities for each State and Territory, exclusive of Federal agency data, are given in the accompanying table. Although there was an increase of 2 million in the number of X-rays in 1953, not every State reported an increase. Eighteen States, the District of Columbia, and Hawaii reported decreases, and one State, Nevada, reported no X-rays taken in 1952 or in 1953.

Five States—California, Illinois, Michigan, Pennsylvania, and Washington—together reported an increase of approximately 2 million X-rays. A communitywide chest X-ray survey in Pittsburgh and Allegheny County, Pa.,

during which 881,646 X-rays were taken, helped Pennsylvania report the largest number of X-rays taken by any of the States and Territories during 1953.

It is interesting to observe how the increase in the number of X-rays taken affected the coverage of the population. For the continental United States, 9.8 percent of the population were reported examined in tuberculosis X-ray case-finding activities in 1953 as compared with 8.6 percent in 1952; for the United States and Territories, 9.9 percent were reported examined in 1953 as compared with 8.7 percent in 1952. When the number of X-rays taken by Federal agencies is added to the number reported by State and Territorial health departments, 1 out of every 8 persons in the United States had an X-ray examination for tuberculosis during 1953. The percentage of the population examined in tuberculosis X-ray case-finding activities varied from a high of 54.2 percent in Delaware, which had a statewide mass X-ray survey during the year, to 1.1 percent in Vermont and 0 percent in Nevada.

Of the total new cases of tuberculosis reported during the year, 32 percent were first discovered as a result of X-ray case-finding activities in 1953 as compared to 28 percent in 1952. Newly reported cases first discovered as a result of X-ray case-finding activities may include both group A cases (active and probably active cases) and group B cases (arrested, inactive, and other reportable cases); therefore, the percentage is based on the total newly reported cases (group A plus group B) for each State and Territory. For the continental United States, the increase in the percentage of population covered by X-ray case finding brought a proportionate increase in the percentage of the total newly reported cases first discovered as the result of X-ray case-finding activities. In fact, the number of new cases found per 1,000 X-rays in 1953 was about the same as the number in 1952, showing that the yield was not adversely affected by the increase in coverage.

As shown in the accompanying table, the per-

centage of total new cases first discovered as a result of X-ray case-finding activities varies widely among the States. It ranged from a high of 77 percent for Alaska to 5 percent for New Mexico. The standards used in screening suspects, the characteristics of the population X-rayed, what constitutes a reportable case of tuberculosis in each State, as well as the prevalence of tuberculosis in each State, all contribute to the differences observed among the States.

The percentage of newly reported cases first discovered as a result of X-ray case finding is not directly related to the number of X-rays taken during 1953 because the number of new cases reported as a result of X-ray case finding is not restricted to those persons whose screening films were taken in 1953. Some of the cases

reported in 1953 were reported as a result of screening films taken in 1952, and cases among persons having screening films taken in 1953, especially during the later months, will be reported in 1954.

The States do not have equally efficient procedures for separating the new cases discovered by X-ray screening from cases discovered by other means; consequently, the data reported by some States may be considered as the minimum numbers of new cases found by X-ray case finding. Even with this restriction, however, almost one-third of the new tuberculosis cases reported in the United States during the calendar year 1953 were reported as a result of screening one-eighth of the population. It is possible that many X-rays were taken in segments of the population having high preva-

Tuberculosis Case Finding in a County Jail

By NORTON G. CHAUCER, M.D., M.P.H.

STUDIES suggest that X-raying inmates of county jails is productive case finding at its best (1). Hence a small-film chest X-ray survey at the Hartford (Conn.) County Jail was made in June 1953, all within a few days. A portable 70-mm. PFX unit was set up in a central portion of the jail. All inmates and jail personnel were screened by the local health department, the sheriff and his personnel co-operating.

Results of Survey

No cases of active disease were found among the jailers. Twenty cases of active tuberculosis, 21 of inactive, and 49 cases of other conditions were revealed among the inmates of the jail.

Active cases were defined as those in which subsequent large films, sputum testing, and other means verified the diagnosis of active tuberculosis and sanatorium care was recommended. With one exception these 20 active cases were newly reported. All were men. Six of the men had minimal tuberculosis, 9 moderate, and 5 far advanced. Together they represent 3 percent of the total number surveyed, 663.

Of the 21 inactive cases, 13 men had minimal tuberculosis, 6 moderate, and 2 far advanced. Four cardiac and 2 tumor cases were among the 49 other findings.

Three men out of 100 jail inmates were

found to have active tuberculosis requiring hospitalization. For comparison the figure for active tuberculosis found in current chest surveys of industrial populations by the Hartford Health Department is 0.15 percent—less than 2 cases per 1,000 individuals filmed. For all persons X-rayed (self, doctor, high school, and industry referral), the rate of active cases of tuberculosis found in the survey clinic for 1953 was 0.35 percent—less than 4 cases per 1,000 persons X-rayed.

Continuous Survey

Since it appeared that the jail population had an inordinately high prevalence of active tuberculosis at the time of the 1953 survey, it was decided to begin a regular program of X-raying all new jail admissions.

A 15-milliamper large film unit was furnished by the local tuberculosis society. In February 1954, X-rays were taken weekly on most of the prisoners admitted during the previous week. An average of 30 films were taken 1 day per week thereafter. The results of this continuous survey of jail inmates were comparable to those of the 1953 survey. To date 1,001 prisoners have been screened by X-ray within one week of admission to jail. Twenty-nine have been found to have active tuberculosis. Some of these were new cases; some were showing an increase of disease previously known but considered arrested; and others had been lost to followup. Three additional cases of active tuberculosis found in jail admissions during this time had been known but lost to the health de-

Dr. Chaucer is deputy director of health in the Hartford Health Department, Hartford, Conn.

**Active tuberculosis cases found among 1,001
X-rayed jail inmates, February–September
1954**

Admission status	Cases		Stage of disease		
	Num- ber	Per- cent	Mini- mal	Mod- erate	Far ad- vanced

Total.....	29	2.9	5	15	9

partment. So here again we found approximately 3 cases of active disease per 100 persons filmed.

These results have convinced us that in this particular urban area the largest reservoir of active cases of tuberculosis is to be found in the group of minor offenders committed each day to the county jail. Although the jail also houses prisoners bound over for trial in higher courts, with one exception the cases of active tuberculosis have been found among the short-sentenced group.

The sheriff estimates that 85 percent of the inmates of Hartford County jail are there because of offenses associated with alcoholism. It has been possible through the police court judges to arrange for speedy transfer of these prisoners to State sanatoriums. This would not have been possible had their offenses been of a more serious nature as there are no locked wards in these institutions. This raises the question of whether these men can be kept under treatment long enough to effect a cure.

This experience emphasizes the changing pattern of tuberculosis spread. With modern high levels of personal and community sanitation lived up to and with good nutrition, the epidemic spread of tuberculosis is unlikely.

Followup

A 15-month followup of the 20 cases of active tuberculosis found in the June 1953 survey shows:

3 remained in sanatoriums until case was arrested.

13 are still in sanatoriums.

3 are out from under sanatorium care against medical advice.

1 is lost to followup by moving out of the State.

Of all these persons with active tuberculosis discovered in the Hartford County jail, 5 left the sanatorium against advice once during this 15-month period. Two left twice, and 2 left more than twice. One of these was rehospitalized 4 times in this period of little more than a year. Of the 19 cases found and accounted for, all have averaged more than 8 months of sanatorium treatment.

In these figures is buried a large amount of work—investigation to find the patient after his signout; discussion to persuade him to reenter the hospital; and transfer, discharge, and re-admission notes made by the sanatorium authorities. That such effort is worth while appears in the combined figures of those arrested or still under treatment—16 of the 19 original cases followed.

Summary

Through chest X-rays taken on all inmates of the Hartford (Conn.) County Jail in June 1953, 20 cases of active tuberculosis were discovered, a case-finding rate of 3 per 100. Weekly X-raying of newly admitted prisoners from February 1954 through September 1954 brought to light 29 additional cases of active tuberculosis. A 15-month followup report on 19 of the 20 original cases showed that at the end of the period all but 3 were under sanatorium care or had been discharged as arrested cases. It is suggested that, in spite of present high standards of community health, the county jails remain an important reservoir of active tuberculosis.

for the American Board of Pathology to recommend that a candidate carry out one or more experimental problems during his residency training.

Opportunity for Active Research

The old method of training men in pathology in the intellectual atmosphere of the university covering a period of 6 to 10 years was ideal in many respects, but it is gradually being abandoned owing to economic pressures. In that situation, a man could devote a good part of his time to teaching, autopsies, and surgical and clinical pathology. During the summer months he would have leisure to carry on an active program in research with no responsibility for teaching students. If a system of training of this type could be established in a certain number of pathology departments and universities and subsidized so that the candidate would have no financial worries, it would increase the number of experimental pathologists.

Organizations should provide funds for research grants on the basis of long-term personal income as well as on readily available money for facilities and conference travel expenses. The symposium suggested for the Public Health Service principal responsibility among government agencies in providing support for developing research in pathology. When the permanent funds of an institution are not adequate, the granting agencies should permit their grant money to be converted at once to rela-

tively firm financial sources to be utilized more freely at the judgment of the pathologist in charge of the research.

The Major Recommendations

Career investigators in pathology should be given funds for 5 years or longer for research, salary, training, and travel to scientific meetings. The research pathologist should be given long-term training in several disciplines such as cytochemistry and electron microscopy to emphasize the importance of the dynamics of the pathologic process. Graduate courses should be developed in departments of pathology in schools of veterinary medicine to provide training in comparative pathology in respect to experimental animal research.

It was strongly recommended that the ad hoc committee of this symposium in collaboration with the American Board of Pathology work with other specialty boards to develop a pattern of research training in the laboratory for the residents of the clinical services to secure better training and establish research in the general hospitals. The ad hoc committee, of which Dr. Robert E. Stowell of the University of Kansas is currently chairman, was charged with the responsibility of implementing the recommendations of this symposium. The committee has already progressed toward bringing these recommendations to the attention of pathologists and administrators, and is carrying the problem to the public by various means.

| *Three potentially pathogenic fungi are reported in polluted water in southwestern Ohio.*

Isolation of Potentially Pathogenic Fungi From Polluted Water and Sewage

By WILLIAM BRIDGE COOKE, Ph.D., and PAUL KABLER, M.D., Ph.D.

DURING the last several years, increasing evidence has accumulated that fungi potentially pathogenic for man can be isolated from the environment. Ajello (1, in tabular summary; and 2), Cooke (3), and Grayston and Furcolow (4) have reported the finding of fungi which are considered etiological agents of some of the deep-seated and the superficial mycoses of man, in habitats such as natural and cultivated soils; wild animal burrows; soils under nesting places of birds and fowl; undisturbed portions of buildings, such as attics, basements, and belfries where birds and animals nest or roost; and hollow trees.

A habitat type recently tapped for the presence of fungi, and which also is relatively rich in nitrogenous compounds, is sewage and polluted water. Here certain fungi occur, partly as members of natural communities, partly introduced by "runoff" or through excrements which form a large part of the solids of the habitat.

The presence of pathogenic fungi in any

habitat does not necessarily imply the widespread occurrence of the disease caused by them, nor does it imply the presence of a case of illness attributable to the disease in the immediate vicinity. In fact, records of diseases caused by the fungi to be discussed below are rare in the southern Ohio area where samples were obtained.

In addition to *Allescheria boydii*, which has been discussed by Ajello (1), *Aspergillus fumigatus* and *Geotrichum candidum* have been isolated repeatedly. *A. fumigatus* is the etiological agent of one type of aspergillosis, a disease which has been described and illustrated in the textbook by Conant and his colleagues (5). Reports in the literature dealing with soil molds, fungus contaminants, and cellulose deterioration indicate that this species is a very common fungus occurring throughout the world (6, 7). It appears to be more common in warmer and more humid areas. Thus, it is not surprising that it would be a common mold associated with polluted streams and sewage disposal plants, where temperatures are usually higher than those of other parts of the environment, especially in colder months.

The pulmonary disease geotrichosis has been described and illustrated by Conant and his co-workers (5). *G. candidum*, also known as *Oidium lactis* or *Oospora lactis*, is the etiolog-

ical agent of this disease (5, 8-10). It is also frequently isolated from sputum and other excretions from patients with other diseases, especially of the respiratory tract. The organism is one of the commonest fungi associated with the activities of man. It is the principal contaminant of dairies, is commonly associated with moldy milk and cottage cheese and other milk products, and may be one of the organisms involved in the manufacture of certain types of

cheese. It is a common laboratory contaminant and is frequently found in soils.

Experimental Material and Techniques

Sources of polluted water and sewage included in this study were: Lytle Creek, receiving the effluent of the sewage treatment plant at Wilmington, Ohio (11), the trickling filter plant at Dayton, Ohio, and the activated sludge

plant at Yellow Springs, Ohio. Techniques of sample collection, dilution, plating, media preparation, and colony counting have been described by Cooke (12).

Results and Discussion

Among the resulting fungus isolates were several cultures of a gray mold, some of which bore bodies which were at first thought to be pycnidia. Further study of young cultures on Leonian's agar showed that these were perithecia containing evanescent asci. These cultures were sent to Dr. Roy F. Cain at the University of Toronto, who identified the fungus as *A. boydii*, a fungus which causes mycetoma. Isolates of this gray mold which did not pro-

duce perithecia were identified as *Monosporium apiospermum* which Emmons (13) demonstrated is the imperfect stage of *A. boydii*.

More recently Ajello, in laboratory reports dated October 21, 1954, confirmed pathogenicity of two cultures through mouse passage tests.

A. boydii has been recovered 37 times and has appeared in 22 colony types on rose bengal agar. The 22 colony types show some polymorphism in the vegetative state, which can be grouped under variations of the following pattern: usually floccose or cottony; rather compact but sometimes rather loose; usually white and with white mycelium reaching above the main colony and spreading around its periphery, with cream to pale- or olivaceous-green shades in the center of the colony and under the white hyphae.

When the *Allescheria* phase was isolated directly, these colonies had perithecia in them. Perithecia were not recognized as such partly because the asci break down soon after spore formation and the whole mass appears as a pycnidium with abundant spores. Within the several types of media on which the fungus appeared, there was no significant difference in colony appearance, and there was no significant difference between colonies obtained in winter or summer. In stock cultures in which the mycelium is gray instead of white, there seems to be a better production of perithecia on dextrose-phytone agar than is indicated in the literature for this species.

The occurrence of this organism in southwestern Ohio isolations in 1952 and 1953 is presented in tables 1-3. From the evidence presented, it appears that *A. boydii* is able to survive and possibly to develop in beds of polluted streams and in sludges in sewage treatment plants. It also appears on trickling filters in warm months. The numbers of colonies cited indicate a theoretical maximum rather than an actual number since the spore or mycelial fragment (or spores or mycelial fragments)

which developed on the primary isolation plates could have been the only viable propagules present in the approximately 100-ml. sample obtained from the habitat sampled. The fungus appears to develop more readily in the spring and summer months, although it has been isolated at other times of the year. No isolations have been made to determine whether or not other reservoirs of this fungus occur in southwestern Ohio.

From this series of isolations it appears possible that *A. boydii* is a member of the natural population of organisms in sewage and in polluted and fairly clean parts of streams. It further seems probable that the fungus is a member of the natural population of the soil, not only from reports of isolations by Emmons (15) and by Ajello (1), but also because the stream and sewage plants under study are fed in part by natural drainage waters which could carry spores and other inoculums from the soil to the stream and the sewage treatment plants of the area.

The isolations of *A. fumigatus* as to source and number of colonies are shown in tables 1-4. This fungus appears to be less abundant in the

more polluted portions of Lytle Creek and in the summer months. At the Dayton sewage treatment plant, it is abundant on the trickling filters in the cooler months, and it occurs commonly in both wet and drying sludges and in the Imhoff and secondary digester tanks. The complete picture of its occurrence at Dayton and Yellow Springs is not given since only sample stations selected as representative of the treatment processes are cited in tables 2 and 3. Its sporadic occurrence may be a result of sampling error.

Table 4 shows that this fungus is present, not only at Lytle Creek and at the Dayton and Yellow Springs sewage treatment plants, but in several other more or less polluted areas sampled only once or sporadically. Several samples taken along a stream draining the effluent from the Schenley Laboratories plant into Tanner's Creek near Lawrenceburg, Ind., yielded large numbers of this fungus. It was found in a sample of Ohio River water, as well as in pool sediment and bank soil in the relatively clean stream, Cowan Creek, in southern Clinton County, and in bank soil along a clean creek draining the south slope of Fort Ancient, Warren County, Ohio. It was found in sewage plant effluent at Ithaca, N. Y., in September 1952, as well as in a sample of water taken from Cayuga Lake.

G. candidum was found to be one of the commoner species associated with polluted water and sewage (tables 1-4). It is exceedingly abundant on the trickling filters at Dayton, although it also occurs in other parts of the treatment plant. It is very common in activated sludge samples from aerators at Yellow Springs. In the small stream carrying the effluent from Schenley Laboratories to Tanner's Creek, it forms a mat on the creek bank as much as 1 cm. deep. It is common on the trickling filter at Glendale, Ohio, and was found in all areas sampled in the vicinity of the sewage treatment plant at Ithaca, N. Y. It occurs in the Ohio River and in riffle sediments and bank soil in the creek along the south slope of the Fort Ancient, Ohio, ridge.

G. candidum is a polymorphic fungus with many variant strains, none of which has as yet been induced to produce a sexual state. It is

possible that, of the many strains which exist, a few may be pathogenic. The many strains of this fungus are morphologically and physiologically fairly closely related so that, although a large number of names has been suggested, only one clearly defined species appears to be involved. In citing this fungus, most people have preferred to use the term "*Geotrichum* sp." In a recent study with 16 strains, Bobrov (8) was able to find only the type of germination of the arthrospore as a basis for the segregation of three major strain types. She found she could not base species on this character. The group of strains she studied included cultures isolated from sewage, decaying leaves, and sour milk, as well as strains from suspected cases of geotrichosis in man and from sputum specimens from patients with other disorders.

"people are more important than potatoes," and that a base of data be made available to scientists to determine the causes of accidents in order to get prevention programs on a sound footing.

From this remark stemmed the discussion of fatigue and endurance limits, nutritional lacks and aids, hazardous habit patterns, emotional stresses, apathy, environmental dangers, and extended insurance systems.

Dr. Conrad Barnes, Seneca, Kans., pointed out that emotional upsets are behind a good many farm accidents. "There's too much ignorance of emotional hygiene," Dr. Barnes said. "It has been proved that most accidents have this emotional behavior pattern . . . the accident victim is momentarily blinded because he is upset."

Another panelist, F. R. Willsey, farm safety specialist at Purdue University, said that modern machinery was now becoming more responsible for accidents than livestock. Tractors, he said, are responsible for most farm accidents. Also common are injuries from cornpickers. Too many farmers think they have a safe way of unclogging a cornpicker without shutting it off. The trouble is, he said, they keep thinking that way as long as they get away with it or until they lose a hand or an arm.

In support of Willsey's point, Ordie Hogsett, safety specialist from the University of Illinois, another member of the panel, showed that he had lost his left hand as well as two fingers from his right in a cornpicker accident in 1943. Since then he has devoted his time to farm safety work.

Helen Becker, health education specialist of the University of Nebraska Extension Service, suggested that more farmers ought to observe Sundays as a day of rest for themselves. In the past, she said, farmers didn't work on Sundays in order, they said, to give their horses a rest. Now that they have tractors, they work longer hours and their fatigue predisposes them to accidents, she said.

Sanitation, diet, physical examinations, immunization programs, safety measures, and

livestock disease control all are the responsibility of the farm family, declared Mrs. C. C. Inman, Bancroft, Iowa, chairman of the women's committee of the Iowa Farm Bureau Federation, in discussing the rural family's responsibility toward health. In addition, Dr. B. L. Masters (see brief) said that the first health measure a rural family should take is to get a family doctor. Lester Lane, Wilmington, Ohio, farmer, pointed out discrepancies in the theory that rural residents enjoy better health than city dwellers. They are, for example, more likely to get brucellosis and certain other diseases. In one community, Lane stated, a survey showed pasteurized milk was used by only 16 percent, sewage disposal was bad, and immunization for preschool children was lax.

The predilection of those present seemed to be to encourage programs which develop in the individual a sense of responsibility toward maintaining his health and improving it and toward working with others on health problems. This cooperative effort, they felt, will solve most, if not all, of the health problems of any rural community in a manner that is satisfactory to the largest number of citizens. An improvement suggested by some for future meetings was to have more representation from the field of public health.

The Council on Rural Health, a section of the American Medical Association, is composed of a chairman, a liaison member from the AMA board of trustees, and 9 regional directors. The council is assisted in its work by an advisory committee selected from national farm organizations, such as the Grange and the American Farm Bureau Federation. Representatives from education, research, and information organizations whose interests are focused on agriculture are also named to this group.

Presented on the following pages are briefs from one complete panel presentation—the one on using present health and medical care resources—and from some of the prepared remarks made by panel members in the other discussions.

The New Frontier In Rural Health

It is hard to conceive that any intelligent, right-thinking person would fail to recognize that as a Nation we have the best health and medical care facilities and services in the world.

Yet we have some relatively large minority groups whose health is to day sorely neglected. They are:

1. The aged with their chronic, degenerative diseases; their health, social, economic, employment, educational, recreational, and housing problems.

2. The disabled who need both treatment and rehabilitation.

3. The mentally ill who need not only treatment and rehabilitation but frequently a helping hand from a neighbor if they are to take and maintain their place in our modern life.

These three do not constitute all of the health problems of today, but they stand out like the communicable diseases did 40 years ago.

Resolved at Local Level

Communicable diseases and the diseases of infancy, childhood, and young adult life are not unimportant, but we have progressed far in developing preventive and curative facilities and services for these problems. In our enthusiasm we have, until recently, forgotten the diseases commonly associated with middle and older age. This is true in the research field, the preventive and curative fields, including rehabilitation, and in the intraining and education of our health, medical, and hospital personnel.

In planning, we should not forget the lessons we have learned in other programs. In maternal and child health programs we taught and dem-

onstrated that the problem could be resolved best at the local level by using local physicians, local hospitals, and related services in providing both the preventive and curative phases. It required education and training of physicians, health and hospital personnel, and finally, of the people themselves to make use of and to assist in providing good hospital and related facilities and services at the local level. It required close cooperation of the local voluntary and official health agencies and provision by the State of services and facilities that could not be provided locally, such as medical schools, graduate medical training, and laboratory services and facilities as well as services in the unusual and very technical fields.

In the case of tuberculosis, the State of Minnesota, as early as 1913, assisted counties in building county sanatoriums and subsidized the care of patients in them. Many of these are no longer needed for the care of tuberculosis patients. They are being converted into nursing homes, which are acutely needed. The same is true of the occasional community hospital which is still a good structure and has been replaced by a new, modern hospital.

Hospitals and Distances

Today, a modern hospital within a reasonable distance is essentially a must for most people. The only argument is, what is a reasonable distance? Is it 20 miles, 30 miles, or 50 miles? In each area, depending upon the population densities, highways, topography, the availability of physicians, and a number of other factors, this determination must be thoroughly studied and carefully made by all persons concerned.

In general, a hospital of 25 to 50 beds, well equipped and providing services for 10 to 15 thousand people economically can provide fairly complete and good services. Such a hospital will usually have 7 to 15 doctors on its staff. The distribution of physicians in the rural areas would average 1 for 1,000 to 1,200 persons in a State which has an average of 1 physician per 700 population.

Hospitals of less than 25 beds usu-

ally have so many limitations because of economics, staffing difficulties, and availability of physicians that it would, I believe, be better to avoid such hospital construction and development until all other possibilities have been explored and exhausted. Certainly, an extra 10 miles of travel for one-third or less of the patients using the hospital is not usually a justifiable reason today.

Physicians and Hospitals

All of us are interested in keeping doctors in rural areas. We would like to have one living next door, in the next block, in our village. In the years past, there used to be one in most villages and towns as there also used to be a dentist, a pharmacist, a newspaper, a bank, a general store, a hardware and farm implement store, a lumber yard, and a high school. In the past 40 years, technical improvements, modernization of services, and transportation advances have changed all this.

Physicians inevitably are moving to nearby communities which are of sufficient size to justify the provision of a modern hospital. Here the physician has services and assistance in doing a good job and associates to help him out of tight spots. He wants a good X-ray service, a good laboratory, a blood bank, good delivery and operating room services, good anesthesia, good nursing care, and physical and occupational therapy in the hospital. He wants a pathologist, a radiologist, and a surgeon on the hospital staff, and he would like other specialists on the consulting staff. In short, he wants to do a good job in the practice of medicine.

Needed Care Facilities

The community needs for the proper care of patients with long-term illness are sufficiently complex and varied to require a wide range of services and institutions. Certainly, the patient's home and the usual type of general hospital, at the two extremes, are not sufficient. Improved intermediate facilities are urgently needed. The range of facilities in the order of increasing complexity is as follows:

By Robert N. Barr, M.D., deputy executive officer, Minnesota Department of Health.

1. *The patient's own home.* This may be best if the patient's disease is not too incapacitating and his need for service is not too great. He should be able to visit the physician's office or the clinic periodically. Care should be provided by a member of the household or by a visiting nurse. Temporary auxiliary assistance, such as the services of a housekeeper, may be necessary. In some communities, the services of a physical therapist may also be available.

2. *Home for the aged.* This institution primarily provides custodial care for older persons who cannot be cared for in their homes.

3. *Nursing home.* This type of facility should provide considerable nursing care and regular medical supervision for indefinite periods of time for patients who do not need intensive hospital services. It has been strongly recommended that nursing homes be associated with general hospitals, thus providing a flexible unit for the hospital as well as an improved standard of care for the patient.

4. *Chronic disease hospital facility.* Except for diagnosis and for acute exacerbations, the general hospital is neither the best nor the most economical place to care for most patients with long-term illnesses who require hospital care. Many new chronic disease hospitals with good nursing service and medical supervision, with adequate equipment and personnel for rehabilitation, and with facilities for research and teaching are now being developed.

Planning Local Facilities

With the aim of reducing costs and improving patient care, it is recommended that groups sponsoring new nursing homes and homes for the aged give serious consideration to locating such facilities in close proximity to existing general hospitals. Local health departments should aid in planning and developing. This will provide a chain of related care facilities where the patient can be transferred readily from one to the other institution as he requires varied types of care. Physicians and other health workers in a community should be familiar

with all the facilities available so that the proper one can be selected for each case. Best use of medical manpower, with less risk of duplicating effort and services, is a possible advantage.

Successful rehabilitation of the disabled must begin in the early stages of hospitalization and must be based on a philosophy of the care of the individual as a whole. Added to the physical changes brought about by chronic illness are the emotional and social changes frequently resulting from long illness and the social withdrawal caused by the illness. Emotional and social needs must be recognized and met through a planned program of activities.

Very often, with skillful functional training and guided practice, patients at least can learn to perform self-care activities regardless of their age.

Shortages of Personnel

The greatest single obstacle to the more rapid development of all types of rehabilitation services is the shortage of trained personnel. The need for physicians, physical therapists, occupational therapists, nurses, and other personnel in the rehabilitation field is tremendous as is the need for sufficient trained personnel to staff our health departments and our general hospitals.

We should start with increased emphasis on recruitment to insure that all of the existing training facilities are being utilized. There is no magic solution to the current personnel shortages in the health field. The recent work of the National Health Council in publishing manuals to aid vocational guidance counselors to alert high school students to careers in public health is an excellent approach. We have a responsibility to plan wisely in using the talent we have and to encourage young people to enter a field where jobs are plentiful and the opportunities for service are unlimited.

Never before have the opportunities for restoration of the disabled been so promising. We must recognize that we are now in a position where we can approach with confidence many conditions which were considered hopeless until recently.

The Community's Responsibility

The community, individually and collectively, must recognize that it has the responsibility for providing the modern physical facilities necessary for the care of these patients. These include health departments, general hospitals, chronic disease units of general hospitals, and nursing homes and homes for the aged planned in close proximity to general hospitals. Equally important is the community responsibility for providing financial support to assure that such modern facilities will be well operated and staffed with qualified professional personnel. Community groups should recognize the social, religious, educational, and recreational needs of these patients.

Each individual must also recognize that he has the responsibility of protecting himself against the ravages of time and its associated physical changes by regularly utilizing the local medical services and their associated diagnostic and treatment facilities. Periodic physical examinations are especially indicated during middle life and should be continued through the declining years. By so doing, the incidence and severity of chronic illness can be reduced and the time postponed when chronic illness may require greater use of these facilities.

The Country Physician And the Rural Clinic

If there are any two things that are more confused than medical care and health, I don't know what they are! Because the doctors themselves get the two confused, they seem to think that when you mention health, you are immediately mentioning medical care. However, that is not true. As I see it, medical resources are the

By Wyatt Norrell, M.D., chairman of the committee on rural health, Kentucky State Medical Association.

job of the medical profession—that is to train boys and girls to become good humane doctors. Health resources are the job of everyone, because it is the job of all to see that the other has good health. You buy medical care, a procurable commodity. The doctors are trained in our medical schools and then go to the communities and set up the proper facilities to take care of the rural people.

Changing a Pattern

The very backbone of our life, as I see it from the medical standpoint, is the family physician. But you're not going to find the family doctor at every crossroad. Why? Well, because transportation is much more rapid than it was 50 years ago. Back in 1915 there were four doctors in my home town. The people could not travel to town in those days as they can and do now.

After World War II, I decided to practice medicine in the county seat of the county in which I was born. When I started, I had an Army jeep procured from the Army surplus. The jeep had some flappy curtains on it, and there were some nights that I arrived at the country home of a patient more frozen than alive. I spent about two-thirds of my working day traveling around the countryside in my jeep, seeing the different individuals in their homes.

This was not the type of medical care that I wished to give the patients. First, it was impossible for me to give good medical examinations in the home; and second, time and distance prevented me from taking care of as many people as I would have liked. I mentioned that fact to the young cashier of the bank, stating that I would like to build a clinic. He took the facts before the loan committee of the bank, and one of the men on the loan committee asked: "What collateral does he have?" His answer was: "Character," and, he added, "We need medical care in this community."

Well, I got the loan; I built the clinic; and I am beginning to see the end of my bank indebtedness. I used this personal illustration to drive home a point. We hear so much about the need for hospitals, and I

believe if you let some individuals have their way there would be a hospital at every two-house crossroad town. The Nation would be bankrupt, and I know it couldn't be very long until the hospital would be in the hands of a receiver.

Clinics and Nursing Homes

The answer to our medical resource work is the use of clinics. Eighty-five percent of the people whom I see can be taken care of and diagnosed in my clinic and then be treated either in the home or by daily visits to the clinic. There is a small 30-bed hospital about 13 miles from where the clinic is located. An individual who is in need of more definitive care can receive it in this hospital.

Another aid to our national medical and health resources is the recent founding of the American Nursing Home Association. This group has done much to help in the care of our aging population. Many of the beds in our hospitals could be released for acutely ill patients if more nursing home beds were available for the elderly and chronically ill patient. It has been proved over and over that the senile patient does react better in the friendly surroundings of the "homelike" nursing home than in the well-regulated hospital atmosphere.

So I say to you as you go back home—help the young doctor when he finishes his medical education. Help him get started in the community. Show him that you want to give him the facilities that he needs. Get the bank to back him; help him to find a home or get one built for him. He needs your help because most doctors, when they finish medical school, not only don't have any money but usually are in debt.

A Personal Responsibility

Now to the questions of how to utilize properly our health resources. Health is a personal responsibility. It is the responsibility of the community in which you live. Each individual is dependent on the other individual. All this goes back to the ideas and ideals on which our Nation was established.

Before a rural health council was established in our county, the tuberculosis X-ray unit came through. We took 520 chest X-rays from a population of 11,000 people. Then the rural health council was established. The next year we got 1,485 chest X-rays. And then everyone seemed to get a beam of light, an idea of what they could possibly do.

So the project was completely organized. One of our young clergymen served as a publicity chairman. A farmer, with a stature of 6 feet 7 inches, weighing 260 pounds, was the "stevedore" or the "whip" of the organization—in other words, the chairman of the rural health council. And he saw to it that there was a shuttle bus system worked out in the county, that the high school children acted as stenographers, that the organization was put over; and therefore we had better than 2,000 chest X-rays done. Isn't this an illustration of what a rural health council can do?

The Four Obstacles

There seem to be four main obstacles to solving our rural health problems as we try to set our sails to reach a goal. All of these four must be defeated before we can successfully utilize our health resources. They are:

1. *Unimportance*—Acting as if what you do, or can do, or are asked to do, is of no importance. Let George do it. What difference does it make if the school children don't get a good diet so long as my kid does. Someone else will do something about it, so why should I worry?

2. *Fatalism*—Believing that man cannot control his environment. In other words, if I may use the statement, "the health as we know it in the rural area was good enough for my grandfather, so it's good enough for my children."

3. *Surrendering en masse*—and forgetting about the greatness of our Nation, and its founding on God, and on certain principles basic to the dignity of man. Each individual should have in his hands his life and not be totally at the mercy of the State. Help from government bodies should not be spoon-feeding types.

4. *Accepting fanaticism*—In other words, accepting some of the fanatic ideas of individuals who do not think clearly. Or accepting the idea that nothing can be done about it. Let's not believe we don't have to do anything about our health problems. But rather, let's take a way of life of accepting the fact that we are our brother's keeper. And remember that when we do something for another person, some of that good is going to fall on us.

Labor and Medicine In Tennessee

Three unusual factors have made the Tennessee experiment to bring medical care to isolated rural areas a success. Organized medicine and organized labor originally cooperated to solve

the medical care problems of rural people, many of whom now work in industry. On-the-scene consultant services reduced total costs to the patient who otherwise was hauled miles away out of his environment for treatment. A new type of internship for medical students gives them a practice in these isolated areas they would never know in a university hospital.

Other organizations and agencies quickly joined medicine and labor. These groups included the Farm Bureau Federation, the Agricultural Extension Service, Vanderbilt University and the University of Tennessee Medical Schools, the Federated Women's Clubs of Tennessee, the Tennessee State Public Health Department, the State Nurses' Association, the State Dental Association, several county courts and one large Society of Doctors' Secretaries.

Frankly, we were shocked into action when a 1952 study of medical care situations in mining communities of nine coal-producing States

showed there were many areas where medical care was almost completely lacking. The study was made by the AMA and it was joined by the United Mine Workers, which last year spent \$56 million for medical care of miners and their families.

Our approach involved these activities.

1. Surveying the actual needs and lacks in four "target communities," such as Clearfork Valley.

2. Stimulating the people to recognize and accept their own responsibilities in the field of rural health.

3. Obtaining money to operate a special organization dedicated to extending medical care to isolated communities.

4. Tapping the resources, brains, and brawn of all organizations to help in this crusade to elevate living standards while providing medical care.

5. Recruiting doctors, nurses, public health personnel, dentists, and sanitarians who were willing to live in communities that appealed only to those with missionary zeal in their hearts.

We organized the nonprofit Tennessee Medical Foundation. Membership at present is confined to doctors, dentists, and nurses. Armed with a functional organization and definite plans to begin work on four "target areas," we appealed to the Commonwealth Fund for some cash.

Armed with a small initial grant of \$19,500 from the Commonwealth Fund and a smaller amount of money from membership dues, the Tennessee Medical Foundation opened offices in Knoxville, the center of the target area. In Clearfork Valley, the miners worked on their off-days and even holidays to rebuild an old commissary into a modern clinic. And they paid for the materials from their own meager earnings, giving to these people a feeling that the clinic belongs to them. This means they will patronize it and fight for its continued growth.

There were headaches, oh yes, and there are headaches still. One of these involves the reluctance of patients to undergo for medical examination. But the knowledge that the examinations frequently revealed no serious conditions, such as can-

cer, has brought some changes in these attitudes.

This experiment has changed several phases of medical care. In Clearfork, where there was not even a licensed practitioner, the patients had to be hauled 75 to 100 miles to be examined by specialist consultants. Not anymore! Under an agreement between the UMWA Welfare and Retirement Fund and several of our local medical societies, 10 specialists make one trip each month to the Clearfork clinic to examine the specialty cases. This examination does not cost the patient an extra cent. The UMWA pays the specialists \$100 per visit for the 160-mile trip. But the physicians endorse their checks right back to the medical foundation.

A special prepayment plan was developed for the Clearfork clinic. The miner, farmer, or lumberman signs this agreement. That entitles his entire family to medical care for an entire month for only \$3.50. There are a few extras, such as costly medicines and X-rays, for which he must pay above this base. The extras also are relatively inexpensive. For example, an X-ray costs \$2. Remember that the miners in this valley average about 9 working days per month and many of them have 6 to 10 children. Their mine wages run from \$18 to \$24 a day. We simply had to offer a realistic program on the dollar side. Even so, this clinic after only 6 months of operation is now breaking even.

What did the other organizations do to help?

The dental association persuaded a young dentist to make a circuit-riding trip to the clinic once a week.

The public health department and the women's clubs are paying the salary of a junior public health nurse who roams the valley in the mornings and then assists the doctor in the clinic in the afternoons.

The extension service aided in advising on community organization, diet, and "doing for yourself." The Farm Bureau is seeking to develop small truck farming in the valley by proving that it will pay. The Society of Doctors' Secretaries collected \$5,000 worth of drug samples.

By Ed Bridges, public service director, Tennessee State Medical Association.

The three other target areas had different problems, so our approach had to be tailored to fit each need. In one prosperous coal mining area, the need was for a large hospital. The medical foundation obtained local, State, and Federal funds, and the hospital will soon be occupied. In still another coal area, the need was for a small overnight clinic, a doctor, and a dentist. After a year of missionary work, one of our doctors convinced the county court that it should appropriate \$25,000 for a clinic and another \$10,000 to equip it, and give both a doctor and a dentist free rent for an initial 3 years.

The two medical schools sent rotating interns, in teams of two, into these isolated areas for periods of 3 months to assist the clinic director. The interns receive pay and full credit for the time.

Northern Plains States' Survey of Health Needs

The region between the mountains and the prairies is sometimes referred to as the "saddle of the Great Plains." These sparsely populated States are largely agricultural. The main-

tenance of all kinds of public services is difficult.

Back in the dust bowl days, destitute conditions among the ranchers and farmers in this region caused the formation of an agricultural council to study ways and means of improving the situation.

One obvious and persistent problem had to do with maintaining health and providing adequate health services. Consequently a special committee, known as the Northern Great Plains Health Committee, was organized. Its objective was to study the health needs and resources of the region and to make these known to the people.

By Mrs. Frances Macdonald, health specialist, Montana State College, and chairman of the Great Plains Health Committee from 1948 to 1954.

Local Studies

The committee made various local studies. It assisted in the original hospital survey. It held workshops for the exchange of information and ideas. In 1953, it agreed to make a county-by-county survey of specific health services in North Dakota, South Dakota, Nebraska, Kansas, Wyoming, and Montana.

This survey was made by local groups of professional and nonprofessional persons. The county extension agent in each county served as the leader of each county survey group. Over 1,000 persons participated. Many improvements have been made by these local community groups as a result of their own study of their own situations.

Most of the States have been trying to keep current information available. For instance, in Montana there were 39 more physicians in September, 1954 practicing in the State than there were in March 1953. Without exception, these physicians located in communities in which there were hospitals, good school systems, adequate housing, telephones, and other desirable features.

The number of dentists in Montana increased by 39 between March 1953 and January 1954. During this same period, the number of dentists in the 17 counties of Montana with populations of over 10,000 increased by 41. So we see that not only are professional workers locating in desirable communities, but, in the case of dentists, they are actually moving from the smaller to the larger communities.

Organized public health services are still lacking in many, many counties in this whole northern Great Plains region. Public land and tax problems are a factor, and again the sparse population makes the delivery of public health services very expensive and sometimes ineffectual.

The committee believes that much can be done to help people understand that modern medical practice can only be carried out efficiently and effectively in some kind of health center, or community clinic, or hospital. We also believe that rural people are coming to understand that good roads and telephones are an es-

sential part of good health services, and that it is no longer necessary to think of a physician or dentist being within so many miles of the family, but rather within so much time of a family.

The Extension Service In West Virginia

A look back over the records of West Virginia extension work shows that from its beginning — more than 40 years ago—health has been woven into the rural life pattern. In

the home demonstration and 4-H club phases, health activities have stood out as an important part of each year's design and have added strength to the entire rural life fabric woven by the people of the State.

You ask why we in extension are concerned about rural health? Why don't we stick to agriculture and home economics and leave health matters to the technically trained professional health workers?

As members of the extension service of a land-grant college, we are charged with the responsibility of giving the kind of information and guidance the people need to make an intelligent, practical approach to the solution of their problems—the kind of information they can use to achieve a satisfactory level of living.

When rural people, particularly homemakers, have an opportunity to list the problems that are of greatest concern to them, and on which they would like to have help from the extension service, almost invariably health stands at or near the top.

Since it is one of their major problems, and since it cannot be separated from foods, clothing, housing, and other essentials of a good level of

By Gertrude Humphreys, State leader, home demonstration work, Agricultural Extension Service, West Virginia University.

4. *Accepting fanaticism*—In other words, accepting some of the fanatic ideas of individuals who do not think clearly. Or accepting the idea that nothing can be done about it. Let's not believe we don't have to do anything about our health problems. But rather, let's take a way of life of accepting the fact that we are our brother's keeper. And remember that when we do something for another person, some of that good is going to fall on us.

Labor and Medicine In Tennessee

Three unusual factors have made the Tennessee experiment to bring medical care to isolated rural areas a success.

Organized medicine and organized labor originally cooperated to solve the medical care problems of rural people, many of whom now work in industry. On-the-scene consultant services reduced total costs to the patient who otherwise was hauled miles away out of his environment for treatment. A new type of internship for medical students gives them a practice in these isolated areas they would never know in a university hospital.

Other organizations and agencies quickly joined medicine and labor. These groups included the Farm Bureau Federation, the Agricultural Extension Service, Vanderbilt University and the University of Tennessee Medical Schools, the Federated Women's Clubs of Tennessee, the Tennessee State Public Health Department, the State Nurses' Association, the State Dental Association, several county courts and one large Society of Doctors' Secretaries.

Frankly, we were shocked into action when a 1952 study of medical care situations in mining communities of nine coal-producing States

showed there were many areas where medical care was almost completely lacking. The study was made by the AMA and it was joined by the United Mine Workers, which last year spent \$50 million for medical care of miners and their families.

Our approach involved these activities.

1. Surveying the actual needs and lacks in four "target communities," such as Clearfork Valley.

2. Stimulating the people to recognize and accept their own responsibilities in the field of rural health.

3. Obtaining money to operate a special organization dedicated to extending medical care to isolated communities.

4. Tapping the resources, brains, and brawn of all organizations to help in this crusade to elevate living standards while providing medical care.

5. Recruiting doctors, nurses, public health personnel, dentists, and sanitarians who were willing to live in communities that appealed only to those with missionary zeal in their hearts.

We organized the nonprofit Tennessee Medical Foundation. Membership at present is confined to doctors, dentists, and nurses. Armed with a functional organization and definite plans to begin work on four "target areas," we appealed to the Commonwealth Fund for some cash.

Armed with a small initial grant of \$19,500 from the Commonwealth Fund and a smaller amount of money from membership dues, the Tennessee Medical Foundation opened offices in Knoxville, the center of the target area. In Clearfork Valley, the miners worked on their off-days and even holidays to rebuild an old commissary into a modern clinic. And they paid for the materials from their own meager earnings, giving to these people a feeling that the clinic belongs to them. This means they will patronize it and fight for its continued growth.

There were headaches, oh yes, and there are headaches still. One of these involves the reluctance of patients to undress for medical examination. But the knowledge that the examinations frequently revealed no serious conditions, such as can-

cer, has brought some changes in these attitudes.

This experiment has changed several phases of medical care. In Clearfork, where there was not even a licensed practitioner, the patients had to be hauled 75 to 100 miles to be examined by specialist consultants. Not anymore! Under an agreement between the UMWA Welfare and Retirement Fund and several of our local medical societies, 10 specialists make one trip each month to the Clearfork clinic to examine the specialty cases. This examination does not cost the patient an extra cent. The UMWA pays the specialists \$100 per visit for the 160-mile trip. The extension service aided in advising on community organization, diet, and "doing for yourself." The Farm Bureau is seeking to develop small truck farming in the valley by proving that it will pay. The Society of Doctors' Secretaries collected \$5,000 worth of drug samples.

By Ed Bridges, public service director, Tennessee State Medical Association.

their counties. A lack of instructors for these courses was, and still is, a serious problem.

The Medical Profession

Another of the problems—"how to get a doctor when needed"—called for the cooperation of the extension service and the medical profession. It seemed advisable to prepare a leaflet to serve as the basis for study and discussion of the problem. A tentative draft was submitted to the School of Medicine of West Virginia University and to an official of the West Virginia State Medical Association.

In counties requesting help on this problem, the home demonstration agent contacted a representative of the county medical society to discuss the purpose of the lesson and to enlist the assistance and cooperation of local physicians. The response was excellent. At county leader-training meetings, physicians and rural leaders sat down around a table as members of a panel and talked over the problems of the physician who practices in rural areas and those of rural people who feel the need for better medical attention.

The use of this lesson represents just one more step in the development of a closer working relationship between the rural people and the medical profession. It began about 8 years ago.

Each year since 1947 the State Home Demonstration Council and State extension workers have cooperated with the State Medical Association in conducting a State rural health conference. These have brought together representatives of the various agencies and organizations interested in rural health and have given those in attendance a better understanding of health problems in the State. Also, they have given the health leadership a greater appreciation of the value of working together on health problems that are countywide or statewide in scope.

Help From Others

In the study of highway safety, the West Virginia State Department of Public Safety assisted all extension groups which requested their serv-

ices. Driver-education instructors cooperated when called upon.

For the fire prevention phase of the safety program, city and town fire department personnel responded to the requests for talks, demonstrations, and other help needed by leaders. Personnel of the electric power companies also assisted with talks on carelessness in the use of electricity.

In the statewide 4-H mental health program, the State health department helped the 4-H and adult groups by arranging for psychiatrists from hospitals, county health departments, and private practice to assist the leaders and local groups.

In connection with civil defense, county health officers and Red Cross workers assisted.

Extension agents and rural leaders work with various organizations to help promote educational and action programs such as the detection and control of tuberculosis, cancer, and heart disease. They work in cooperation with health departments and with schools on dental health problems and school lunch programs. They assist county health departments to hold immunization clinics and well-child conferences. They are active members of the State Nutrition Council.

Farm Organizations In Ohio

The two farm and rural organizations with which I am most familiar—the Grange and the Farm Bureau—along with many other rural organizations are making concerted efforts in developing health programs based on the expressed needs of the local groups.

A brief look at the health program of the Ohio Farm Bureau Women's Committee will show what are con-

By R. Bruce Tom, chairman of the Health Committee, Ohio State Grange.

sidered to be our resources and at the same time bring out how they are being used through the organizations.

Get more money for public health when needed.

Study county health needs and facilities.

Study school health program.

Secure health education courses in schools.

Establish and support well-child conferences.

Get doctors for communities.

Sponsor and recruit members for home nursing courses.

Help establish and support organizations dealing with special diseases.

Get full-time public health personnel.

Help with blood donor program or get it established.

Promote blood typing program.

Organize and support mental health associations.

Help to establish schools for mentally retarded children.

Help to establish and furnish hospitals.

Cooperate with other groups in organizing county health councils.

Grange Health Program

More than 4,100 subordinate Granges across the Nation participated in the 1954 community service program. A large percentage of the activities reported had to do with health and the use of our health resources and medical care. No attempt will be made to give numerical results but a mere listing gives a picture of what is being done:

Health clinics have been started; X-ray units, bloodmobiles, blood banks and blood typing have been provided; thousands of pads for cancer patients have been made; eye and teeth examinations for children instigated; county nurses obtained; portable therapy tank, respirator, and life saving equipment purchased; donations have been freely and generously given to many voluntary health funds.

Other health projects included dog vaccination drives; obtaining doctors for local communities; encouraging health insurance groups; providing equipment and food for hospitals;

school who are at the time of decision on further education, a job, or marriage. Good homes will create emotional balance and security for children. This cannot be emphasized too strongly, and it may be that such a course as it applies to parenthood could be well instituted in many of our schools with great profit to the community and to our country as a whole.

Illinois Pilot Program On Weight Control

Medical and health authorities generally agree that overweight is one of America's most serious health problems today. This makes control of weight an important practice which every person and family should know about and follow. From studies by health agencies and insurance companies, it is estimated that about 20 to 25 percent of the population in the United States today, or 1 person in every 4 or 5, is overweight to the point that his health is affected.

Being an extension worker, I naturally called on the specialists in the fields of health and nutrition at the University of Illinois to assist the weight control project requested by the Nutrition Committee of the Rockford Council of Social Agencies.

Medical Society Assistance

After county medical society approval was received in May 1953, an internist and a dentist were appointed by the county medical and county dental societies to the committee's medical advisory committee. A pediatrician and a general practitioner joined this group later. The work of this committee was to review and approve the educational materials developed for the weight

control course and also to review and approve the commercial materials before distribution to the class members.

In August 1953, a nutritionist, a health specialist, a health educator, a rural sociologist, and a home economist arranged for a meeting in September with presidents, or their representatives, of civic and service club organizations.

Preclass Activities

The "kick-off" meeting was held on November 17, 1953, at the Y. W. C. A. in Rockford with 150 persons in attendance. The program consisted of a talk by a doctor and a nutritionist and a showing of a film on obesity. Classes were announced to start the second week in January 1954.

Three nutritionists—1 from the University of Illinois Extension Service and 2 from the Illinois Department of Public Health—developed the course of study. This included 8 lessons of 2 hours each. Two of the sessions were joint ones at which time a psychiatrist and a general practitioner talked to the class members on "Why Am I Overweight" and "The Doctor Speaks." The third joint meeting was the low-calorie dinner.

Topics presented to the group on a discussion and lecture basis were: "Weighing In," "Calories Especially for You," "Food and You," "Choose Your Foods Wisely," "Your Rewards," "Your New Figure."

No one was admitted to the classes without a referral from his family physician. Only women with degrees in home economics were taken as leaders for the project. They were homemakers, dietitians, college instructors, and home advisers.

A refresher course for the leaders was held for 2 days in December 1953 when all the subject matter was reviewed by 2 of the nutritionists who authored the lessons.

The Course Is Tested

When the first classes were scheduled to begin, we found we had 159 persons enrolled. This necessitated the opening of 7 classes.

The course of study was outlined so members could plan their menus according to calories recommended

by their physician; the basic seven was reviewed; a visual aid, which was a comparison of foods with sugar cubes, was set up; portions of actual food for the 3 daily meals giving a 1,400 calorie diet were shown.

Classes were a combination of discussion, lectures, and work sessions, and only one class exceeded the quota of 25 considered an ideal discussion group.

At the last class meeting an evaluation sheet was presented to each class member. We wanted to find out where the member heard about the class; what he thought about the lessons; if he had put any of the class information into use; if he was interested in attending another series of meetings; what he would like to discuss at future meetings; and if he felt he could continue to lose weight without further assistance. It was also at this meeting that members took their measurements and weight for a comparison with those they had taken 7 weeks earlier.

The low-calorie dinner served at this final meeting was 4 ounces of lean roast beef, one-half of a cup of green beans, three-fourths of a cup of tossed vegetable salad with lemon dressing, 1 small roll, one-half a teaspoon of butter, and an apricot dessert prepared with a synthetic sweetener, and coffee (served with synthetic sweetener and skim milk for those who had not learned to drink it without the trimmings).

Results of the Course

As a summary, a total of 115 persons, or 72 percent, completed the course with nearly perfect attendance. Most of the others attended at least part of the time but dropped out because of inconvenience of time, moved away, or other reasons.

Losses of weight ranged from 4 to 28 pounds, with an average of 11 pounds, for the 115 persons. The men lost an average of 13.5 pounds and the women 10 pounds.

At the close of the series, 109 said that they would like to attend another series of classes, and most of them preferred such a series soon. Most made plans to continue meeting together informally for a period of time.

By Alfretta E. Dickinson, Winnebago County, home adviser, Agricultural Extension Service, University of Illinois.

About 68 persons said that they would be able to maintain or continue weight control without further assistance, but 36 said that they would like to have more help.

Persons heard about the weight control classes through the radio, newspapers, television, physicians, friends, and home economics extension classes.

Sixty-five physicians made referrals to the weight control classes.

At the close of the program, questionnaires were sent to all members of the Winnebago County Medical Society. All but two physicians indicated interest in having the weight control classes continued regularly.

This pilot study showed the need for a weight control-nutrition program in communities, and it also proved that group work is an asset to the person striving to lose weight. As a result of this study, a brochure, entitled "Guide For A Community Weight Control-Nutrition Project," has been published by the State committee and is available from the Illinois Department of Public Health, Springfield, Ill.

Operation Rescue Squad In Wisconsin

Rural communities and small towns can increase their medical services at no cost by establishing skilled teams of rescue workers to work closely with physicians, nurses, and other health officials. These can be instantly available for service in time of local emergency, natural disaster, or military attack.

In every person's life, there have been occasions when a skilled and understanding hand could have relieved suffering and possibly avoided grief. Crises occur without warning—the accident in the home, the highway crash, the farm mishap.

By Joseph Banach, safety director, Ansul Chemical Company, Marinette, Wis.

Help is needed and needed immediately.

And today, even with increasing and improving medical facilities, the necessary medical care is not always available. This is a particular menace in small towns and rural areas, where a declining population is limiting the number of doctors and nurses. Distances are vaster in small towns and rural areas, also. Time is a vital and often a life-or-death factor. Doctors and nurses are very busy meeting the many demands on their time. Frequently, these demands overlap, and, being only one person, the country doctor is unable to be in two places at one time.

There is need for a group of men, women, and even children with highly developed skills in emergency, first aid, and rescue procedure. The good these people can accomplish cannot be calculated, except in the priceless terms of a saved life and spared pain.

A trained rescue unit, instantly available, can provide sorely needed and invaluable assistance to a physician, surgeon, or nurse. A rescue unit spells the difference between life or death for thousands of seriously injured Americans each year.

Organizing the Squad

The need of a skilled rescue team in your community and in mine should be self-evident. I'm sure each of us feels that it would be an ideal situation, if only we knew how to go about it. We found a way, perhaps by accident, perhaps by unseen direction.

About 5 years ago in our small city of Marinette, Wis., with its population of 14,000 persons, a few of us working for a chemical company realized that we were in no position to handle any kind of a plant accident or disaster. There was no organized program of first aid; there were few persons with more than a smattering of skill in caring for people injured or taken sick on the job.

Eight of us decided to form a first aid team. For 21 weeks, meeting twice a week for 2- or 3-hour periods, we went through the Red Cross first aid training manual. At the end of that time the fire chief of Milwaukee

permitted us to spend a week with one of the Milwaukee rescue units.

Mostly, however, we were observers. We realized then that the plant first aid training program we'd originally thought of was not broad enough.

We returned to Marinette, continued our training, and awaited our first call for service. But in a factory of only 500 people, plant accidents are fortunately very, very rare. So we decided to make our first aid rescue services available to the families of our employees. Our company had spent a few hundred dollars in obtaining basic equipment for us—a resuscitator, ropes, first aid kits, respiratory protection, cutting torches, crowbars, and fire equipment. We also obtained the use when needed of a company automobile.

Why not offer the services of our eight-man unit to the people of our city—Marinette, Wis.—and to our sister city—Menominee, Mich.?

Acceptance Is Slow

We consulted the mayors of the two cities, the city councils, police chiefs, fire chiefs, and a few of the leading doctors. They were somewhat skeptical, but they certainly had no objections to the idea. The local telephone companies agreed to put our name in their new telephone directory, along with the police and fire department telephone numbers. The telephone company also agreed to provide us with direct service on any emergency call.

The townspeople, like their elected officials, were slow to accept the rescue squad. From time to time—weeks apart—a call for help did come in to us. But we had not yet overcome the widespread reluctance to accept us.

Then 1 day about 3 years ago a tragic accident took place. A drunken driver rammed into a hay-wagon carrying 26 high school students, chaperoned by the city manager and his wife, on an old-fashioned hayride. The 28 people on the wagon were strewn along the highway. A call went out to the rescue squad for immediate help. Upon arrival, the few members of the squad sized up the situation and im-

mediately called local physicians and the entire rescue squad. Within minutes help was obtained for all of the injured.

All recovered from their injuries, and the praise from a grateful community began to accumulate. The local newspaper ran editorials; the local medical association cited us for outstanding public service; the parents of the stricken children were lavish in their appreciation.

Overnight we achieved the general acceptance that we had been seeking for many, many months. And then the 2 cities began to use our rescue squad for all emergencies. Our battle for understanding was won. Today, we have 26 members, each highly skilled in rescue and first aid techniques. In fact, our men are creative, and, with the complete co-operation of the 32 doctors in our community, have worked out new first aid techniques and equipment with which to do a better job.

The employees of the company as well as the squad members feel that the company they work for is interested in the welfare of their family and neighbors not only at work but at home. This creates pride and a feeling of satisfaction that I don't believe can be obtained in any other manner.

Training a Key Factor

There are several factors that are important in organizing a rescue squad. It takes more than equipment and the name and men. It takes training—hard training. The members must be trained and demonstrate a sincere interest in order to become a squad member. Proper selection must be made to eliminate those who merely enjoy blowing sirens. Only after a person performs under pressure will you know the individual and know his ability. He must train perpetually to keep abreast of new techniques.

The squad at the present time trained about 1,800 people include the twin cities police, fire department, and several industrial and civic groups. It conducts a radio program and instructs the citizen of the communities in how to take care of themselves in the event of emergency.

In my opinion, I do believe industry has somewhat of an obligation in a small community to that a group of this nature is organized, trained, and maintained adequate service.

You folks carrying the brunt of the load of maintaining and proving the health in the rural areas of America—if you can encourage your local leaders to get behind project like this, you may get kind of citizen support you so richly deserve in your work of saving life and making a stronger America.

CDC Laboratory Refresher Training Courses

The Communicable Disease Center of the Public Health Service will give its annual laboratory refresher training courses in Chamblee, Ga., September 1955 through March 1956 according to the following schedule:

Laboratory diagnosis of parasitic diseases:

Part 1. Intestinal parasites. September 12–October 7.

Part 2. Blood parasites. October 10–28.

Laboratory diagnosis of bacterial diseases:

Part 1. General bacteriology. September 12–23.

Part 2. General bacteriology. September 26–October 7.

Enteric bacteriology. October 17–28.

Laboratory diagnosis of viral and rickettsial diseases. October 17–28.

Laboratory diagnosis of rabies. October 31–November 4.

Laboratory methods in medical mycology:

Part 1. Cutaneous pathogenic fungi. October 31–November 11.

Part 2. Subcutaneous and systemic fungi.

(Part 1 or the equivalent is a prerequisite for this course.) November 14–25.

Laboratory diagnosis of tuberculosis. November 14–25.

Laboratory methods in the study of pulmonary mycoses. November 28–December 9.

Laboratory diagnosis methods in veterinary mycology. December 12–16.

Laboratory diagnosis of viral and rickettsial diseases. March 12–23.

Laboratory diagnosis of rabies. March 26–30.

By special arrangement the following courses will be offered:

Laboratory diagnosis of malaria.

Virus isolation and identification techniques.

Typing of *Corynebacterium diphtheriae*.

Special problems in enteric bacteriology.

Phage typing of *Salmonella typhosa*.

Information and application forms should be requested from Laboratory Training Services, Communicable Disease Center, Public Health Service, P. O. Box 185, Chamblee, Ga.

Taking steps in the right direction, the Community Welfare Council of Milwaukee County has recently broadened the scope of its nurse recruitment program to include all auxiliary health professions. The council's Health Division Careers Committee is coordinating the recruitment efforts of 22 community organizations and health professions.

Milwaukee's Health Careers Committee

By EVELYN B. ROUSE, R.N., M.S., ALICE H. SANDERS, R.N., M.A.,
and FLORENCE L. PHENIX, R.N., B.S.

AS MILWAUKEE's population has increased, there has been a growing concern over the inadequate number of hospital beds to serve the needs of this large population center. In November 1951 the United Hospitals Fund of Milwaukee County was established as a continuing organization to provide leadership in planning and financing needed hospital expansion.

Accompanying this upswing of interest in expansion of hospitals has been the concern expressed by hospital administrators and directors of nursing over the problem of staffing the proposed new facilities. Expansion of present facilities will, they maintain, only serve to aggravate the difficulties of trying to fill existing vacancies.

At the annual meeting of the Health Division of the Community Welfare Council of

Milwaukee County in 1950, its Medical Care Committee presented a panel discussion based on the committee's study of staff shortages as they affect nursing home and hospital services. The chairman introduced the discussion by likening medical care to a symphony orchestra with the physician as conductor: Just as the conductor is dependent on the members of his orchestra to produce the desired symphonic effects, he said, so the physician is dependent on the kind and amount of available staff to produce the desired results for his patients.

The panel reported the need for more workers to meet the current demands in nursing, anesthesia, laboratory and medical technology, and medical record library work. These shortages were illustrative of the current problems in other health fields, too, problems which would be accentuated with expansion of hospital and other community health facilities. The chairman, at the conclusion of the program, asked that thought be given to plans for the preparation of more workers to staff the present facilities and meet the demands of expansion.

As a result of the interest shown by increasing numbers of hospital administrators and service directors in the problems of staff shortages, the Milwaukee Hospital Council in September

Mrs. Rouse is the assistant director of nursing education, Deaconess Hospital School of Nursing, Milwaukee, and chairman of the Committee on Careers, Community Welfare Council of Milwaukee County. Mrs. Sanders is the health division secretary of the council, and Miss Phenix is associate secretary.

1951 instructed its Public Relations Committee to give attention to recruitment matters.

The committee learned that the National Nurse Anesthetist Association had 500 known vacancies in its field and no applicants in prospect. Wisconsin and Milwaukee had their proportionate share of this shortage as well as of the more drastic one in the nursing field. The Wisconsin State Department of Nursing had already reported a dropoff in enrollment in schools of nursing in the State, and Milwaukee nursing school statistics reflected this. Reversing this situation in the nursing schools and finding methods of increasing school enrollment in all of the health professions were essential steps in meeting the increasing service demands.

Working With School Counselors

Taking note of the fact that high school guidance counselors are key persons in guiding young people in their choice of a profession, the public relations group met with counselors and representatives of universities and colleges and professional organizations to present the need for more workers in the health professions and to consider effective methods of recruiting young people for these professions.

When the counselors requested that more information be made available to them on the health specialties, they were informed that nursing was the only field for which material had been prepared.

The Wisconsin Medical Society Women's Auxiliary had assembled and placed in every high school of the State a notebook (1) outlining opportunities in the nursing profession. This brochure had been initiated by the Wisconsin State Board of Nursing and prepared and underwritten by the Wisconsin State Nurses Association. The counselors wanted similar material for the other health fields and also asked assistance in obtaining representatives of the various health fields as speakers.

These and other methods of making available to students factual information regarding fields of health service proved helpful.

The guidance counselors emphasized the need to avoid the element of competition among the various specialties. They explained that coun-

seling must be keyed to the interests and capacities of the individual and must not be distorted by competitive recruitment pressures. Basically sound guidance, they told us, gives the individual student information regarding the needs of the job, helps him identify his interests and determine what his capabilities best fit him to do.

The Public Relations Committee saw the careers pamphlet published by the Michigan State Medical Society (2) and agreed that a similar one keyed to Wisconsin needs would partly help in providing the material needed by the counselors. With the assistance and sponsorship of local and State medical and hospital groups, a brochure for Wisconsin (3) was developed and published in June 1953.

Three thousand copies were released to high school and college guidance counselors, libraries, and hospitals. Distribution outside Milwaukee County was handled through the

State medical society and the State hospital association and within the county by the county medical society and the local hospital council.

The interest of the Kiwanis Club in career days programs in the high schools was reported by a member of the hospital council who was also active in the club. Since these programs were an important potential for recruitment in the community, the council felt it desirable to maintain close association with the club's activities and appointed a representative for liaison between the two groups.

As the program of career days grew in the high schools, the use of speakers from the various professional fields increased. The Milwaukee League for Nursing developed a speakers bureau in order to handle requests for speakers in the nursing fields. Other professional groups made plans to follow suit.

The Recruitment Committee

With the developing interest in nurse recruitment, the Community Nursing Council of the Milwaukee County Community Welfare Council had established a nurse recruitment committee in 1952. Its objective was the coordination of nurse recruitment efforts of the professional organizations with the work of other community groups interested in assisting with student nurse recruitment activities.

Membership of the Nurse Recruitment Committee included representatives from the nursing organizations, nurse executives from hospitals and agencies in the community, citizen leaders, representatives from the county medical society and its women's auxiliary, and spokesmen for the hospital council, the Kiwanis Club, and the public and private schools.

During the early days of the committee's organization it was somewhat difficult for the group to establish the understanding that its purpose was to give additional support to the professional organizations already actively working to relieve the nurse shortage and not to take over direct recruitment.

Some months later the group's function was clarified, and it began to make an increasingly important contribution to the recruitment efforts in the field of nursing.

About this time another conference for high

school guidance counselors was held under the joint sponsorship of the Nurse Recruitment Committee and the hospital council. Representatives of a number of the professional fields were present for discussion.

Following this meeting, the executive committee of the health division of the Community Welfare Council recommended that the committee's name be changed from Nurse Recruitment Committee to Recruitment Committee of the Health Division and that the renamed committee direct its attention toward coordination of recruitment efforts for all health service specialties.

The membership of the committee was then expanded to include 15 different health specialties and 7 civic and professional organizations functioning as channels of student recruitment for the health professions represented by the groups (see inset). The objective of the new committee remained that of synchronizing the recruitment efforts of professional organizations and coordinating the methods for getting career information to potential students.

The committee now faces a change in name again, to that of Careers Committee, as being more descriptive of its present activities. This seems to be more in keeping with its broadened scope and with its growing responsibility for interpretation of the various professional fields both to each other and to the public.

Effective Materials and Programs

During the first year of its broadened functions (1954), the recruitment committee developed window displays for recruitment purposes, and it began developing and publishing recruitment materials for the use of committee members and their respective organizations. These materials are composite in nature, yet contain pertinent information about the individual health professions. They are intended to supplement—not duplicate—other available materials.

As of the present, the committee and its member organizations now have at their disposal the following pamphlets for career guidance as well as additional detailed recruitment materials published by the several professional organizations as part of their individual programs:

"In Planning Your Career Consider the Opportunities and Vast Fields Open to You as a Medical Associate," the brochure prepared for the use of vocational counselors and as library reference material (3).

"We Have Raised the Money for New Health Facilities, Now We Must Help Staff Them," a talk outline guide for adult groups such as parent-teacher associations (4).

"There's a Place on a Health Service Team for You," a pamphlet for student use, giving general information on 12 different health careers (5).

The recruitment committee is particularly fortunate in having good outlet representation among its members. Through their active interest and participation, much that is not necessarily a committee function has been accomplished.

For example—

The Milwaukee Advertising Club has given valuable assistance to the committee in the layout and editing of materials being developed for publication. The advertising club has helped arrange for newspaper space and radio time for spot announcements and has made it possible to obtain effective poster display materials.

The Women's Auxiliary of the Milwaukee County Medical Society has developed an active program of future nurse clubs and is promoting the interest of young people in professional preparation for health fields. This group has also provided scholarship assistance for nursing education.

Assessment of Progress

Up to this point the values from the work of the recruitment committee have been apparent chiefly to its member organizations. The individuals comprising this multiprofessional group have gained greater understanding of the problems and the functions of the professions outside their own. There has been a stepping up of recruitment efforts on the part

of some of the member organizations as a result of the interest sparked by the committee's promotion activities.

Since the work of the committee represents a considerable expenditure of time as well as money from the member groups, it seems reasonable that some means of actual measurement of value should develop within the committee.

We can expect an increase in the number of enrollment applications in the Milwaukee and the State accredited schools which provide a curriculum of professional health training.

We have already observed an improvement of interprofessional understanding within the committee itself. The community value of this development will be in proportion to the degree of its reflection within the membership of the respective organizations.

As a corollary to the improvement of interprofessional understanding, the committee may expect to see increased community understanding of the contributions which the individual health professions make to the health needs of the community. This is a slow process but one which should make a constructive contribution.

Functional Distribution of Working Time in Five County Health Departments

By EDWARD M. COHART, M.D., and WILLIAM R. WILLARD, M.D.

IN the fall and winter of 1952-53, the Yale Public Health Personnel Research Project conducted a time study in five county health departments in Maryland. As explained in a previous article (1), this study was designed to measure the allocation of time to technical activities (usually activities associated with direct services), ancillary activities (essential but usually routine, stereotyped activities), administration, and community activities. It was hoped that the data obtained, together with data collected through interviews, would provide new knowledge about the public health worker and his job.

Participating in the time study were 114 professional and semiprofessional workers—85 percent of those meeting the qualifications established by the Yale project (2). They were classified according to public health service, which was usually but not always synonymous with discipline, as follows: medical service, 8; nursing service, 71; sanitation service, 11; laboratory service, 3; secretarial service, 13; and other services, 8. Time logs were kept 2 days

each month for the 5-month period, September 1952 through January 1953. Different days of the week and different weeks of the month were chosen so that the data would be representative of the period. Information as to place in the administrative hierarchy, educational background, and salary was obtained through interviews. (Details of the methods used can be found in references 1 and 2.)

The Working Day

The average daily elapsed time on the job, on the basis of a 5-day week, for all workers in the five county health departments was 8 hours and 41 minutes. An average of 57 minutes daily was spent in personal activities, such as meals, "coffee hours," rest periods, and sick leave. Thus, the effective working day was 7 hours and 44 minutes.

The average working day of 8 hours and 40 minutes for medical personnel was approximately an hour longer than the average working day of the personnel in the other services. As might have been anticipated, executive, supervisory, and consultant personnel worked longer hours than staff personnel.

For all personnel, the working time was allocated to the four functional categories as follows: 37 percent to technical activities, 33 percent to ancillary activities, 17 percent to administration, and 12 percent to community relations and organization. The time spent in these activities in relation to service affiliation, position in the administrative hierarchy, level

Dr. Cohart, associate professor of public health, Yale University School of Medicine, and Dr. Willard, dean of the College of Medicine at Syracuse, State University of New York, were co-directors of the Yale Public Health Personnel Research Project. The project was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

of education and public health training, and salary is shown in the accompanying tables.

Technical Activities

Personnel of the sanitation service devoted more time to technical, or direct service, activities than did the other health department workers. Whereas technical activities accounted for 37 percent of the time of all the workers, they absorbed more than 50 percent of the time of sanitation personnel, 40 percent of the nurses' time, about 30 percent of the time of medical personnel, and about 6 percent of the time of the secretarial group (table 1). It is surprising to find secretarial personnel engaged in technical services even to this limited extent

High-echelon personnel, with the exception of program directors and consultants, devoted much less time than did junior staff personnel to these activities (table 2). Twenty-five percent of the time of all high-echelon personnel was devoted to technical activities, as compared with 41 percent of the staff's time.

Level of education did not seem to be a major determining factor in the extent of participation in technical activities, but the amount of public health training was (tables 3 and 4). Whereas workers without graduate public health training spent about 39 percent of their time in technical activities, those with graduate public health training devoted only 24 percent of their time to these activities.

There was no correlation between salary and

percentage of time spent in technical activities (table 5).

Ancillary Activities

Personnel of the nursing and sanitation services spent about 30 percent of their working time in performing ancillary, or supporting, activities, near the average for all personnel, but medical personnel spent only 10 percent of

their time in these activities (table 1). Secretarial personnel, even though all those whose work was entirely restricted to ancillary activities were excluded from the study, still spent about 80 percent of their time in these activities. It is evident, therefore, that even when a secretary has assumed nonsecretarial functions, she has done so on a rather restricted basis.

Staff-level personnel spent appreciably more time in ancillary activities than did personnel

most all of it in activities with other agencies.

An unexpected finding was the fact that workers with bachelor's degrees and those with undergraduate public health training tended to participate in community activities to a lesser extent than did workers without a college degree or formal public health training (tables 3 and 4). This situation was, in large measure, a result of their spending less time in activities related to public information and education. Personnel with graduate education and those with graduate public health training, on the other hand, engaged in community activities to a much greater extent than either of the other two classes of personnel, principally because of their extensive activities with other agencies.

Time devoted to community activities varied directly with salary, primarily because the top-salaried workers engaged in activities with other agencies to a much greater extent than did the other personnel (table 5). Their participation in public information and education and in professional education was generally not as extensive as that of the workers in other salary brackets.

Salient Patterns

From this study of the distribution of working time in five county health departments in Maryland, a number of patterns are evident. These relate to the differences according to service affiliation, administrative and educational levels, and salary.

Physicians and personnel at the higher levels of the administrative hierarchy tended to spend less than the average percentage of time in technical, or direct service, activities and in ancillary, or supporting, activities. On the other hand, relatively large segments of their time were devoted to activities in administration and community relations and organization.

While no clear-cut association was shown to exist between salary and participation in technical activities, a negative association between salary and participation in ancillary activities and positive associations between salary and participation in administrative activities and community relations and organization were found. In general, similar associations were found for level of education and public health training.

Thus, the picture that emerges is one in which relatively greater emphasis is placed on administrative and community activities by personnel on the higher rungs of the administrative ladder and in the higher salary brackets and by those who have had more education, both generally and specifically in public health, than by other personnel. However, staff-level personnel, those with less education, and workers in the lower salary brackets are nevertheless making major contributions to these activities since they constitute the larger proportion of health department personnel.

In view of these findings, a question that should be asked is: Is the preparation of public health workers, in terms of specific education and training, for administration and community relations and organization adequate? The findings that emerged from other portions of the Yale study would seem to indicate that this question should be answered in the negative. At least, it is a question that warrants attention.

As an example of the differences in patterns of activity among the several services, it will be recalled that the sanitation personnel devoted more time than the nursing personnel to technical activities, whereas the reverse was true with respect to administrative activities and community relations and organization. Why do these differences exist? Are the nurses failing to discharge satisfactorily all of their direct service responsibilities and overemphasizing administrative and community activities, especially supervision and inservice training? Or, are sanitation personnel failing to give proper emphasis to inservice training, for example? Or, is the present distribution of time by each service entirely appropriate to the nature and responsibilities of the service? In

order to determine which of these explanations is correct, an intensive evaluative case study of these health departments would have to be made. A time study can be of value to any individual agency only when it is combined with a qualitative case study.

In the health departments studied, public health is roughly one-third technical activities, one-third ancillary activities, one-sixth administration, and one-eighth community relations and organization. If the assumption is made that ancillary activities support the administration and community organization activities and the technical activities almost equally, and this assumption cannot be too far from the truth, then it can be said that roughly half of the health department time is devoted to administration and community activities and the other half to activities that provide direct service. A question that can be asked here is: Is this distribution of time proper? The answer will depend upon two major considerations: (a) the basic philosophy of public health under which the organizations operate and (b) the character of the communities involved and the nature of their health problems.

Finally, we should like to call special attention to the finding that ancillary activities consumed one-third of the health department time. This finding is more than food for thought; it is, we believe, an indication for a searching re-examination of public health practices.

two or three decades of the usual lifetime, whereas women have a higher rate during the childbearing years. In fact, at about age 35, approximately twice as many women as men are found to have a malignant tumor. After the childbearing period, however, the rate for males catches up with and exceeds the rate for females.

4. In women, nearly half of all cancers originate in the reproductive organs and nearly one-fourth, in the digestive system. Among men, the reproductive organs account for only one in eight cancers, whereas one-third originate in the digestive system.

5. The reported incidence of cancer in the nonwhite population is less than two-thirds of

that for the white group, a difference due largely to the lower susceptibility of Negroes to skin cancer (one of the more common neoplasms among white persons). However, the age-adjusted mortality rates are almost identical for both races.

6. The chance of developing cancer is about one-third greater for white persons living in the south and the west than for those living in the north, due in large measure to the higher incidence of skin cancer in these areas. Twenty-eight percent of newly diagnosed cases of cancer among white persons living in the south originate in the skin; corresponding percentages for the west and north are 20 and 10, respectively.

idea

Emergency Mental Care

MONTGOMERY COUNTY, MD. alarmed at the number of mental patients being put into the county jail pending medical care, Montgomery County, Md., now provides temporary care in the psychiatric unit of a local hospital.

The community considers this solution a workable plan but one which still needs legal clarification, a more satisfactory arrangement for the highly disturbed patient, and still further study.

The problem, as it existed in 1951, had many aspects. The sudden onset of mental illness presented a baffling situation to the community, local police, and other authorities. Its occurrence at night or on weekends created a special emergency. The jail had only cells and detention rooms for the general handling of prisoners. Yet there was the possibility that the emergency patient

might become unmanageable and dangerous before he could be placed under control. Often he had no family or friends to help him or to find a resource to care for him. The easiest way out had been to place him in jail.

Psychiatrists studied the problem, and likewise many local groups gave it their attention and understanding. Representatives of these groups were brought together in an official committee in order to define the areas of difficulty in the proper handling of emergency cases. The health department arranged and coordinated the many meetings and conferences, helped in locating possible facilities and in providing consultants.

The committee first worked out a temporary arrangement whereby health department nurses served on a 24-hour emergency standby basis, working with police, local physicians, and State mental hospitals to find a satisfactory solution for each individual patient.

In 1953, when a local general hospital opened a unit exclusively for the treatment of mentally ill patients, the police no longer had to call the emergency duty nurse when

they were faced with an emergency situation.

Instead, if no private source of care is practical or available, they call the supervising nurse of the psychiatric unit of the hospital. The situation is explained, and the nurse, after consultation, if necessary, with the psychiatrist on call, decides on the best procedure.

If the patient is dangerous, she may recommend the use of the police to bring him to the hospital, where he can be seen by a psychiatrist.

If the patient is a parolee from a mental hospital, the nurse may call the hospital to arrange for his immediate readmission.

If the patient needs local overnight care, he may be admitted to the psychiatric unit of the hospital.

If the patient is medically indigent, the county can remunerate the hospital for either outpatient or inpatient care.

—Reported by Dr. Eugene H. Guthrie, Public Health Service, and Dr. Valcoulon L. Ellicott, respectively the former public health resident and the former county health officer, Montgomery County, Md.

Responses to Smallpox Vaccination in Military Recruits

By SUNG J. LIAO, M.D.

THE IMMUNITY of young men to contagious diseases is being studied in a group of recruits from the Army, the Navy, and the Air Force, and preliminary and secondary reports of a survey of this group carried out during April-June 1951 have been submitted to the Surgeon General of the Army. These reports include details of the manner in which the vaccination survey was conducted and definitions of the geographic divisions of this country and of the home communities of the recruits. Reports have been published on the results of Schick tests in relation to geographic origin and residence (1) and on the results of mumps complement fixation tests (2).

The survey reported here was carried out to determine the results of smallpox vaccination as practiced by the Armed Forces under conditions existing in early 1951 and to consider how such measurements can be used as a national index of certain vaccination practices. It was felt that this group, although subject to some bias in its selection, was nevertheless quite

representative of the population of the Nation. The study does not, of course, represent an investigation to determine how thoroughly all young adult males of this country have been vaccinated.

A number of attempts have been made to review the extent of mass immunity against smallpox in the population of this country. Collins (3) found that, for the 4-year period 1928-31, 54 percent of almost 40,000 individuals of all ages residing in various parts of this country had been vaccinated. Of the males in his series, 65 percent of 2,415 individuals aged 15-24 years had been vaccinated, and 4 percent of the same group stated that they had had a clinical attack of smallpox.

Bull and Rankin (4) analyzed the records of 5,488 students who were vaccinated between 1924 and 1936 after admission to Lehigh University. Only 193 (3.5 percent) had not been vaccinated before entering the university, and 7.5 percent of the entire group gave a primary reaction to vaccination. Loy and Husband (5, 6), in 1936 and 1937 found that 75 percent and 78 percent of two groups of students of about 1,000 each had been vaccinated before entering another university. They came mainly from rural areas and small towns of Kansas. About 60-65 percent of them were considered "susceptible to vaccination," as shown by a primary or a vaccinoid reaction.

More recent information on the response to smallpox vaccination of the general population of this country is rather fragmentary. I have been unable to find a report based on data collected within the past 20 years on a nationwide

Dr. Liao, an assistant professor of preventive medicine at Yale University School of Medicine at the time this study was made, is at present a fellow in training in physical medicine at the Massachusetts General Hospital, Boston, Mass. The work reported was done under the auspices of the section of preventive medicine, Yale University School of Medicine, for the Commission on Virus and Rickettsial Diseases, Armed Forces Epidemiological Board, with the assistance of officers of the Armed Forces.

basis; therefore, the results of the present study might be considered to be a progress report on a national basis.

The manner in which this vaccination survey was conducted has been similar to that recorded in earlier reports to the Surgeon General of the Army. All of the recruits were males. The only criteria of selection were: (a) that the recruit be able to recall whether or not he had been vaccinated before admission to the military services and, if so, when; and (b) that the results of the current vaccination could be evaluated by the group making this study. Throughout this paper, the term "current vaccination" is used to mean the smallpox vaccination done by Armed Forces personnel when this survey was conducted in 1951.

About 95 percent of the entire group examined were between 17 and 22 years of age. The recruits came chiefly from the North Central and the Southern States and were more or less evenly distributed among urban, town, and rural communities. All were apparently in good health and none reported a clinical attack of smallpox.

Smallpox Vaccination

The recruits who were entering the Army, the Navy, or the Air Force, were vaccinated at the processing centers when they were inducted—2 to 7 days, usually 4 days—prior to their arrival at the training camps where the surveys were conducted. These training camps were: Fort George G. Meade, Md.; Aberdeen Proving Grounds, Md.; Lackland Air Force Base, Texas; and Great Lakes Naval Training Center, Ill. The actual vaccination procedure was carried out by medical personnel of the Armed Forces. The vaccination responses were read by a group of third- and fourth-year medical students from the Yale University School of Medicine and were recorded twice. The first reading was usually taken 5 to 9 days after the vaccination and the second reading, 4 days later. These readings were often supplemented by examining the immunization records of the recruits for reports of earlier readings made by others during the current period of observation.

Classification of the responses to smallpox

vaccination was that recommended by Leake (7) and readings were evaluated, in relation to the time of vaccination, as "primary," "accelerated," and "immune" reactions. The corresponding terms preferred by some authors to describe similar types of responses to smallpox vaccination are "vaccinia," "vaccinoid," and "immediate" reactions. Each time the responses were read, measurements of the erythematous area were taken carefully, and the character and size of the vesicle or pustules were recorded.

In interpreting vaccination results, only the primary reaction was considered to be an indication of lack of specific immunity (8). No emphasis was laid on the accelerated and immune reactions for a number of reasons, some of which have been emphasized by Horgan and Haseeb (9). These authors have indicated that possible erroneous results may be due to differences in the skill of the operator and to the potency of vaccine lymphs. They suggested that such variations are even more important in revaccinations than in primary vaccinations. In line with these observations are those of Benenson, Kempe, and Wheeler (10), who demonstrated that even an inactivated lymph (containing no live vaccinia virus) could give accelerated or immune reactions in repeatedly vaccinated persons similar to the reaction induced by potent lymph, although the inactivated lymph could not provoke a rise of complement-fixing antibodies or hemagglutination inhibition antibodies characteristic of the potent lymph.

Results

In the evaluation of readings at the first interview during the immunity survey, 2,682 individuals were questioned with regard to their histories of previous smallpox vaccinations. The interview was usually supplemented by an examination for vaccination scars. Almost 10 percent had never been vaccinated before entering military service (table 1). About one-half had been vaccinated more than 10 years previously and almost one-third, within the last 10 years. Few could recall having been vaccinated more than once. None reported a clinical attack of smallpox.

Table 1. History of previous smallpox vaccination and evaluability of vaccination in 2,682 military recruits

History of previous vaccinations	Total recruits interviewed		Results of current vaccination			
			Not evaluable		Evaluable	
	Number	Percent ¹	Number	Percent ¹	Number	Percent ¹
Total-----	2, 682	100. 0	393	14. 65	2, 289	85. 35
>10 years ² -----	1, 510	56. 30	213	7. 94	1, 297	48. 36
<10 years ³ -----	882	32. 88	122	4. 55	760	28. 33
Never before ⁴ -----	258	9. 62	52	1. 93	206	7. 69
Unknown ⁵ -----	32	1. 20	6	. 23	26	. 97

¹ All percentages are based on the total of 2,682.

³ Vaccinated within the last 10 years.

² Vaccinated more than 10 years previously.

⁴ Never vaccinated before induction into military service.

⁵ Could not remember whether or not he had been vaccinated before.

The results of the current vaccination program in 393 recruits (15 percent of the entire group) could not be satisfactorily evaluated for various reasons. The major reason for the loss of these men from the series was that a good proportion of them were not vaccinated after entering military service. Another group of recruits reported that they had been vaccinated, although the results were not marked on their immunization records nor was any scarring detectable. A very few were absent at the second reading of the vaccination responses, either because of sickness or for other causes. Among those whose vaccination results could be evaluated, 26 persons could not give a definite statement about their previous smallpox vaccination. Thus, excluding the 419 individuals in these

two categories, only 2,263 military recruits were included in the subsequent analyses.

Table 2 summarizes the history of previous vaccinations and the results of the current vaccination. About 18 percent of the entire group gave a primary reaction; 48 percent, an accelerated reaction; and 33 percent, an immune reaction. Among those who had never been vaccinated before, 85 percent gave a primary reaction. A higher percentage of primary reactors were observed among those who had been vaccinated more than 10 years previously than among those who had been vaccinated within the last 10 years, although the difference was not remarkable.

Distribution of the previously unvaccinated recruits according to their geographic origins

Table 2. History of previous smallpox vaccination and result of current vaccination of 2,263 military recruits

Previous vaccination history	Vaccinated recruits with definite history of vaccination	Reaction to vaccination					
		Primary		Accelerated		Immune	
		Number	Percent ¹	Number	Percent ¹	Number	Percent ¹
Total-----	2, 263	415	18. 3	1, 105	48. 4	760	33. 3
>10 years ² -----	1, 927	163	12. 6	727	56. 0	407	31. 4
<10 years ³ -----	760	76	10. 0	343	45. 1	341	44. 9
Never before ⁴ -----	206	176	85. 5	⁵ 25	12. 1	⁵ 5	2. 4

¹ Percentage of total in each history group

² Vaccinated more than 10 years previously.

³ Vaccinated only once in the military services.

⁴ Vaccinated within the last 10 years.

⁵ Never vaccinated before induction.

Whether a different response could be obtained by further repeated vaccination was not investigated.

Table 3. Percentage distribution of 2,263 military recruits reporting no smallpox vaccination before induction, by type of community and geographic area of residence

Type of community	Total		Geographic area							
			Northeast		North Central		South		West	
	Number interviewed	Percent never vaccinated	Number interviewed	Percent never vaccinated	Number interviewed	Percent never vaccinated	Number interviewed	Percent never vaccinated	Number interviewed	Percent never vaccinated
Total.....	2, 263	9. 1	293	2. 7	920	10. 5	923	9. 3	127	11. 8
Urban.....	798	4. 8	189	1. 6	342	7. 0	241	2. 9	26	15. 7
Town.....	839	9. 4	86	4. 6	349	10. 9	356	8. 2	48	16. 7
Rural.....	626	14. 2	18	5. 6	229	15. 3	326	15. 7	53	5. 6

and domiciliary communities is shown in table 3. Of the 293 persons from the Northeastern States, only 8 (2.7 percent) had never been vaccinated prior to induction. These 8 were more or less evenly distributed among urban, town, and rural districts. The occurrence of such a distribution by chance was approximately 1 in 3, with $\chi^2=1.35$.

Nine hundred twenty recruits came from the North Central States. Almost 11 percent had never been vaccinated previously. More, previously unvaccinated, recruits from the North Central region came from rural areas than from urban communities. The difference was statistically significant ($\chi^2=10.3$ and $p=1$ in 1,000, approximately).

Nine hundred twenty-three recruits came from the Southern States; 9 percent had never

been vaccinated before. In these States, more of the unvaccinated recruits had lived in rural areas than in urban communities. The difference was statistically significant ($\chi^2=23.7$ and $p<1,000$).

The number of recruits from the Western States was too small to subject to critical analysis.

The distribution of recruits with primary reactions to the current vaccination is shown in table 4.

Eighteen percent of the recruits from the Northeast gave a primary reaction; corresponding figures for the North Central States, the South, and the West were 19 percent, 18 percent, and 14 percent, respectively. There was no significant difference among the four geographic areas in the proportions of recruits

with a primary reaction to the current vaccination.

Fifteen percent of the urban recruits, 19 percent of the town recruits, and 22 percent of the rural recruits gave a primary reaction to the current vaccination. The difference in percentage of primary reactions in recruits from urban communities and from rural areas was statistically significant ($\chi^2=14.2$ and $p<1$ in 1,000).

The percentage distribution of primary reactions among the recruits in individual States or groups of States is shown in table 5. The percentages regarded as significant varied from 5 to 27 percent. Factors responsible for the high values are probably multiple.

¹ For 4 of the original recruits, data on "home State" were not available.

² Results probably not representative, because of the small numbers of recruits included.

Twenty years ago, Collins (3) found that 65 percent of 2,415 males aged 15-24 years had been vaccinated and 4 percent reported that they had had smallpox. From our survey, it appeared that in 1951 the situation had been

improved—approximately 90 percent of a somewhat similar age group of males (17-22 years) had been vaccinated and none reported an attack of the disease.

From our interviews with these military recruits, the impression was gained that fewer young adult males from the Northeastern States (3 percent) had not been vaccinated before entering the armed services than had those from other parts of the country—North Central, 11 percent; South, 9 percent; and West, 12 percent. Nevertheless, similar proportions of primary reactions were obtained from each of these four geographic regions.

When rural and urban communities were compared, it was found that more of the recruits from rural areas gave a primary reaction than did those from urban communities. Assuming that vaccination was performed with equal skill in both rural and urban localities, this difference could be taken merely to reflect the fact that more of the rural recruits than urban recruits had never been vaccinated before entering military service.

Because of the very nature of the population included in this survey, these results should not be taken to indicate the immunity status of the population of the United States as a whole. Nevertheless, it represents the type of survey that it is desirable to conduct from time to time to serve as an index of the general effectiveness with which vaccination against smallpox is being practiced on a regional basis throughout the country.

Summary

This survey concerns the response to vaccination as performed by Armed Forces medical personnel on United States military recruits who were vaccinated and examined at the time of their induction into the services in 1951.

Almost 2,700 male recruits, the majority aged 17-22 years, were interviewed as to their history of previous smallpox vaccination, and their responses to the current smallpox vaccination were recorded.

About 10 percent of this nationwide sample had never been vaccinated before. None reported a previous attack of smallpox. Fewer recruits from the Northeastern States than from

other parts of the country had never been vaccinated before. More recruits from rural areas than from urban communities had never been vaccinated previously.

About 18 percent of 2,263 recruits gave a "primary" reaction to the current vaccination. Of those who had never been vaccinated before, about 85 percent gave a primary reaction. More primary reactions were observed among those who had been vaccinated 10 years ago than among those who had been vaccinated within the last 10 years. However, the difference was not remarkable.

There was no difference in the proportion of primary reactions among recruits from the four geographic regions of the United States.

The percentage of primary reactions among recruits from individual States or groups of States varied from 2 percent to 26 percent.

ACKNOWLEDGMENT

Nine students (now doctors) from the Yale University School of Medicine were responsible for reading the vaccination results: H. M. Goldberg, A. S. Kaplan, A. D. Katz, R. D. King, J. K. Luce, R. B. Schultz, H. M. Sterling, W. A. Taylor, and J. Walker.

Legal Note—Liability for Pooled Blood Plasma

The New York Court of Claims recently held that the State of New York is not civilly liable for the death of a hospital patient who died from homologous serum hepatitis which he developed as a result of a nonemergency transfusion of pooled unirradiated blood plasma. The plasma had been distributed to the hospital, free of charge, by the State of New York. *Hidy v. State of New York*, 137 NYS 2d 334 (Ct. Claims, N. Y., 1955).

The court held that the State was under no duty to affix warning labels to the plasma containers nor to distribute literature concerning the dangers of pooled blood since such information was readily available to practitioners through the professional journals. The Appellate Division of the New York Supreme Court has previously held that the State cannot be held liable for the death of a patient when the contaminated blood plasma is administered under emergency conditions where "safer" types of transfusion material are not available. *Parker v. State*, 280 App. Div. 157, 112 NYS 2d 695 (1952), leave to appeal denied 304 NY 989, 109 NE 2d 474.

DDVP . . .

The New Insecticide's Present Status

By KENNETH D. QUARTERMAN, B.S., M.P.H.

THE DISCOVERY of dimethyl 2,2-dichlorovinyl phosphate, a new and potent insecticide known as DDVP, was announced February 1, 1955, by the Secretary of Health, Education, and Welfare. The new organic phosphorus compound was developed by chemists on the Savannah, Ga., laboratory staff of the Public Health Service's Communicable Disease Center. Preliminary tests have proved the compound to be about equally as toxic to houseflies as parathion, but only one-fifth to one-tenth as toxic to rats as parathion.

Since the discovery announcement, subsequent publicity unfortunately has, to some extent, overemphasized the presently apparent potentialities of this new insecticide. At the same time, little or no information has been given to the public as to its availability. The Public Health Service has received many inquiries for information on uses, costs, manufacture, and distribution of DDVP.

DDVP is not now being produced commercially and is not available for use by the general public. Before it can be released for general use, much investigation is needed to determine dosage requirements for specific insects, suitable formulations, and the toxicological hazards associated with its usage. Considerable time will be required to develop such information and to register labels with the United

Mr. Quarterman, a biologist, is chief of the Technical Development Laboratories, Technology Branch, Communicable Disease Center, Public Health Service, Savannah, Ga.

States Department of Agriculture as required by the Federal Insecticide, Fungicide, and Rodenticide Act.

Invention for Public Use

It has been determined that the Federal Government is entitled to the entire right, title, and interest in the invention of DDVP. It was decided also that the Government should not seek to obtain a domestic patent on the invention because prior publications on the invention by the Government scientists who developed it are deemed sufficient protection against the prosecution of a successful patent application by a later inventor. These publications will, within 1 year from the first date of publication, constitute a dedication of the invention to the public. Such a dedication adequately protects the interests of the Government. On the basis of this determination and decision, any manufacturer who wishes to do so may proceed with the domestic production of DDVP in the United States without seeking a license from the Government.

Manufacture of DDVP

A number of chemical manufacturers have expressed an interest in producing DDVP. How many companies may ultimately engage in its manufacture cannot be determined at this time, and the number undoubtedly will be governed by the demand for the product. At the present time, only one company is known to have a pilot plant in operation. The limited quantities of DDVP being produced are available only to qualified research units for further study and field evaluation against a variety of insects. Until DDVP is produced commercially, estimates concerning its cost are impractical.

Extent of Usefulness

What insects DDVP may prove useful in controlling cannot be predicted accurately. Be-

cause of its chemical properties and the present knowledge of its insecticidal activity and toxicity to warm-blooded animals, it appears that DDVP is apt to find only limited use against insects of public health significance. It has been shown to be effective on DDT-resistant houseflies by topical application (1) and in poison baits (2). It may be reasonable to expect that DDVP will be useful in such situations as outdoor space sprays to control adult flies and mosquitoes. There also may be some usage for it as a larvicide against flies and mosquitoes. Because of its relatively high volatility, DDVP is not likely to be useful as a residual spray; and because of its toxicity, it appears unsuitable for use in vaporizers in occupied buildings.

DDVP should find wider use in agriculture than in public health. It should be effective against many of the agricultural pests now controlled with parathion and tetraethylpyrophosphate (TEPP). Since DDVP appears to be considerably less toxic than these compounds, and since it will offer less residue problem on food crops than many other insecticides now in use, it is reasonable to anticipate considerable

usage of DDVP in agriculture, especially on food crops.

In summary, DDVP is a promising new insecticide, the full potentialities of which remain to be developed by further research, much of which is already in progress. It is not available to the public and is not likely to be before 1956, at the earliest. The Government has dedicated the discovery of DDVP to the public; and any manufacturer may engage in its production in the United States without obtaining a license from the Government. Its sale in this country, of course, will be subject to compliance with the requirements of the Federal Insecticide, Fungicide, and Rodenticide Act as are all other insecticides.

Epidemiologists' Conference Organized

The Conference of State and Territorial Epidemiologists was organized in Atlanta at the close of the second national meeting of epidemiologists, May 16-18, 1955. The conference was sponsored jointly by the Communicable Disease Center and the National Office of Vital Statistics of the Public Health Service.

Since the first meeting of State epidemiologists in 1951, called by the Public Health Service at the request of the Association of State and Territorial Health Officers, epidemiologists have been active in recommending improvements in the various communicable disease control programs and in Federal and State morbidity reporting systems. Through the conference a broader avenue of approach will be open to them.

The officers for the newly organized conference are: president, Dr. Roy F. Feemster, Massachusetts; president-elect, Dr. A. C. Hollister, Jr., California; vice president, Dr. A. L. Gray, Mississippi; secretary-treasurer, Dr. Samuel B. Osgood, Oregon. Chosen as members of the council were: Dr. Ruth Church, Illinois; Dr. L. L. Parks, Florida; and Dr. Robert F. Korns, New York.

Our Growing Demands for Water

—What To Do About Them—

By CARL G. PAULSEN, B.S.C.E.

THE BLEAK RUINS of the cliff dwellings in the southwest and the associated remnants of irrigation ditches built by a people long forgotten suggest that a former civilization of our country was a mortal victim of a shortage of water. Water is also the key resource of our present civilization, and, as population increases and industry expands, we are confronted more and more frequently by the question of what to do about our growing demands for water. Fortunately, we of the present day have the knowledge and mechanical facilities to deal with problems of water supply in ways infinitely better and more effective than those antecedent tenants of our country.

Taken as a whole, the earth has a marvelously efficient water supply system. In a sense the sun acts as a huge pump circulating water in a closed circuit, the hydrologic cycle. As water comes within our reach, we use it as we need

it, and after its temporary service, it continues its natural course in the cycle. Notwithstanding the remarkable efficiency of this system, a serious problem of utilization is presented by its lack of uniformity. The quantity and quality of our water supply are variable in time and place. The present extended drought in the south and southwestern States and many of the numerous public water supply shortages experienced throughout the United States during the last few years are evidence of this variability.

The shortages are also aggravated by our ever-increasing requirements for water. Our withdrawal use of water increased fourfold between 1900 and 1950, and it has been estimated that it will double between 1950 and 1975. Modern domestic conveniences have greatly increased our water requirements. Air conditioning, automatic home laundries, and automatic dishwashers were unheard of 50 years ago and were not common even 25 years ago. Many household appliances that are not ordinarily thought of as heavy users of water have greatly increased the electric power consumption, and that, in turn, has increased the water use at the central hydroelectric or steam powerplants.

Advances in technology have added greatly to industrial water requirements, both in quantity and quality. Synthetic fibers, such as rayon and nylon, require much larger quantities of water for processing than the natural materials they replace. Synthetic rubber produc-

Mr. Paulsen, chief, Water Resources Division, Geological Survey, Department of Interior, has served continuously in the Survey since 1913, as a hydraulic engineer on water investigations. He is the author and co-author of many technical papers and articles on water and of many water supply papers of the Geological Survey. Mr. Paulsen's paper was presented at the annual meeting of the American Association for the Advancement of Science, December 27, 1954, at Berkeley, Calif.

tion requires large quantities of water not needed in production of natural rubber. Each additional stage in oil refining requires additional process water, increasing the quantity required per unit of crude oil considerably above that needed by earlier simple stills.

Large Supply—Unevenly Available

Much has been said and written concerning the nationwide water situation. If we use long-term average runoff as an index, we can estimate our annual available water supply at about 1,300 million acre-feet, as compared with a withdrawal use at present of about 195 million acre-feet. Even regionally the situation is not serious, but in certain local areas it is critical. The total average annual supply in the 17 western States is about 390 million acre-feet, as compared with the present withdrawal use of about 100 million acre-feet. Except for irrigation, only a small part of the water withdrawn for use is consumed; some estimate the amount to be as little as 10 percent. Therefore, the ratio as a whole between supply and demand appears even more favorable if consumptive use, rather than withdrawals, is taken into account.

We can see that nationwide this country is blessed with a plentiful supply of water. However, some areas have a surplus of water all of the time, whereas other areas may have a surplus during some seasons, and still other areas seldom have sufficient water. Differences in water supply are striking. Using the runoff as an index of available supply, the greatest supply at any place in the United States is along the coast of the Pacific northwest, particularly in the Olympic Mountains, where the average annual runoff of Wynoochee River at Oxbow, Wash., would cover its drainage to a depth of about 150 inches. On the other hand, several areas in the southwest have an average annual runoff of less than one-fourth inch, and no streams flow out of the Great Basin.

The variation in daily streamflow may be very great. In some arid or semiarid regions 90 percent of the annual runoff may occur in a single week. On the other hand, some streams have an exceptionally uniform rate of flow. The Loup River and its tributaries draining the

Sand Hill region of Nebraska are noted for their uniform flow. The average flow on about 75 percent of the days is within 10 percent of the average annual flow. The Deschutes River, a spring-fed stream in Oregon, is another example of uniformity of flow.

The annual runoff of most streams, however, is highly variable. A stream in which the variability is especially high is the San Gabriel River in California in which, during the 56-year period 1896 to 1951, the annual runoff averaged 116,000 acre-feet but ranged from 10,000 acre-feet in 1899, or less than 9 percent of the average in 1922, to 410,000 acre-feet or 353 percent of the average.

The ready availability of the large quantities of good water required by our modern communities was not a consideration in their original establishment, and, as those communities grow, the problems of water become more and more difficult and costly of solution. Los Angeles is an extreme example of this kind of situation. There, 3 percent of the Nation's population lives in an area that receives only 0.04 percent of the Nation's precipitation and has less than 0.0005 percent of the Nation's streamflow. Consequently, it has been necessary to import large quantities of water great distances at great expense.

This is the broad picture then, the base from which we must proceed: In terms of the entire country, we have a generous supply of fresh water, but it is so unevenly distributed that the supply is more than ample to meet our present requirements in some places and insufficient in others. Our water supply, very large though it may be, is variable in time, place, and quality. We must recognize, therefore, that in many areas there will never be as much water as can be used. Consequently, our concern is to take stock of these variables so that we may undertake such steps as seem feasible to derive more benefit and service from our water resources.

Several possible steps are suggested: It may be possible to develop new sources of supply, as by inducing artificial precipitation and demineralizing saline waters. The present supplies may be developed further by storage, control of pollution, and so forth. Water losses may be

reduced. Existing supplies may be utilized further through more efficient use and by re-use.

Developing New Sources of Supply

The possibility of increasing precipitation by cloud seeding is being explored by several groups, but definite conclusions as to the success of cloud seeding in stabilizing or increasing to a substantial extent water supplies in areas of short supply seem not yet conclusively demonstrated.

The prospect of increasing our fresh water supply by converting saline water to fresh water appears to be promising under certain conditions.

Congress, in 1952, passed Public Law 448, providing for research which may lead to development of practical processes for converting saline water to fresh water. The Saline Water Conversion Program is conducted by the Department of the Interior by coordinating and encouraging research in this field through federally financed grants and contracts.

It is possible that converted saline water can be used economically by some municipalities, especially those in water-short areas of high productive value, if fresh water can be provided at the cost of about \$125 an acre-foot, and for irrigation in highly productive areas if fresh water can be supplied at a cost of \$40 an acre-foot or less.

One of the processes being investigated—the ion-permeable membrane process—might prove to be an answer to some water needs since its cost is proportional to the dissolved solids content of the raw water. Typical preliminary cost estimates of conversion of fresh water are about \$450 an acre-foot for sea water, \$40 an acre-foot for saline water from Texas containing about 10,000 p.p.m. of dissolved solids, and \$4 an acre-foot for water from South Dakota with a dissolved solids content of about 855 p.p.m.

The present fresh water supplies can, of course, be developed further and in many places quite extensively by the use of additional storage reservoirs and by improving the quality of the water. As our water resources become more highly developed, water quality becomes increasingly important. Poor quality is detri-

mental to the utility of a supply because it makes the water unsuitable for some use and for certain other uses, such as irrigation, it necessitates the application of larger quantities to prevent an undesirable accumulation of minerals in the soil.

Storage facilities, both surface and underground, enable us to extract more service from our water supply. During the last 7 years the surface reservoir capacities for the Nation have been increasing at an annual rate of more than 16 million acre-feet. In January 1954 there were 1,300 reservoirs in the United States having a usable capacity of more than 5,000 acre-feet. Their combined usable capacity was 278 million acre-feet.

In the 17 western States, the total usable reservoir capacity amounted to 193 million acre-feet of which more than 59 million acre-feet is provided for irrigation. Many additional reservoirs of less than 5,000 acre-feet capacity are used for irrigation. According to the Bureau of the Census, about 5,500 reservoirs having a capacity of less than 1,000 acre-feet were used for irrigation in the 17 western States in 1950.

Although the water stored at any one time in all the rivers and lakes of the Nation is enormous, the volume of fresh water stored in the countless natural openings in the soil and rocks beneath the water table is probably several times greater. The volume of water stored beneath the land surface is dependent primarily upon the physical characteristics of the rocks and the climate. Nevertheless, the continued usefulness of a ground water reservoir ultimately must depend, not on its extent and the quantity of water originally contained but on the conditions affecting both replenishment and transmittal of the water from recharge areas to the point of use.

Surface and subsurface reservoirs have several characteristics in common. Sufficient water must be available to replenish them. Both are refilled during wet periods, so, in order to be of maximum use, water should be withdrawn during dry periods to make room for a new supply. A reservoir which is full all of the time is not serving its primary function. This is a characteristic of subsurface reservoirs that may be overlooked since they are not visible.

tion requires large quantities of water not needed in production of natural rubber. Each additional stage in oil refining requires additional process water, increasing the quantity required per unit of crude oil considerably above that needed by earlier simple stills.

Large Supply—Unevenly Available

Much has been said and written concerning the nationwide water situation. If we use long-term average runoff as an index, we can estimate our annual available water supply at about 1,300 million acre-feet, as compared with a withdrawal use at present of about 195 million acre-feet. The ready availability of the large quantities of good water required by our modern communities was not a consideration in their original establishment, and, as those communities grow, the problems of water become more and more difficult and costly of solution. Los Angeles is an extreme example of this kind of situation. There, 3 percent of the Nation's population lives in an area that receives only 0.04 percent of the Nation's precipitation and has less than 0.0005 percent of the Nation's streamflow. Consequently, it has been necessary to import large quantities of water great distances at great expense.

This is the broad picture then, the base from which we must proceed: In terms of the entire country, we have a generous supply of fresh water, but it is so unevenly distributed that the supply is more than ample to meet our present requirements in some places and insufficient in others. Our water supply, very large though it may be, is variable in time, place, and quality. We must recognize, therefore, that in many areas there will never be as much water as can be used. Consequently, our concern is to take stock of these variables so that we may undertake such steps as seem feasible to derive more benefit and service from our water resources.

Several possible steps are suggested: It may be possible to develop new sources of supply, as by inducing artificial precipitation and demineralizing saline waters. The present supplies may be developed further by storage, control of pollution, and so forth. Water losses may be

roughly estimated to be about 15 million acre-feet per year. This does not include evaporation from water surfaces of natural streams. Although the evaporation process is unavoidable, the total loss by this cause can be held to a minimum by careful locations of reservoirs and by establishing suitable operating procedures. Climatic factors affecting evaporation often vary widely within a drainage basin. If alternate reservoir sites are available, evaporation losses can be held at a minimum when the site selected is one which has the smallest surface area and climatic conditions that are least favorable for evaporation. Water losses from a system of reservoirs can be reduced by using water from those reservoirs having a high evaporation potential first so that their surface area is appreciably reduced.

The Geological Survey of the Department of Interior in collaboration with several other Federal agencies has completed a research project to test several methods of measuring evaporation reliably from large bodies of water. The results of these tests are now being applied to Lake Mead, Nev.

The Geological Survey is also making a study of the evaporation from Lake Colorado City in Texas. This lake is used as a cooling pond for a large steam powerplant. The object of the study is to determine evaporation from the lake, including the effect of added heat, and to determine the effect of added heat on the thermal structure of the lake. The results of this study will enable us to estimate the extent that ponds may be used for cooling and enable us to decide whether the use of cooling ponds is good conservation practice.

Bodies of ground water, like surface reservoirs, may be subject to large losses. One source of large losses is transpiration by phreatophytes, or water-loving plants, such as salt cedar which have little or no economic value. It has been estimated that salt cedar may transpire as much as 7 acre-feet of water per acre annually. A Geological Survey engineer has estimated that phreatophytes of all kinds now cover about 15 million acres in the 17 western States and may consume in the aggregate as much as 20 to 25 million acre-feet annually, a volume of water equal to about twice the average

annual flow of the Colorado River at Lees Ferry, Ariz.

A second source of substantial loss from ground water is evaporation from areas where the water table is only a few feet below the land surface and its overlying capillary fringe extends up to the land surface. Evaporation from such areas is continuous, being sustained by water which rises through the capillary fringe, just as a flame is sustained by capillary rise of fuel in the wick of a kerosene lamp. Evaporation losses from such areas are large. In the Big Smoky Valley of Nevada evapotranspiration losses may be considerably in excess of 100,000 acre-feet a year.

Large losses from shallow ground water bodies by evapotranspiration have an adverse effect on the quality of the remaining water. Plants use only a very small part of the dissolved solid content of the water, and none of the minerals are carried away by the evaporated water. As a result, these dissolved solids become concentrated in the water that remains or are precipitated in the soil, to be redissolved by subsequent rains. Therefore, the reduction of losses in these various ways would not only increase the quantity of water available but would also improve its quality.

Re-use of Waste Water

Use of waste or polluted water, wherever quality requirements will permit, is another way of increasing the effective water supply. The practice of using sewage effluent for irrigation is not new; it has been known for almost 100 years. Treated sewage effluents have been used also as a source of water for industry and for ground water recharge. As an indication of this trend, the Shell Oil Company recently made arrangement to reclaim waste water from the Ventura, Calif., sewage disposal plant at the rate of 2 million gallons a day. Some sewage is not suitable for re-use, especially if the raw water contains a high concentration of dissolved solids, or if the sewage contains undesirable industrial wastes. In general, the domestic use of water will increase the dissolved-solids concentration by an average of 100 to 130 p.p.m.

The University of California Engineering

Department recently estimated that in California there is approximately 1 million acre-feet of waste water available for re-use. The Geological Survey estimated that about 4 million acre-feet of water was used for industrial and domestic use from public supplies in the 17 western States during 1950.

Industry frequently uses its waste water by recirculation. Re-use of water in industry does not reduce the consumptive use of water but greatly reduces the withdrawal use. The water requirements within an industry range widely, indicating a wide range in economy of water use.

Many examples can be cited where re-use of water has tremendously reduced the water intake. Probably the most frequently cited example is the Fontana Plant of the Kaiser Steel Company where the intake per ton of steel is only 1,100 gallons as compared with the industrywide value of 65,000. A steam electric powerplant recently constructed in Texas uses only 1 gallon of water per kilowatt hour output, as compared with 60 to 100 gallons for steam powerplants where the cooling water is not circulated.

The Water Resources Division of the Geological Survey recently made a survey of the water requirements of the pulp and paper industry. On the average, the maximum rate of water use per ton of paper produced was about 5 times the minimum rate in making similar products in the same general area. A similar survey of the water requirements of the carbon black industry shows an even wider range in water use. Process water required to produce a pound of carbon black ranged from 0.79 gallon to 20 gallons by the furnace process and from zero to 0.19 gallon by the contact process.

Much of the industrial water is used for cooling and, therefore, cooling towers and ponds become important where water is re-used. Each recycling of the water through a cooling tower reclaims about 95 percent of the water. The only loss from the system is that small quantity evaporated to accomplish the cooling and a small amount of blowdown to maintain reasonable concentrations of dissolved solids in the recirculated water. The loss from a cooling pond is the evaporation owing to the addition of warmed water plus natural evaporation and

seepage. The present rate of installation of cooling towers indicates increased re-use of water. In 1953, the member companies of the Cooling Tower Institute sold 38 installations to private and public steam-electric generating plants having a combined capacity of 1 million gallons a minute.

Many of the industry's water requirements, particularly that for cooling, can be adequately fulfilled by salt water where it is available. To safely use saline water, industrial equipment must be fabricated of material to resist the chemical aggressiveness of the water. The quantity of saline water used is imperfectly known, but we do know that at least 14 million acre-feet is used annually and that the total quantity is probably much larger. If industry could afford to pay the higher installation and maintenance costs, a great deal more saline water could be used.

Stretching the Available Supply

Although over much of the Nation there is plenty of water, the supply is extremely variable, and many communities will at times not have enough to satisfy their growing needs. A major problem then is to derive the maximum benefit and utility from our water resources.

Several courses of action are open by which we can stretch the available supply to satisfy the optimum use:

We can develop our present supplies more intensively by construction of additional reservoirs, development of presently unused ground water reservoirs, and more extensive use of artificial recharge of ground water reservoirs.

We can increase the usable supply by reducing or preventing contamination from saline waters, urban wastes, or industrial wastes, along the lines encouraged by the Public Health Service under the Water Pollution Control Act. Many acre-feet of water are lost annually by unproductive evaporation and transpiration. Reduction of these losses will in effect increase the quantity and improve the quality of our usable water supply. Our water supply will go further if we closely match water quality and water requirements, that is, if we use high qual-

ity water for uses that require high quality water and use water of poorer quality where it can be tolerated. Thus, we may be able to use some sewage effluents and saline waters which are presently wasted. A large quantity of waste water can be salvaged by re-using or recirculating water in our industrial plants. An acre-foot of water salvaged and re-used is just as effective as an acre-foot of newly developed water. Possibly some additional water can be provided by conversion of saline water to fresh water.

In many parts of the Nation many of the inexpensive sources of water have already been developed. As our water resources become more and more intensively developed, the cost of new developments will continue to increase. At the present time, most of the conservation measures that are mentioned are technically feasible. In some places they are economically feasible. The economic feasibility of these

measures will become widespread as competition for water increases.

The solution of our problem requires facts—facts on a local scale involving all the variables of streamflow, storage, and movement of ground water, and the mineral and sediment concentration and temperature characteristics of the water. We have made considerable progress in collecting, compiling, and interpreting data on water resources, but we need to know more, especially more details on the local scale. We need to know more about evaporation and transpiration losses, their magnitude and methods of reducing them. We need to know more about reclaiming waste water and about the water requirements of industry both as to quantity and quality.

Detailed knowledge of our water resources and of their uses is a prime essential to assure the most benefit and utility from our water resources.

Departmental Announcements

Oveta Culp Hobby, Secretary of Health, Education, and Welfare, resigned from her position effective August 1, 1955. Mrs. Hobby was appointed Federal Security Administrator on January 21, 1953, and was made Secretary on April 11, 1953, when the Federal Security Agency became the Department of Health, Education, and Welfare. She resigned the positions of editor and publisher of *The Houston Post* and executive director of Station KPRC-AM-FM-TV, Houston, Tex., at the time of her appointment.

Mrs. Hobby came to her Cabinet post with a distinguished record of public service. She directed the Women's Army Auxiliary Corps in 1942. In 1943 she was appointed director of the Women's Army Corps with the rank of colonel. She was awarded the Distinguished Service Medal by the United States Government and the Military Merit Medal by the Philippine Government. The author of a textbook on parliamentary law, Mrs. Hobby served for several years as parliamentarian in the Texas House of Representatives. She also served on the board of directors of the American Society of Newspaper Editors.

Marion B. Folsom, Under Secretary of the Treasury since January 1953, has been named by President Eisenhower to succeed Secretary Hobby. Active in Government and private industry social security programs for more than a quarter of a century, Mr. Folsom was a member of President Roosevelt's advisory council which helped draft the original Social Security Act in 1934. In subsequent years, he served on advisory councils which studied operations of the social security system and made recommendations to the Congress. He worked with the Department of Health, Education, and Welfare on the plans which in 1954 resulted in congressional amendments to extend social security coverage and benefits. He also was chairman and a founder of the Committee of Economic Development.

Mr. Folsom was instrumental in the development of the group life insurance program for Federal employees which was put into effect in August 1954. Several years earlier he had helped organize the Group Medical Care Insurance Plan in Rochester, N. Y.

A graduate of the University of Georgia and the Harvard Business School, Mr. Folsom was treasurer and a director of the Eastman Kodak Company from 1914 until January 1953, before he came to the Department of the Treasury.

Technical Report on Poliomyelitis Vaccine

ON June 10, 1955, the Public Health Service sent a Technical Report on the Salk Poliomyelitis Vaccine to the Secretary of Health, Education, and Welfare. Published below are the summary, the report on epidemiological experience and new developments in biologics, and an expanded calendar of events. Copies of the report were made available to all State and local health departments. Since only a limited number of copies are available through the Public Health Service, it is recommended that interested health department employees obtain a copy in their own agency.

Summary

The report presents the technical problems involved in the production, testing, and safety of Salk poliomyelitis vaccine. It also describes the responsibilities of the Public Health Service in control of the manufacture of the vaccine as a biological product.

The vaccine as prepared for the 1954 field trial was an experimental product made by commercial producers for the National Foundation for Infantile Paralysis. After some initial difficulty, the industrial firms were able to turn out a good product, and the field trial was carried out successfully. Vaccine production for the field trial permitted the laboratories of industry and the Public Health Service to acquire experience in testing.

As a result of its studies over a period of 2 years, which included participation with industry and with Dr. Jonas Salk in testing of vaccine for the field trial, the Public Health Service planned to act quickly on licensing if the analysis of the field trial data showed that the vaccine was safe and effective. It had issued prospective minimum requirements in May 1954, as advisory for pharmaceutical labora-

tories which might wish to manufacture and store vaccine intended for commercial use pending decision to license the product. When the success of the field trial was reported April 12, 1955, official minimum requirements were issued. Six manufacturers, each of which had produced vaccine under the provisional requirements, were granted licenses.

Records and samples of vaccine lots had been submitted to the Public Health Service Laboratory of Biologics Control prior to April 12, and, within the next few days, those which were considered acceptable were released. Most biological products for commercial distribution are released on the basis of an examination of the detailed record of events in manufacture and testing (known as a protocol), with or without further testing by the Laboratory of Biologics Control. Release of most of the lots of poliomyelitis vaccine was based on review of the manufacturing protocols. Tissue culture tests for the presence of live virus were completed prior to release by the Laboratory of Biologics Control on about half of these lots and monkey tests were completed on 6 lots involving at least 1 lot from each of 5 manufacturers.

On April 26, six cases of poliomyelitis were reported among children who had received vaccine manufactured by the Cutter Laboratories. At the request of the Public Health Service, this firm immediately recalled all of its vaccine. The ensuing investigation of the Cutter Laboratories was later extended to the entire industry and led to a temporary suspension of the nationwide vaccination program.

The Public Health Service on April 28 established a Poliomyelitis Surveillance Unit within its Communicable Disease Center in Atlanta, Ga. This unit is investigating all reported cases of poliomyelitis, whether or not asso-

ciated with vaccine. Sixteen virus laboratories, throughout the Nation, are cooperating in examining and reporting upon specimens collected from cases and suspected cases. The epidemiological data so far obtained clearly define the Cutter incident as an outbreak with characteristics of a common source epidemic. The cases of poliomyelitis following use of vaccines made by the other manufacturers have not been more numerous than would be expected at this season except for a few cases which suggested (but were too few to be conclusive) an association with one lot of vaccine produced by Wyeth Laboratories. That firm has withdrawn the unused portion of this lot.

The Salk vaccine is a suspension of poliomyelitis virus inactivated by formaldehyde to make the virus harmless but still capable of inducing the production of antibodies. The vaccine contains inactivated virus of each of the three types. The original concept of vaccine preparation was that the process itself assured a wide margin of safety. Safety tests for the vaccine were conceived to detect both mass contamination resulting from accidents in manufacture and residual live virus which the process was intended to eliminate.

The intensive investigations of the past 5 weeks indicate that the records manufacturers were required to submit did not include certain data which are essential for an adequate assessment of consistency in performance. The protocols submitted related only to lots of vaccine proposed for clearance and gave no information concerning lots discarded in the course of manufacture. Further, the information requested did not bring out certain data on processing and testing now known to be important.

The total experience of the manufacturers now reveals that the process of inactivation did not always follow the predicted course, since positive tissue culture tests not infrequently occurred after the expected completion of the inactivation process. Greater dependence, therefore, must be placed on sensitive tests for very small quantities of residual live virus as part of process control.

Two types of tests are used to determine the presence or absence of live virus in the vaccine: the monkey test and the tissue culture test. The tissue culture test has been found to be more

sensitive than the monkey test. It must be performed with a large enough sample of vaccine and under closely controlled conditions if it is to have the maximum value. The theoretical considerations which govern inactivation and testing have been analyzed in the light of information developed during this inquiry.

As a result of the inquiry and of analysis of the manufacturers' experience and records, changes were made in processing control and safety testing. Revised requirements in the testing procedures were established, and the release of vaccine was resumed. The modifications provide greater assurance of safety. As a result of the review and the institution of revised requirements, the production and availability of vaccine has been delayed.

The Salk vaccine applies new practices in the production of viral vaccines. The vaccine has progressed from the experimental level to large-scale production with unprecedented rapidity. This speed, reflecting the increased tempo of all medical research, created problems in biologics control amenable to solution only with the accumulation of knowledge and experience. It is likely that other problems of equal complexity will be raised by the development of other new viral vaccines. Action taken by the Public Health Service for dealing with both the current and the long-range problems include:

1. Amendment of minimum requirements for the production and testing of poliomyelitis vaccine.
2. Incorporation of minimum requirements in official regulations as mandatory standards.
3. Creation of a Technical Committee on Poliomyelitis Vaccine.
4. Creation of a Division of Biologics Standards, with strengthened staff and facilities.
5. Increased onsite plant surveillance and consultation.
6. Reoriented testing and research program.
7. Establishment of a Poliomyelitis Surveillance Unit.
8. Review of legislative authority.

Epidemiological Experience

Investigation of reports of paralytic poliomyelitis occurring in association with injections of vaccine was assigned to the Communicable

Disease Center. The newly established Poliomyelitis Surveillance Unit has operated to yield precise field information on the occurrence of poliomyelitis throughout the country. As a result of this activity the Cutter incident was clearly defined as an outbreak with characteristics of a common source epidemic.

Poliomyelitis Surveillance Program

The Public Health Service conducts a surveillance program through its Communicable Disease Center to help the States in rapid recognition, study, and control of such diseases as malaria, typhus, smallpox, diphtheria, psittacosis, and rabies. In 1954, CDC personnel collaborated in the poliomyelitis field trial evaluation, under the direction of Dr. Thomas Francis.

The Public Health Service had prepared, with State health departments and cooperating lab-

oratories, to extend surveillance over poliomyelitis this season. This surveillance was highly desirable to study the durability of immunity in the half a million children who had been immunized during the field trials in 1954, and even more desirable if the results of the field trial led to a general immunization program in 1955.

When the first occurrence of poliomyelitis cases in vaccinated children was reported, this program was quickly brought into play to collect and evaluate field and laboratory data which might indicate the nature and significance of the disease outbreak. Although some cases of poliomyelitis could be expected to occur by coincidence following vaccination, each reported case deserved thorough investigation.

On April 25, 1955, the Public Health Service received a report of poliomyelitis in a Chicago

Poliomyelitis Vaccine Distribution

Plans for the voluntary control and distribution of poliomyelitis vaccine this autumn rest at present on two conditions:

1. The completion of the program of the National Foundation for Infantile Paralysis to provide vaccine for first and second grade school children. When this occurs, an agreed-upon system of voluntary controls will go into effect. Vaccine will be shipped into each State by the manufacturers under a plan that will assure equitable distribution among the States, and which will take into account the desires of States as between public vaccination programs and distribution in normal drug channels.

2. The assumption that the vaccine will still be in short supply. If this condition prevails, it will demand strenuous efforts to assure that available supplies are distributed equitably among the States and among children in the priority age group in all parts of the States.

Statement by Otis L. Anderson, Assistant Surgeon General, and chief, Bureau of State Services.

The Public Health Service responsibilities for allocating vaccine equitably among the States are described in this chart.

For instance, under Step 1, the National Advisory Committee on Poliomyelitis Vaccine recommended that vaccine initially be given to children of 5 through 9. As increased supplies of vaccine become available, additional age groups will be included. In Step 2, a State's share of this child population will determine its share of vaccine. Thus, if a State has 2 percent of the Nation's population of children in the priority group, it will be entitled to 2 percent of the available supply of vaccine.

The other steps describe the procedures developed to assure a proper division of vaccine, as determined by each State authority between public agencies and private distribution outlets. Public agencies include local health departments, State clinics, public hospitals, and any other facilities whose services are provided through tax funds; private channels of distribution include drug stores, physicians, and pri-

vately operated hospitals, etc. The proportion of immunizations provided by public agencies in each State will vary, depending on how much vaccine the State decides to purchase, plus the amount, if any, purchased by other funds.

Once the Public Health Service has advised the State of the amount of vaccine available to it, and has advised the manufacturers of the State's allocations to public agencies (Steps 3 through 7), the task of assuring fair distribution within the State will be borne by the State authority.

The key to intrastate distribution is the quality of planning in the State itself. Through regional meetings and individual consultation the Public Health Service has worked with all States and Territories in devising the basic elements of intrastate plans. Obviously, no single plan can be devised that would fit the needs and resources of all States. The Executive Committee of the State and Territorial Health Officers' Association collaborated with the Public Health Service in the development of suggested princi-

child who became paralyzed approximately one week after injection of vaccine manufactured by the Cutter Laboratories.

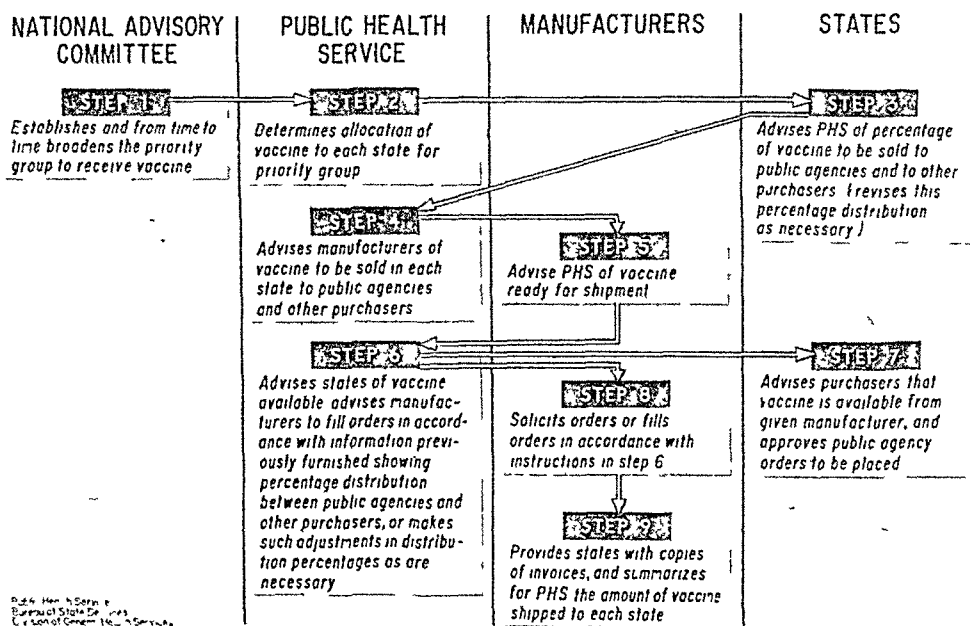

On April 26, at noon, illness suspected to be poliomyelitis was reported from the Napa Valley, Calif., in a child who also had received Cutter vaccine about one week previously. On the evening of April 26, four other cases of illness following injection of Cutter vaccine were reported from widely separated areas in California. California State health authorities immediately started investigation of the cases.

The absence of other known poliomyelitis in some of these areas at the time, the interval between vaccination and onset of the disease, and correlation between site of injection and site of paralysis created sufficient presumptive evidence of association with the vaccine to cause the Public Health Service to take action.

On April 27, the Surgeon General requested the Cutter Laboratories to recall all of its product pending a complete investigation. On April 28 he directed that the surveillance program be expanded to aid in evaluation, by epidemiological observations, of the occurrence of poliomyelitis in relation to vaccination. The data presented here are derived from reports of the Poliomyelitis Surveillance Unit through May 27, 1955, and constitute the field data which the Public Health Service has considered in determining actions since April 26.

Poliomyelitis Associated With Vaccination

A total of 113 poliomyelitis cases, with 5 deaths, were recognized among nearly 5½ million individuals within one month after injection of poliomyelitis vaccine (table 1). The greatest number of cases associated with the

ples of intrastate distribution. Included in this material are the following suggested objectives:

1. Equitable distribution of vaccine to eligible persons—the priority age group—in all areas throughout the State.
2. Public acceptance of the vaccine and the distribution plan.

3. Acceptance of and adherence to program principles by physicians, local health officers, pharmacists, and other related professional groups. (Accurate records and either a plan for screening orders in advance or a "post-audit" system will be necessary to assure equitable distribution, and to prevent the piling up of

stocks in some areas and consequent deprivation in others.)

The manufacturers have cooperated fully in setting up their part of the voluntary control system. The public health profession has the job of planning its corollary organization and of making the whole system function.

Table 1. Poliomyelitis cases and attack rates in recipients of poliomyelitis vaccine, with onsets between Apr. 20 and May 21, 1955

Vaccine manufacturer	Approximate number of vaccinees (total)	Cases			Total attack rates per 100,000 per month ¹
		Paralytic	Non-paralytic	Total	
Total-----	5,394,000	78	35	113	2
Cutter-----	409,000	59	10	69	17
Lilly-----	2,514,000	10	19	29	1
Parke Davis-----	1,234,000	2	0	2	<1
Pitman-Moore-----	461,000	0	2	2	<1
Wyeth-----	776,000	7	1	11	1

¹ These attack rates are of limited significance in themselves, since vaccinees of some manufacturers were used in areas in which the seasonal rise in incidence already had begun.

product of any one manufacturer was 69—59 of them paralytic. These cases occurred among approximately 409,000 recipients of vaccine prepared by the Cutter Laboratories. The attack rate in this group was 17 per 100,000 in 1 month.

Most of these cases were reported from California and Idaho where the National Foundation for Infantile Paralysis provided Cutter vaccine for school clinics, but a scattering of cases occurred in other parts of the country where the vaccine had been released in small quantities through commercial channels. Cutter vaccine was used for school clinics in Arizona and New Mexico; but no cases have been reported among vaccinated children from these States.

Among approximately 4,985,000 persons who received the products of four other manufacturers, a total of 44 cases was reported, only 19 of which were paralytic. The attack rate in this group was less than 1 per 100,000 in 1 month. The nonparalytic cases are of epidemiological significance but of little clinical or social importance. The reporting of nonparalytic poliomyelitis depends upon diagnostic practices, which vary from place to place; 12 of the 25 nonparalytic cases were reported from Texas. Since, however, official weekly morbidity reports from States do not always distinguish between paralytic and nonparalytic cases, the latter are included in this analysis in

order to compute "expected" cases by comparison with 5-year trends based on State reports.

Cases associated with vaccine produced by other manufacturers include: 19 paralytic and 10 nonparalytic Lilly-associated cases, largely from southern States; 7 paralytic and 4 nonparalytic Wyeth-associated cases from the midwest and east; 2 paralytic Parke Davis-associated cases from Illinois; and 2 nonparalytic Pitman-Moore-associated cases from Nebraska.

Type 1 poliomyelitis virus has been isolated from 17 Cutter-associated and 2 Wyeth-associated cases. One isolation of type 2 and one isolation of type 3 virus have been made from two separate Lilly-associated cases.

Cases Reported and Number Expected

It was only among first and second grade children who received vaccine that age is known with sufficient accuracy to calculate expected numbers of cases. It is not possible to compare the vaccinated group with a nonvaccinated group in the same areas because a very high proportion of the children of this age received vaccine. The method used in computing ex-

Table 2. Comparison of reported and expected numbers of poliomyelitis cases in children receiving poliomyelitis vaccine in National Foundation for Infantile Paralysis clinics, Apr. 15—May 7, 1955

Vaccine manufacturer	Approximate number of vaccinees (NFIP clinics only)	Poliomyelitis cases, with onset from Apr. 20—May 21	
		Reported number ¹	Expected number ²
Total-----	4,844,000	79	36
Cutter-----	309,000	35	5
Lilly-----	2,514,000	29	24
Parke Davis-----	834,000	2	3
Pitman-Moore-----	411,000	2	2
Wyeth-----	776,000	11	2

¹ Reported cases aged 6-8 years with onset between Apr. 20 and May 21. Includes both paralytic and nonparalytic cases since expected numbers for comparison are based on crude rates which include all cases reported as poliomyelitis in previous years.

² Expected cases if the estimated, age-adjusted, median attack rate for the previous 5 years had pertained in the vaccinees of 1955.

NOTE: These rates are specific for geographic areas where the various poliomyelitis vaccines were used.

pected cases has been to apply the median attack rate for the past 5 years in each geographic area to the number of children who were vaccinated. This is a crude measure, since poliomyelitis incidence undergoes wide and unpredictable variation in successive years, but it provides the best available tool to determine whether cases among children vaccinated are more common than would be expected by coincidence (table 2).

The difference between the numbers observed and expected (35 and 5) is significant in the case of those receiving Cutter vaccine and demonstrates an association between the Cutter product and an increased poliomyelitis incidence. The excess of reported cases over the expected number vaccinated with the Wyeth product (11 and 2) may be significant, but the numbers are too small to permit firm interpretation of such crude data.

Among the children who received vaccines made by Lilly, Parke Davis, and Pitman-Moore, the numbers of cases reported are within the range expected by chance occurrence.

Evidence of Infectious Virus in Vaccine

Evidence supports the hypothesis that the excess cases among individuals receiving Cutter vaccine may have resulted from the use of vaccine containing infectious virus. This evidence falls into three categories:

1. The interval between injection of vaccine and first paralysis in Cutter-associated cases ranged from 5 to 20 days (table 3). The median case occurred on the ninth day and the spread of the mid three-quarters was from 6 to 14 days. This finding parallels the frequency distribution of incubation periods in monkeys infected by intramuscular injection of virus. Moreover, the temporal distribution of cases following injection of Cutter vaccine is the expected distribution in a common source outbreak resulting from a single exposure to the infectious agent.

Additional significance attaches to these findings when comparison of the intervals between inoculation and first paralysis is made specific for geographic area and calendar time. Large numbers of children received Cutter vaccine in clinics in California and Idaho, the California clinics being held slightly before those in Idaho.

Table 3. Paralytic poliomyelitis cases by interval between poliomyelitis vaccine inoculation and onset of paralysis, Apr. 20–May 21, 1955

11-13-----	8	0	0	1	9
14-16-----	9	1	1	0	3
17-19-----	2	1	0	1	3
20-22-----	1	1	0	1	1
23-25-----	0	0	0	2	1

¹ Data abstracted from David Bodian: Viremia in experimental poliomyelitis. *Am. J. Hyg.* 60:358, November 1954. Mahoney virus was injected into the right calf of 32 cynomolgus macaques and the interval between inoculation and paralysis recorded.

² Data not available on interval for 9 Cutter cases and 1 each of Lilly, Parke Davis, and Wyeth.

Yet, the distributions of cases following vaccination in these two areas show marked similarity when adjusted for time differences.

2. Cutter-associated cases show a high degree of correlation between the extremity injected with vaccine and the extremity which was first paralyzed; 43 of 55 cases (78 percent) on whom records are complete showed this relationship (table 4). This finding is strikingly similar to the experimental experience in monkeys.

In contrast to this high degree of correlation for Cutter-associated cases, only 1 of 10 Lilly-associated cases showed this relationship.

Paralytic cases associated with Wyeth and Parke Davis vaccine, although consistent with this observation on correlation, are too few to warrant conclusion.

3. A number of poliomyelitis cases have occurred among household associates of vaccinated children (table 5). A total of 47 such cases (39 paralytic and 8 nonparalytic) had been recognized by May 27. These were distributed about equally between parents and children. Of the 47 cases among household associates, 35 (29 paralytic and 6 nonparalytic) were associated with Cutter-vaccinated children; 9 (7 paralytic and 2 nonparalytic) were associated with

¹ Bodian, D. Unpublished data from experiment cited in table 3.

² Data not available on site of first paralysis for 4 Cutter and 1 Lilly cases.

Wyeth-vaccinated children; and 3 (all paralytic) were associated with Lilly-vaccinated children. About one-third of the vaccinated children in these households had developed a minor illness within 2 weeks after inoculation and prior to the onset of poliomyelitis in the household contacts.

The interval between vaccination of children and the onset of poliomyelitis in their parents and siblings approximates two incubation periods in the 35 Cutter-associated and the 9 Wyeth-associated cases, as would be expected if the vaccinated child were the source of infection. The 3 Lilly-associated cases followed shorter intervals.

Table 5. Poliomyelitis cases in household contacts of vaccinees with onset between Apr. 22 and May 27, 1955

¹ Excludes 1 case where interval was 2 days.

Evidence Against Provocation

Another hypothesis considered in the investigation of cases of paralytic poliomyelitis in children following injection of vaccine was that central nervous system involvement may have been precipitated by the intramuscular injection of vaccine in individuals who were already infected with poliomyelitis virus. Had this been the case, the excess cases would be expected to occur in areas known to be experiencing some poliomyelitis. One might have expected naturally occurring cases at this season in the southern States and in southern California. The excess cases did not adhere to this pattern but occurred unexpectedly in Idaho in association with Cutter vaccine where no other poliomyelitis was being observed. They failed to occur in the southern States where a very large number of children received Lilly vaccine in areas where poliomyelitis was known to be present. These data do not support the provocation hypothesis.

Results of Epidemiological Survey

A total of 113 poliomyelitis cases (78 paralytic and 35 nonparalytic) had developed by May 21 among more than 5 million individuals vaccinated against poliomyelitis since April 14, 1955. Comparison of reported and expected numbers of cases indicate association between Cutter poliomyelitis vaccine and an increased incidence of poliomyelitis. The distribution of Cutter-associated cases by interval between inoculation and date of paralysis and the correla-

tion between sites of inoculation and paralysis are strikingly similar to experimental data. These findings indicate that at least some of the Cutter-associated cases developed from use of poliomyelitis vaccine containing infective virus. Additional data relating cases to specific lots of vaccine are under analysis in connection with the study of the Cutter plant processes, and will be included in a report to be made when all phases of this study are completed.

Evidence is not conclusive but suggests there may have been a similar association with a few cases following the use of Wyeth vaccine. In contrast, the data indicate that the incidence of poliomyelitis after use of the products of other manufacturers was probably coincidental.

New Developments

A number of aspects of the production and testing of the Salk poliomyelitis vaccine are unique. During the vaccine's development, field trial, and initial use, many problems arose, to which precedents and experience could not be applied. The progress of the vaccine to practical usability involved the National Foundation for Infantile Paralysis, local and State health officers, practicing physicians, university research laboratories, the pharmaceutical industry, and the Public Health Service. All these took part in arriving at major decisions, many of which established new precedents.

Progress in medical science is not always an uninterrupted forward motion. Throughout the history of medicine and public health, most great advances have been made step by step, with each new and unforeseen obstacle overcome, usually slowly, as it has been encountered. This has always involved a certain amount of acceptance of risk, trial and error, discovery of new knowledge, application of this knowledge in production and clinical use, and resumption of forward movement.

The development of the Salk vaccine is an example of this process in action at a very rapid rate. Events have been telescoped in time so that the vaccine has been developed, tested, and used in a matter of months instead of years. Procedures which appeared sound and adequate several months ago on the basis of experience up to that time have had to be modified in the light

of scientific and technical data now available.

The increase in scientific knowledge from this experience has been considerable. The Public Health Service is in a position to use the experience of recent months, superimposed upon experience of past years, as a basis for extending and improving its biologics control functions.

The Public Health Service's new measures are discussed below:

Amendment of Minimum Requirements

The minimum requirements for vaccine production and testing have been revised to provide a substantially greater margin of safety. Essentially, these changes provide for a required uniformity of sampling, which should provide a more uniform sensitivity of the test, and application of more tests at two critical points in the manufacturing process. One of these is a tissue culture test for virus, using samples of final container material to exclude contamination incidental to breaks in manufacturing routine subsequent to clearance of the trivalent pool. These and other less formal changes incidental to the recent review of the total manufacturing process will reduce still further the possibility that tested and released vaccine could contain sufficient active virus to be harmful to man.

In using any preventive or therapeutic substance, some risk always exists. This risk must be negligible in comparison with the hazard of a disease like poliomyelitis. Although the Salk vaccine has generally shown a remarkable degree of safety, the amended requirements still further reduce the risk involved in its use.

Incorporation as Mandatory Standards

The amended requirements for poliomyelitis vaccine will be incorporated in official regulations to establish their status as mandatory standards. In the past, these minimum requirements served only as guides which, however, have been fully accepted and applied.

Creation of a Technical Committee

The Surgeon General on May 25, 1955, created a standing expert advisory committee on poliomyelitis vaccine. The members of this committee are Drs. David Bodian, Thomas Francis, Jr., Jonas Salk, Richard Shope, and

Joseph Smadel, with Dr. James A. Shannon, associate director of the National Institutes of Health, as chairman. The committee was made responsible for: (a) formulating recommendations on measures to assure improved safeguards and greater effectiveness of the Salk vaccine, (b) recommending release of lots of vaccine, and (c) fostering collaborative research by industry, the National Institutes of Health, and university scientists on problems which must be solved in connection with vaccination against poliomyelitis.

Creation of a Division of Biologics Standards

The Public Health Service biologics control program has operated heretofore as a constituent laboratory within one of the large research programs of the National Institutes of Health—the National Microbiological Institute. Now the Surgeon General has requested authority to organize expanded biologics function, with the status of a separate division in the National Institutes of Health, to be called the Division of Biologics Standards. The Secretary of Health, Education, and Welfare has approved this request.

This step is taken as the culmination of developments in medical research related to: (a) the expanding range of diseases to which biological products may be applicable, (b) the kinds of new biologics which may be available, particularly in the field of virology, and (c) the compressed time interval between the discovery of new biologics and their use.

The principles utilized in the control of virus infections successfully applied to the Salk vaccine offer promise of solutions to a hitherto baffling group of disease problems. The so-called "wonder drugs"—antibiotics and sulfa compounds—have made little impression on the problems of virus infection. We can expect the development of potent new biologics which will have unprecedented application, particularly to control of virus diseases.

The fact that new products are developed, tested, and used over progressively shorter time periods is one of the boons of modern medical research. But it creates an essentially new set of tasks in the field of biologics control. The new tasks can be performed more effectively under the new arrangement.

The change also removes the biologics control activity from a framework in which emphasis has been on research not primarily related to biologics control. As a separate division, the staff will have both a clearer mandate and a better opportunity to conduct such research as is essential to deal with trends, advances, and problems in biologics.

The professional staff of the new division will be augmented. Broader professional coverage will be provided by the addition of senior members to the staff. The division will also be strengthened by additional facilities and by augmented administrative and statistical services.

Onsite Plant Surveillance and Consultation

Public Health Service staff members and expert part-time consultants drawn largely from university research centers will conduct a program of surveillance and technical consultation in the plants of the manufacturers while vaccine is under production. These scientists will collect information for the division and will foster collaborative work deemed essential by the Technical Committee on Poliomyelitis Vaccine. Similar procedures will be followed as other problems of biologics control arise in the future.

Expanded Testing and Research Program

The testing program of the new division will be directed primarily toward determination of the exact significance of safety and potency tests, and modification of tests and their interpretation to make test data yield more penetrating information.

When an industrial product must meet highly precise standards, whether the product be a jet engine or a biologic, primary dependence is placed on "tests in process" rather than tests of the final product. A final test must be made, but it is in no sense a substitute for the many tests conducted along the way.

Great emphasis will not be placed on simple repetition of the testing already done in industrial laboratories since this adds little to the safety factor. The mechanism of onsite plant consultation, described above, will determine that such testing is well done, and will interpret critically the test results.

The development and interpretation of these tests is of paramount importance in controlling safety and potency. Much remains to be learned about their underlying significance. These questions, for example, are not now answerable: How long must a tissue culture be watched before definitive readings can be taken? What is the effect of calf serum on virus growth in tissue culture? How can the monkey safety test be made more sensitive? Resolution of questions of this sort is better calculated to insure the safety of virus vaccine than are any number of repetitive tests. Working toward their solution will be a major responsibility of the new division.

Poliomyelitis Surveillance Unit

The Public Health Service has established a nationwide network for supplying precise and

current information on poliomyelitis cases, and for obtaining from collaborating university laboratories effective laboratory support for epidemiological studies. The purpose is to study vaccine performance.

Review of Legislative Authority

The Biologics Control Act was passed in 1902, and amendments since then have not fundamentally altered the basic act. The terms of the act are being carefully reviewed in the light of the increasing complexity and scope of the biologics control function. If amendments appear advisable, recommendations will be made to the Congress. In this connection, it is to be emphasized that industrial cooperation, particularly in the course of the recent review of the processes of the six manufacturers, has been excellent.

Calendar of Vaccine Standards and Distribution

July 1953. In preparation for the expected clinical trial of the poliomyelitis vaccine developed by Dr. Jonas Salk under the auspices of the National Foundation for Infantile Paralysis, Dr. William G. Workman, chief of the Public Health Service Laboratory of Biologics Control, visited the Connaught Laboratories in Toronto, Canada, to discuss and observe techniques for growing bulk poliomyelitis virus.

December 1953. Dr. Joseph Smaedel, Army Medical Services Graduate School, and Dr. Workman consulted with the National Foundation for Infantile Paralysis in the preparation of provisional standards for the manufacture of poliomyelitis vaccine. These standards, derived largely from the experience of Dr. Salk in making an experimental vaccine in his own laboratories, were designed as a guide for industry in the preparation of vaccine for the field trial.

February 1954. The provisional standards were sent by the National Foundation for Infantile Paralysis to 10 manufacturers with demonstrated competence and experience

in the production of biological products, inviting them to make poliomyelitis vaccine for the field trial. Two of these (Parke Davis and Lilly) had been in experimental production since the fall of 1953, working collaboratively with Dr. Salk. Five manufacturers responded, Parke Davis, Eli Lilly, Cutter, Wyeth, and Pitman-Moore. (Later, Sharp and Dohme elected to enter the field, making a total of six manufacturers.) The vaccine they were to produce was experimental, on contract to the National Foundation for Infantile Paralysis, and to be used only for investigative purposes.

February 1954. The Laboratory of Biologics Control had agreed in late 1953 to cooperate in testing the vaccine, at the request of the National Foundation. In February 1954, it began participation in triplicate safety testing of the experimental vaccine, receiving large numbers of test samples. This triplicate testing was done to gain experience in safety testing and to take advantage of the opportunity to further developmental research on a biological product. The National Foundation agreed that no vaccine would

be used in the field trial until polyvalent pool material, taken prior to division and final bottling, had been tested for safety in the manufacturer's laboratory, Dr. Salk's laboratory, and the Laboratory of Biologics Control and after approval by the Vaccine Advisory Committee of the National Foundation for Infantile Paralysis.

March 1954. At the request of the National Institutes of Health, a series of meetings was held with National Foundation representatives, Dr. Salk, the Vaccine Advisory Committee, and the manufacturers. Two out of the first 6 lots of experimental vaccine tested in the Laboratory of Biologics Control had failed in safety tests, and an additional 2 had failed the manufacturer's tests, indicating the presence of active poliomyelitis virus in the vaccine. The Vaccine Advisory Committee resolved to delay the initiation of the field trials for 4 weeks to permit a review of the vaccine tested during the extra time and to enable Dr. Salk to complete inoculation studies on some 7,500 children in the Pittsburgh area who were given commercially produced vaccine.

April 1954. The Vaccine Advisory Committee of the NFIP reconvened in Washington. Representatives of the National Institutes of Health and the manufacturers were present. The data on the vaccines produced and tested since the March meeting (10 batches in number) were considered, together with Dr. Salk's data concerning the 7,500 inoculated children. All results were of a negative character, and the committee recommended that the field trial proceed. The statement issued following the meeting, which was concurred in by the Public Health Service, contained the following statement: "... the possibility of infectious activity remaining in any vaccine meeting the specifications and minimal requirements has been reduced to a point below which it cannot be measured by practicable laboratory procedure."

May 1954. The field trial was begun, using vaccine supplied by Parke Davis and Eli Lilly. Three other manufacturers (Cutter, Wyeth, and Pitman-Moore) produced lots of material which passed the tests, but the National Foundation's decision was to use the vaccine from the two largest producers only in order to reduce variability from multiple manufacturers. The Public Health Service officially indicated a belief in the sound judgment of the Vaccine Advisory Committee in its recommendation to the NFIP to conduct the field trial.

May 1954. A document entitled "Minimum Requirements, Poliomyelitis Vaccine" was prepared by the Laboratory of Biologics Control with the advice and cooperation of the manufacturers and Dr. Salk. This was distributed to vaccine manufacturers and interested parties as a guide to prospective standards if the product were later to be licensed.

July 1954. The inoculation phase of the field trial was completed. The results, which were not available until April 12, 1955, indicated that there was no evidence of disproportionate frequency of paralytic poliomyelitis in vaccinated children up to 4 weeks after injection, nor of selective localization of paralysis.

August 1954. The National Foundation for Infantile Paralysis contracted with Dr. Thomas Francis, Jr., University of Michigan School of Public Health, for analysis of the data derived from the field trial. It was understood that his results could not be expected before March or April 1955. The Public Health Service provided about 20 epidemiologists and statisticians to assist Dr. Francis with his study.

August 1951. The National Foundation placed orders with the five manufacturers for the purchase of up to 27 million cc. of vaccine. This was done to encourage the manufacturers to stay in production after the field trial.

September 1954. Beginning in this month, and continuing through to January 1955, the Laboratory of Biologics Control inspected the plants of each of the six vaccine manufacturers except for one that had been inspected in July (Wyeth). These were general inspections required by regulations and included attention to poliomyelitis vaccine production plans and facilities.

November 1954. Two meetings, attended by representatives of the National Foundation, the manufacturers (including Sharp and Dohme, which had now entered the field), NIH staff, and representatives of the Connaught Laboratories in Toronto, Canada, were held in Pittsburgh to discuss deterioration of potency in some lots of vaccine. This was learned through tests made on vaccine left over from the NFIP field trial, and it was believed to be caused by merthiolate which was used as a preservative in the vaccine. This problem was then intensively studied by all concerned, with a view to preventing the deleterious effect of merthiolate or selecting another preservative which did not have this action. The manufacturers had to discard several millions of doses of vaccine containing merthiolate, produced by that time.

December 1954. The Laboratory of Biologics Control advised the manufacturers, the National Foundation, and Dr. Salk that, before licensing, it would require additional

clinical data on vaccine prepared without merthiolate since it was technically a different product from the one used in the field trial. Data supplied on 6,000 children injected with nonmerthiolated vaccine indicated that the vaccine without merthiolate was safe and potent. (An additional 3,000 were reported injected by Dr. Salk, but no data were submitted to the Laboratory of Biologics Control).

January 1955. The manufacturers began to submit to the Laboratory of Biologics Control protocols and samples of their first production lots of vaccine in anticipation of a favorable report on the results of the field trials. The Laboratory of Biologics Control began review of protocols and testing of materials well in advance of the expected date of actual licensing and of the official establishment of minimum standards for potency in order that vaccine might be available for the summer of 1955, should field trial results be favorable.

April 1955. By April 12, 1955, a total of 40 protocols with samples had been submitted to the Laboratory of Biologics Control. Six regular production lots had been fully tested in monkeys and in tissue culture by the Laboratory of Biologics Control with negative results. Additional tissue culture tests had been run on some other lots. Sterility tests were run on all lots. Protocols on all lots were reviewed independently by two or more Laboratory of Biologics Control scientists to determine conformity with the minimum requirements.

April 5, 1955. The director of the National Institutes of Health and the chief of the Laboratory of Biologics Control visited Dr. Francis in Ann Arbor, Mich., to discuss any preliminary data from the analysis of the field trial which would have a bearing upon the minimum requirements and licensing. The immediate need was for data permitting establishment of criteria for acceptable potency levels for poliomyelitis vaccine, some lots of which had already been submitted for release. This information from Dr. Francis was sup-

plemented by personal communications with Dr. Salk.

April 7, 1955. New draft requirements for potency standards were transmitted to the manufacturers.

April 12, 1955. At Ann Arbor, Mich., Dr. Francis announced the results of the analysis of field trials carried out in 1954 under the auspices of the National Foundation.

April 12, 1955. The Laboratory of Biologics Control issued the first official minimum requirements for poliomyelitis vaccine, revising the provisional minimum requirements issued in May 1954 to include standards for potency and a requirement that the manufacturer show that any preservative added to the finished vaccine causes no appreciable loss of potency within the period during which the vaccine may be used.

April 12, 1955. A group of special consultants met with the chief of the Laboratory of Biologics Control in Ann Arbor, to review the report of Dr. Francis and the minimum requirements and to make recommendations as to the licensing of Salk poliomyelitis vaccine. They agreed unanimously that the evidence available warranted licensing of the vaccine.

April 12, 1955. The Secretary of Health, Education, and Welfare issued to six companies (Parke Davis, Eli Lilly, Wyeth, Cutter, Pitman-Moore, and Sharpe and Dohme) licenses to manufacture poliomyelitis vaccine. The Secretary took this action on the recommendation of the chief of the Laboratory of Biologics Control, transmitted through and approved by the Surgeon General of the Public Health Service.

April 12-13, 1955. The first lots of poliomyelitis vaccine were released by the Laboratory of Biologics Control after having met the new minimum requirements. Thirteen lots of vaccine (6 Cutter, 2 Eli Lilly, 3 Parke Davis, and 2 Pitman-Moore) were approved. This rapid action was possible because the protocols and samples had been received in advance.

April 27, 1955. By this date, 40 lots of vaccine containing a total of 10.5 million cc. had been released. (This represents volume prior to final bottling. There is 15- to 20-percent shrinkage in filling due to overfilling and other causes.) Of this total, nearly 5 million cc. were used in first injections (approximately 4½ million under the National Foundation program and one-half million by others with vaccine distributed through commercial channels).

April 26, 1955. The Laboratory of Biologics Control received word of five cases of paralytic poliomyelitis in California among children who had received Cutter vaccine. There had been one earlier case in Chicago within the previous 24 hours. The incidence seemed to be above the rate expected from natural infection, and there was correlation between the site of injection and the paralysis.

April 27, 1955. Following advice from the National Institutes of Health staff, who held a telephone conference with a group of advisers, the Surgeon General requested Cutter to withdraw its vaccine from use. The Cutter Laboratories agreed to do so, and within less than an hour notified all their distributors to recover all of their unused vaccine.

April 27, 1955. The National Institutes of Health sent two experts in virology and in the operation of biologics production plants to make an examination of the Cutter Laboratories and report on all details of their laboratory processing and testing. A sanitary engineer assisted in some of the later phases of the inspection. This team was also directed to check the recovery of all unused Cutter vaccine.

April 28, 1955. The Public Health Service set up a special Poliomyelitis Surveillance Unit in the Communicable Disease Center, Atlanta, Ga., for rapid investigation of all cases reported as poliomyelitis. A nationwide epidemiological network was established through State and local health officials. This was supplemented by cooperating laboratories for recovery, identification, and typing of viruses. The Poliomyelitis

Surveillance Unit was directed to make daily reports to the Surgeon General and State health and other medical officials.

April 28, 1955. The Laboratory of Biologics Control (later augmented by 16 cooperating laboratories) began a series of tests on all Cutter vaccine, seeking to determine whether active virus could be detected. Meanwhile, testing of vaccine from other manufacturers continued.

April 29-30, 1955. An advisory group of advisers, 11 of the Nation's outstanding virologists and immunologists, was convened at the National Institutes of Health to review the situation and make recommendations on necessary action. By this time there were 17 reported cases of paralytic poliomyelitis among children injected with vaccine from the Cutter Laboratories. The group viewed protocols submitted on Cutter vaccine, discussed the situation with senior technical representatives from each of the six vaccine manufacturers, and submitted a unanimous report. The most important findings were that: (a) the action of the Public Health Service in recalling the Cutter vaccine was justified; (b) the continuation of vaccinations with the product of other manufacturers was warranted; (c) careful epidemiological and laboratory studies should be continued and extended; (d) it was probable that method of production and testing could be improved; and (e) a small committee of experts should study the minimum requirements to determine if changes were indicated.

April 30, 1955. Based on the recommendations listed above, the chief of the Laboratory of Biologics Control concluded that he could not prove any additional lots of vaccine until the review of the minimum requirements could be completed, and so advised the manufacturers. At this time, action was being withheld on a total of 3.9 million cc. of vaccine for which samples and protocols had been submitted but about which additional information had been requested by the Laboratory of Biologics Control, and on 330,000 cc. s

mitted for clearance a day before the meeting on requirements.

May 5-6, 1955. A six-member subcommittee of the April 29-30 ad hoc advisory group was convened at the National Institutes of Health to consider the adequacy of the minimum requirements, including the precise method of vaccine production and testing, the basis for decisions reached by review of protocols, and related matters. Technical representatives of all six vaccine manufacturers attended part of the meeting; they provided detailed data on their total manufacturing experience, including lots of material on which protocols had never been submitted for approval because of failure to meet requirements during processing. The subcommittee: (a) noted the accumulating epidemiological evidence of significant association between Cutter vaccine and the occurrence of paralytic poliomyelitis and the absence of evidence implicating poliomyelitis vaccine produced by the other manufacturers; (b) stated the desirability of increasing the margin of safety in the vaccine (they prepared a tentative draft for revision of the minimum requirements); and (c) believed it might be well to withhold further injections until a team of scientists could visit each plant and study the production processes, facilities, records, and protocols in the light of what was now known about the experience of the various manufacturers.

May 7, 1955. The Surgeon General recommended to the medical and public health professions that vaccinations should be suspended pending completion of study of the recommendations.

May 8, 1955. In a detailed statement, the Surgeon General repeated his recommendation that new vaccinations should not be given for the time being and announced that the manufacturers' production and testing procedures and facilities would be inspected by a team of scientists on a plant-by-plant basis, in the order of their entry into the poliomyelitis vaccine production field.

May 13, 1955. Based on the recommendations of the inspection team at Parke Davis, followed by a careful analysis of their protocols at the National Institutes of Health, approximately 4½ million cc. of Parke Davis vaccine already released were recleared. Of this supply approximately 1 million cc. remained unused. Clearance on one lot previously approved, but as yet unused, was withheld.

May 15, 1955. A scientific review panel meeting at the National Institutes of Health, hearing the report of the plant inspection and reappraising the protocols on Eli Lilly vaccine, cleared approximately 3½ million cc. of Lilly vaccine previously released; of this, only about 378,000 cc. remained unused. The Parke Davis lot on which reclearance was withheld on May 13 was ordered withdrawn, and an additional Parke Davis lot was released. The group also suggested modifications of the manufacturing and testing processes of all manufacturers seeking to build in additional factors of safety.

May 15, 1955. An ad hoc group of epidemiological advisers met at the National Institutes of Health simultaneously with the group on revisions of the minimum requirements. At that time at least 54 cases of paralytic poliomyelitis appeared to be associated with the Cutter vaccine. The group felt: (a) that there might possibly be some correlation in a few children receiving the product of another manufacturer; and (b) that the number of sibling or parental contact cases following vaccination of a member of the household warranted careful and continuing check.

May 16, 1955. The director of the National Institutes of Health reported to the Surgeon General that two manufacturers, after a long period of producing consecutive lots of vaccine that met all requirements, had recently experienced difficulty getting consistent results. Under the proposed revisions of the minimum requirements, which were under consideration, some of these lots of vaccine could not be approved.

These manufacturers were withholding request for clearance of a large amount of vaccine pending a clarification of this problem. This forecast production delays which would require revision in the expected vaccine supply in the immediate future.

May 16-20, 1955. A Public Health Service team of scientists and advisers visited the Wyeth and Pitman-Moore plants. Although the manufacturing techniques and professional competence of the firms were excellent, it was concluded that no action would be taken on reclearance of their vaccine until there could be an opportunity to assess all the data from all the plants and reach conclusions on the factors that should govern release of vaccine already processed as well as steps that might be built into the manufacturing and testing processes as additional safeguards in the future.

May 20, 1955. A special advisory group met at the National Institutes of Health to consider questions of dosage and use of vaccine during epidemics. The dosage question was considered because of some experimental evidence suggesting that injecting 0.1 cc. of vaccine intradermally instead of 1 cc. intramuscularly might be effective. The group, after reviewing all the data, recommended the following: (a) adherence to the existing dosage and route of injection, based on evidence of the vaccine's protective value during the 1954 field trials; (b) approval of extension of time between first and second dosage of vaccine to 5-6 weeks if necessary; and (c) caution concerning use of injections during or near epidemic periods or in areas of high prevalence, with decisions made by local authorities.

May 23, 1955. Members of the Vaccine Advisory Committee of the National Foundation for Infantile Paralysis, the American Medical Association, and the Association of State and Territorial Health Officers met at the National Institutes of Health and were given a review of the poliomyelitis immunization and vaccine situation.

May 25, 1955. An amendment to the minimum requirements was decided upon and discussed in detail with the vaccine manufacturers' technical representatives, who were also given summary information on the current epidemiological picture, the data derived from the five plant inspections, and the analysis of the sensitivity and reliability of the safety tests as performed under the existing minimum requirements. The executives of the manufacturing firms were asked to study the revised standards further and be prepared to bring their technical staff chiefs to a meeting the following day for final discussions.

May 26, 1955. A new, permanent advisory group was established by the Surgeon General and held its first meeting at the National Institutes of Health. Called the Technical Committee on Poliomyelitis Vaccine, this group was asked to perform two functions: to advise on the release of vaccine under the minimum requirements as amended, and to give continuing guidance in vaccine production and testing with particular emphasis on research leading to improvements and refinements in the vaccine.

May 27, 1955. The representatives of all six firms declared their individual support of the amended requirements in the interest of making a safer vaccine, and the Surgeon General made public announcement of this fact. Industry was asked to provide the Public Health Service with revised estimates predicting the amount of vaccine they might be able to make available this summer under the amended requirements.

May 27, 1955. In a press conference at the National Institutes of Health, Public Health Service officials made public the details of the amendments to the minimum requirements and their possible implications in regard to availability of vaccine. It was stated that there would be a net slowdown immediately; that the revisions did not entail any consequential lengthening of the total manufacturing process,

once placed in use in each plant; and that small amounts of vaccine would probably be made available beginning early in the week of May 30 and progressively thereafter.

June 1, 1955. The reclearance of 200,000 cc. of vaccine manufactured by Pitman-Moore and by Wyeth was announced. Surgeon General Scheele also stated that "no important differences were found in the quality of performance or the scientific caliber of the manufacturers now releasing the vaccine for general use."

June 9, 1955. A new Division of Biologic Standards was established at the National Institutes of Health. The biologics control program heretofore was the responsibility of a laboratory of the National Microbiological Institute.

Increasingly complex problems in the biologics field, among them the virus vaccines, made establishment of the new organization necessary, Dr. Scheele stated.

June 10, 1955. A detailed technical report [parts of which are published in this issue—Ed. note] was presented by Surgeon General Scheele to Secretary Hobby and made public.

June 22, 1955. The following recommendations on vaccine distribution were made by the National Advisory Committee on Poliomyelitis Vaccine (under the chairmanship of Dr. Chester S. Keefer, special assistant to Secretary Hobby):

(1) When the available supply of vaccine warrants changes in the designated age group to whom immunization is limited, such adjustments will be made by extending the existing priority group so that it becomes increasingly broader; (2) For the time being, the 5 through 9 priority age group should be adhered to. As vaccine becomes available, the committee will broaden the age group to include equal additions below and above this group to the extent that production of the vaccine indicates; (3) Since success of the voluntary plan depends largely upon the development of effective intrastate

plans, States should take immediate action to develop and implement plans to assure equitable distribution within their respective populations; (4) In order to insure equitable distribution, plans for intrastate distribution of the vaccine should include a system for obtaining reports of shipments from the manufacturers and reports of sales from retail outlets; (5) A coordinated nationwide educational campaign should be developed to assist health departments and physicians in keeping the public informed about the poliomyelitis vaccine program.

July 8, 1955. The Public Health Service announced the release of 300,000 cc. of Wyeth vaccine, making a total of about 1,837,000 cc. made available since the revision of testing requirements on May 26. Since April 12, the total released was approximately 10,837,000 cc. The Division of Biologic Standards assigned 6 scientists to the plants of the 6 manufacturers to serve as technical aides on production and testing procedures, and in research development.

July 8, 1955. Surgeon General Scheele announced the formulation of a tentative program for developmental research aimed at discovering new knowledge immediately applicable to further improvement of production and testing of poliomyelitis vaccine. The program will consider other strains of poliomyelitis virus for inclusion in the vaccine, improved tests for potency, the improvement of monkey safety tests, the development of concentration methods for use both in safety testing and in routine production processes, and studies on standardization of tissue culture susceptibility to poliomyelitis virus. The research plans call for a positive, cooperative endeavor, in which university, industrial, and government laboratories combine to concentrate their research resources. This program is expected to gear in with programs supported by the National Foundation for Infantile Paralysis and other organizations sponsoring similar and related research.

Functional Distribution of Working Time in a State Health Department

By EDWARD M. COHART, M.D., and WILLIAM R. WILLARD, M.D.

TO SUPPLEMENT the data obtained in a time study in five county health departments in Maryland (1), the Yale Public Health Personnel Research Project conducted a similar study in the Maryland State Department of Health. The time study in the State health department, as in the county units, sought to measure the allocation of working time to each of 21 functional categories of activity, using a technique developed by the project (2). Time studies were considered an essential part of the Yale project, which attempted to learn what public health workers actually do on the job in the belief that such information is a necessary prerequisite to any recommendations concerning recruitment, training, or utilization of personnel.

Participating in the study in the State health department were 137 professional and semi-professional workers, 88 percent of those meeting the standards set by the project (3). They were classified according to service, which is

usually but not always synonymous with professional affiliation, as follows: medical service, 12; nursing service, 10; sanitation service, 29; laboratory service, 40; secretarial service, 24; and other services, 22. Time logs were kept for 2 days each month from September 1952 through January 1953, the days of the week and the weeks of the month being staggered so that the data would be representative of the 5-month period. Information as to place in the administrative hierarchy, educational background, and salary was obtained from each worker through interviews.

The Working Day

The average daily elapsed time on the job, on the basis of a 5-day week, was 8 hours and 22 minutes. Sixty-two minutes of this time were employed in personal activities, such as sick leave, meals, coffee hours, and rest periods, leaving an effective working day of 7 hours and 20 minutes.

The average working day for physicians, nurses, and sanitation workers was approximately 1 hour longer than that for statistics, secretarial, and laboratory personnel. There was an 80-minute spread in the length of the working day in accordance with administrative level of the workers: Program directors had the longest working day; supervisors and staff-level personnel, the shortest.

For all personnel included in the study, the working time was apportioned among four major groups of activity as follows: 30 percent

Dr. Cohart is associate professor of public health, Yale University School of Medicine. Dr. Willard, formerly associate professor of public health at Yale University, is now dean of the College of Medicine at Syracuse, State University of New York. Dr. Cohart and Dr. Willard were co-directors of the Yale Public Health Personnel Research Project, which was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

to technical activities (usually direct service activities requiring professional or technical training); 37 percent to ancillary activities (essential but usually routine, stereotyped activities for which training can be acquired on the job or in a short training course); 21 percent to administration (program planning, management, giving and receiving supervision and education or training); and 11 percent to community relations and organization (activities with other agencies, public information and education, and giving professional education). A detailed analysis of the time spent in these activities in relation to service affiliation, administrative level, level of education, amount of public

health training, and salary is presented below and in the accompanying tables.

Technical Activities

Sanitation personnel devoted more time than other workers to technical activities (table 1). More than 50 percent of the sanitation workers' time was spent in these activities, as compared with about 40 percent of the laboratory workers' time and less than 25 percent of the nurses' and physicians' time. Only 3 percent of the time of the secretarial personnel was spent in technical activities.

Staff-level personnel devoted almost twice as

Table 1. Percentage of working time devoted to each of 20 activity categories, by service, in the Maryland State Department of Health

Activity category	Service						
	Medi- cal	Nurs- ing	Sani- tation	Labora- tory	Secre- tarial	Other	All

much time as high-echelon personnel to technical activities (table 2).

Workers who had a bachelor's degree tended to devote somewhat more time to technical activities than those without a degree (table 3), but workers with either a graduate degree or undergraduate training in public health devoted less time to these activities than did those who had not had such training (table 4).

Salary was not directly associated with time spent in technical activities (table 5).

Ancillary Activities

Laboratory workers devoted appreciably more time to ancillary activities than did any other professional workers (table 1). They spent almost 50 percent of their time in these activities,

whereas the medical, nursing, and sanitation workers were similarly engaged only 13 to 16 percent of the time. Secretarial personnel spent 80 percent of their time in ancillary activities.

Almost 50 percent of the time of staff-level personnel and slightly more than 20 percent of the time of workers in the high administrative echelons was absorbed by ancillary activities (table 2). Among high-echelon personnel, supervisors appeared to be particularly burdened with these tasks.

About 60 percent of the time of workers without a college degree and 16 percent of the time of those with a college degree was spent in performing ancillary activities (table 3). An essentially similar relationship existed with respect to public health training (table 4).

Salary increased as participation in ancillary activities decreased (table 5).

Administration

The 21 percent of the time of all personnel spent in performing administrative duties was apportioned among the four major categories as follows: 4 percent to intramural program planning, another 4 percent to management, 8 percent to giving supervision and inservice training, and 5 percent to receiving supervision, education, and training. As previously reported (1), the personnel in the five county health departments in Maryland spent 17 percent of their time in administration, the difference stemming from less participation in management and giving supervision and training.

Medical personnel, who devoted 34 percent of their time to administration, greatly exceeded the average (table 1). However, nurses spent even more time than medical personnel in administration, since half of their time was devoted to such activities. This extensive participation by nurses in administration was mainly a reflection of the fact that they devoted 25 percent of their time to giving individual and group inservice training, a percentage which was 12 times as large as that for the laboratory personnel and which exceeded that for the medical and sanitation personnel to an even greater extent. The percentage of time devoted to administration by the sanitation personnel was slightly below the average, while the laboratory

and secretarial personnel spent about half the average percentage of time in these pursuits.

The most extensive participation in both program planning and management occurred in the

medical service, followed by the nursing, sanitation, and laboratory services, in that order. The percentage of time devoted to receiving supervision, education, and training was in excess of the average in the nursing, medical, and sanitation services and below the average for laboratory and secretarial workers.

High-echelon personnel devoted almost four times as much time to administration as did staff-level personnel (table 2). This ratio prevailed, in general, for the several categories of administration; it was highest for giving supervision and training and lowest for receiving supervision, education, and training.

Time devoted to administration was positively associated with level of education and with formal public health training. Workers with a bachelor's degree or a graduate degree devoted more than three times as much time as those without a college education to administration, with somewhat similar ratios prevailing for each of its major categories (table 3). Similarly, personnel with a graduate degree or undergraduate training in public health devoted 3 to 4 times as much time to administration as those without formal public health training (table 4). The somewhat higher percentage for personnel with undergraduate public health training than for those with a graduate degree in public health results from the fact that the former devoted a greater proportion of their time to giving supervision and inservice training. Graduates in public health, on the other hand, spent much more of their time in program planning and in personnel, financial, and general services management.

Workers in the highest salary bracket devoted more time than those in any other bracket to administration as a whole and to each of its major categories, with the exception of giving supervision and inservice training (table 5). In this category, personnel in the second highest salary bracket spent the most time.

Community Relations and Organization

Of the 11 percent of the time devoted to community relations and organization, 6 percent was spent in activities with other agencies; 4 percent, in public information and education; and 2 percent, in professional education.

10 percent to giving professional education. Nursing and sanitation personnel devoted about 13 percent of their time to community relations and organization, the nurses concentrating on activities with other agencies and the sanitation personnel, on public information and education. A relatively minute percentage of the time of laboratory personnel was devoted to community relations and organization. Secretarial personnel spent 7 percent of their time in these activities, more than half of it in public information.

High-echelon personnel spent four times as much time as staff-level workers in community relations and organization (table 2). The time spent by each of these two groups in public information and education was approximately the same, but the former spent considerably more time in activities with other agencies and in professional education.

Participation in community relations and organization increased with level of education and extent of public health training (table 3 and 4). The exception to this general finding was the relatively small percentage of time that workers with a bachelor's degree and those who had received undergraduate public health training devoted to public information and education.

Salary level was also positively associated with the extent of participation in community relations and organization (table 5). This held true for each of the major categories in this group, except public information and education. Workers in the second highest salary bracket were engaged in giving information to the public to a much greater extent than those in the other salary brackets.

Summary and Discussion

Summarizing the data obtained in the time study in the Maryland State Department of Health, it can be seen that roughly one-third of the working time was devoted to technical activities; one-third, to ancillary activities; and one-third, to administration and community activities. This distribution is essentially similar to that found in the five county health departments in Maryland, but there were minor differences, as might be expected.

State health department personnel devoted

somewhat less time to technical activities and somewhat more time to administration than did the county personnel. Since a local health department has primary responsibility for direct health services, it would logically devote relatively more time than a State health department to direct service, or technical, activities.

On the other hand, the State health department, probably because of its larger and more complex organizational structure, devoted more time than did the local units to management. It also devoted more time to the training of personnel, principally because of its training programs for local workers.

Another interesting difference was in the apportionment of time to public and professional education. The county units were involved in public education to a much greater extent than the State health department; the State health department, however, devoted three times as much time as the county health departments to professional education.

As a general pattern, it was found that the extent of participation in administration and community activities in the State health department was positively associated with position in the administrative hierarchy, level of education, and public health training, in much the same fashion as was found in the county health departments. In another part of the Yale study, it will be shown that only infrequently are per-

sonnel adequately prepared for these duties in their general college education or in their education in public health.

The various services differed considerably as to the amount of time that they devoted to many of the functional activities. Sometimes, as in the case of the laboratory service, differences appeared to be the natural outcome of the duties of the service. More often, however, differences did not appear to be related inherently to the fundamental character of the responsibilities.

The whole question of the relative importance of the several types of activity currently performed by health departments is a question that warrants serious consideration. The Yale study served merely to report existing practices, as a basis for further study.

Supply of Rhesus Monkeys

As result of negotiations, the United States Mission to India and the United States Embassy in India have secured the agreement of the Government of India to permit for the period ending June 30, 1956, the continued exportation of rhesus monkeys for medical research and production of antipoliomyelitis vaccine. All needs must be certified by the United States Government through the Public Health Service.

Experiments With Isoniazid As a Preventive Measure Against Tuberculosis

ISONIAZID, which has shown remarkable powers in the treatment of tuberculosis, shows promise of being equally potent as a preventive.

At the annual meeting of the National Tuberculosis Association in Milwaukee, May 23-27, 1955, Dr. Carroll E. Palmer and Shirley H. Ferebee, chief and assistant chief, respectively, of the Operational Research Branch, Tuberculosis Program, Division of Special Health Services, Public Health Service, presented their report, entitled "Experimental Studies on Prevention of Tuberculosis," in which they demonstrated the effectiveness of isoniazid as a preventive against tuberculosis in guinea pigs.

Methods and Results

The studies incorporated these basic principles: large numbers of animal subjects, controls, random allocation of animals to treatment groups, and unbiased observations. About 1,250 guinea pigs were first isolated for 3 weeks. The death rate during this period was about 1 percent per week. The 1,224 living pigs were distributed into 5 comparable experimental groups.

In the drinking water of the first 3 groups were placed concentrations of isoniazid in amounts of 0.25, 0.05 and 0.01 milligram per milliliter, respectively. There were two groups of untreated pigs, one held for challenge and

one reserved as normal, uninfected controls. By weighing each animal every week and by measuring the amount of water consumed each day, it was found that the pigs drank a fairly constant amount of water every day. The amount of isoniazid taken daily in the 3 drug groups approximated 25, 5, and 1 milligram per kilogram of body weight.

All groups except the "normals" were challenged intraperitoneally with virulent tubercle bacilli. The normal pigs received a placebo challenge. The controls—those that received no isoniazid—died rapidly after the challenge infection, and by the 10th week only 7 percent remained alive. Eighty-eight percent of the normals—those that had not been infected—were still alive in the 10th week. The pigs that received 1 mg./kg. of isoniazid received some protection since they did not die as rapidly as the controls. Thirty-seven percent were still alive by the 10th week. The challenged pigs that received either 5 or 25 mg./kg. of isoniazid did not have a greater death rate than the normal pigs.

For the first 10 weeks after challenge with tubercle bacilli the daily dose of 5 mg./kg. was enough to protect the pigs against an infection that was sufficiently virulent to kill nearly all of the controls.

At this point, the investigators considered the problem of the effect of withdrawal of isoniazid. They withdrew the drug, 10 weeks after infection, from pigs selected at random in each of the three treatment groups. The pigs that had received 1 mg./kg. of isoniazid continued to fare better than the controls. The animals that had received 5 or 25 mg./kg. survived as well as the normal animals over a period of 26 weeks.

At the 26th week, 75 percent of the pigs that received at least 5 mg./kg. for only 10 weeks, 74 percent of those that received 5 or 25 mg./kg. for the entire 26 weeks, and 71 percent of the unchallenged normal controls were still alive. This part of the experiment appears to indicate that as little as 5 mg./kg. of isoniazid per day for only 10 weeks is sufficient to knock out a

Prepared by the Tuberculosis Program, Division of Special Health Services, Public Health Service. The report mentioned will be available upon publication in the American Review of Tuberculosis.

virulent tuberculosis infection in guinea pigs.

Fourteen weeks after the date of the first challenge, randomly selected parts of each group of animals that had received 5 and 25 mg./kg. were rechallenged. Part of the original group of normals were challenged at the same time to obtain a new group of controls.

The new, untreated controls died rapidly, as expected. The animals that survived the first challenge while receiving isoniazid and had then been taken off the drug after the first 10 weeks, when rechallenged, did not die as rapidly as the controls even though they were not receiving the drug. This evidence suggests that a relatively small amount of isoniazid in the drinking water of guinea pigs not only protects them from getting tuberculosis but also allows them to develop a certain amount of resistance to a later untreated infection. This resistance is at least as great as has been produced in guinea pigs by vaccination with BCG.

The pigs that received 5 or 25 mg./kg. of isoniazid continuously during two challenge infections survived as well as the normals that had never been challenged.

Summary

A daily dose of isoniazid of not more than 5 mg./kg. of body weight, given in the drinking

water, is apparently sufficient to protect guinea pigs completely from a large intraperitoneal challenge of virulent tubercle bacilli. This dose given for only 10 weeks after a virulent challenge was sufficient to prevent the appearance of disease after the drug was discontinued. Resistance to a later virulent infection, at least equal to that produced by BCG vaccination, develops in guinea pigs during the course of an isoniazid-treated challenge.

Whether isoniazid will be effective as a preventive of human tuberculosis depends on the results of controlled trials in large population groups, which are now being planned. Continuing experiments with laboratory animals will provide additional information essential to trials among human beings. Isoniazid has been used extensively since 1952 in treating tuberculosis, and its effectiveness and harmlessness have been conclusively demonstrated. The drug can be produced easily in large quantities, and its cost is low. Persons who are reactors to tuberculin or persons who exhibit suspicious shadows on X-ray films might be the first to benefit from the preventive and curative properties of isoniazid. These findings may mean that whole populations could be treated for as little as a penny a day per person.

CDC Slide Series

A series of approximately 35 color slides with descriptive notes has been prepared by the Public Health Service Communicable Disease Center. These slides emphasize the importance of communicable disease in the United States today. They outline Federal and State organization for control and show several phases of the center's program activities, such as orientation lectures, training courses, and other public presentations. Latest statistics are interpreted in diagrammatic and flow charts. Actual photographs of program activities are included. The series is available on loan in either 2- by 2-inch or 3¼- by 4-inch size. Requests should be addressed to James A. King, Jr., Special Assistant for Operations, Communicable Disease Center, Public Health Service, Atlanta, Ga.

Appraisal of Tuberculosis Case Finding

—Des Moines and Polk County, Iowa—

By ABRAHAM GELPERIN, M.D., Dr.P.H., LEON J. GALINSKY, M.D., and ALBERT P. ISKRANT, M.A.

IN an area and time in which the discovery rate of active tuberculosis is low, it is important to study present methods of case finding and diagnosis for program guidance.

How such a diagnosis becomes attached to a particular patient was the subject of a study of the tuberculosis control program in Polk County, Iowa. Our primary interest was in the succession of events leading to the definitive diagnosis among the 83 persons found to have active tuberculosis during the 2 years 1952 and 1953. The survey was undertaken in order to discover also to what extent the major case-finding methods were responsible for the diagnosis, the failures of accepted methods, some reasons for those failures, what might improve the application of current methods, and finally, whether new approaches should be introduced?

Des Moines and Polk County, Iowa, with a population of some 235,000 persons, have had a tuberculosis incidence pattern comparable to that in the rest of the State of Iowa. One health official directs the Des Moines City and Polk County Health Departments. The county

hospital has a tuberculosis unit of 87 beds. The medical director of the tuberculosis unit is responsible for the care and management of the patients during both their hospital and outpatient care.

Organized community case finding for tuberculosis operates in three major areas:

1. Screening: By use of a mobile X-ray unit, concentrated on industrial groups; and by tuberculin testing of segments of the school child population. During the past 5 years, some 66,000 photofluorograms have been made by the mobile unit. Two-thirds of these covered industrial groups. Annual tuberculin testing of Des Moines public school children is carried out in kindergarten and in the 9th and 12th grades. Each county school has its entire population tested every 4 years. Positive reactors in these groups have usually amounted to less than 6 percent for any age group.

2. Contact investigation: Each patient reported to have active tuberculosis is visited at home by a public health nurse, who applies tuberculin tests to members of the family and to others considered to be close contacts of the patient. The nurse arranges for chest X-rays of these individuals. She also makes a home visit whenever a miniature film report indicates a shadow suggestive of tuberculosis and advises the patient on the subsequent steps to be taken—a visit to the family physician or to one of the diagnostic clinics.

3. Prolonged followup of all persons known

Dr. Gelperin is director of the Des Moines and the Polk County Health Departments, and Dr. Galinsky is director of the tuberculosis division of the Broadlawn Polk County Hospital, Des Moines, Iowa. Mr. Iskrant is chief statistician of the Division of Special Health Services, Public Health Service.

to have had active tuberculosis: This is a regular function of the hospital's tuberculosis unit; for those patients who do not have legal residence in the county, the Christmas Seal clinic provides the service.

Of the 83 individuals with a diagnosis of active tuberculosis, only 7 (8.4 percent) were in the minimal stage, whereas 33 (39.8 percent) had moderately advanced tuberculosis, and 39 (47 percent) were considered far advanced. Four persons (4.8 percent) had extrapulmonary tuberculosis. Although a low discovery rate was anticipated in a low incidence area, the detection of only 7 minimal cases was of real concern.

Each patient diagnosed as tuberculous was visited by a specially trained public health nurse who was familiar with the objectives of the study. The nurse discussed with the patient and others close to him, and with the family physician and members of the hospital staff, the events related to the illness. The health department attempted to locate and review all previous X-ray films. Information was obtained concerning contacts and the results of their examinations.

A form was constructed to include this information, together with identification data; the motivation of the patient to seek medical care; a description of symptoms leading to diagnosis; place and date of diagnosis, stage and activity of the disease, and date of hospitalization; record of previous treatment for tubercu-

losis, including place, date, and outcome of treatment; and if previously reported as tuberculosis, date of report, county, or whether outside Iowa. If previous X-rays had been taken, the results and their interpretation were also entered on the form. Page 2 of the form provided space for data on contacts: name, age, and relationship to patient; tests for tuberculosis, with date and result of each test; miniature X-rays and 14" x 17" X-rays; diagnosis, whether previously known as having tuberculosis; and whether this tuberculosis activity was discovered by the present investigation.

Reasons for Coming to Diagnosis

Most of the patients (52 of the 83) came to diagnosis because of symptoms. Thus, approximately 60 percent of all persons with active tuberculosis were diagnosed because of a sense of illness which prompted them to seek medical care either in the office of the family physicians or in a special clinic. Two of the group with minimal tuberculosis, 20 of the moderately advanced and 27 of the far-advanced groups, and 3 patients with extrapulmonary tuberculosis were so motivated. In 9 patients, the diagnosis was made as a result of an examination which included a routine chest X-ray. Four cases were discovered because the patients were examined as contacts. Routine screening of hospital admissions at the veterans facility in Des Moines resulted

in the discovery of 3 residents of Polk County with tuberculosis; and X-ray examination of hospital staffs and patients hospitalized for other disorders revealed another 3 cases. The mobile X-ray unit screening service supplied the first evidence of disease in 3 patients; 6 were found through followup of previously known tuberculosis patients, and in 3, post-mortem examination supplied the diagnosis (table 1).

In this group of patients, 52 were men, 31 women. Approximately equal numbers of men and women made up the moderately advanced classification; but in the groups with minimal and far-advanced tuberculosis, there were more men than women. The median ages in relation to stage of disease were: minimal, about 30 years; moderately advanced, about 45 years; far-advanced, about 55 years. Among those who sought medical attention because of symptoms, there were slightly more women than men in the group with moderately advanced tuberculosis, whereas in the group with far-advanced tuberculosis there were almost four times as many men as women.

For patients who came to diagnosis because of symptoms, the elapsed time between onset of symptoms and diagnosis varied considerably. However, there was no essential difference in this time interval between men and women;

about the same proportion were diagnosed within 3 months. Of the 83 patients in the study, the largest number (22) were diagnosed within 3 months from the date symptoms of tuberculosis were first noticed (table 2).

Nevertheless, the median time between onset of symptoms and diagnosis is over 6 months, with 19 persons having a delay of more than 1 year. Persons coming to diagnosis for reasons other than symptoms were usually diagnosed within 3 months. Two persons in whom the diagnosis was established at post mortem had a duration of symptoms of more than 1 year.

It is of some interest that, according to these figures, the interval from first evidence of the disease to establishment of the diagnosis increased with advancing stages of the disease. All of the minimal cases with definable duration reached diagnosis within 6 months, as did two-thirds of the moderately advanced cases and a little more than half of the far-advanced cases. It required more than a year from the estimated date of onset to develop the diagnosis in 5 of 33 moderately advanced cases and in 13 of 34 far-advanced.

Of the 20 cases of moderately advanced tuberculosis coming to diagnosis because of symptoms of tuberculosis, 10 had been observed for possible tuberculosis for more than 6 months. Of 7 persons with positive screening X-rays,

only 3 had been suspected originally: 4 miniature films were reinterpreted as indicating possible tuberculosis.

Of 27 cases of far-advanced tuberculosis coming to diagnosis because of symptoms of tuberculosis, 16 had been suspected by the patient for more than 6 months, including 4 cases which had been for more than 3 years. Five persons had had previous miniature films, of which 4 had been read positive and 1 misinterpreted.

Missed Opportunities for Diagnosis

At least 12 persons had previous suspicion of tuberculosis which could have led to diagnosis. We reviewed the records for all cases in which symptoms motivated the person to seek diagnosis to determine if we could identify additional opportunities for diagnosis which had been missed. The findings are presented in table 3.

For minimal tuberculosis, we found no evidence that the disease could have been suspected earlier, but for moderately advanced, far-ad-

Table 4. Results of contact investigation of cases of active tuberculosis diagnosed in Polk County, Iowa, 1952 and 1953

¹ For purposes of this table a contact is defined as a case that could be located and does not include "source" cases, that is, persons who previously had reported the case as a contact.

vanced, and extrapulmonary disease, missed opportunities could be considered in two-thirds of the cases. Following is a recast of our interpretation of "missed opportunities."

1. "Symptoms otherwise diagnosed" included cases reporting to physicians with symptoms that might have been associated with tuberculosis as well as with the respiratory tract disease that was under treatment. The patients were ultimately diagnosed as active tuberculosis primarily because of the persistence of symptoms.

2. "X-ray misread" included cases in which rereading showed abnormalities which were "suspicious" of tuberculosis and which should have led to further followup.

3. "X-ray positive—followup interrupted or not done" included cases in which the "suspect" did not return for scheduled examination or in which for some other reason followup observation lapsed.

4. "Contact—followup interrupted or not done" included cases in which repeated examinations were not made frequently enough or in which investigation was not instituted.

5. "Previous tuberculosis" including "positive tuberculin test"—followup interrupted or not done. We feel that adequate patient education and followup should have led to a diagnosis of reactivation of disease before symptoms motivated the patients to seek medical care. In none of these cases was an X-ray performed within 3 years of the date of suspicion of active disease.

6. "None." This group includes patients found as a result of sudden hemoptysis, or with a history of vague, "unimportant" symptoms.

Contact Investigation

We have previously noted that four of the active cases of tuberculosis are described as having come to diagnosis because of contact investigation (table 1). Table 4 presents the results of contact investigation of the 83 active cases of tuberculosis diagnosed during the period. The number of contacts named and examined approximated three per patient. Three previously unknown cases of active tuberculosis were found through the examination

of 237 contacts. Many of these contacts had not had the opportunity to have repeated examinations at the time this tabulation was prepared and further cases may be discovered in subsequent months. The relationships of the three active cases to the source cases were wife, husband, and mother.

Discussion

In this group of patients, an average time lapse of about 3 to 6 months occurred between the onset of symptoms and the establishment of a diagnosis of tuberculosis.

Such a delay may be attributable partly to the patient himself, who may be slow to recognize the vague symptoms of fatigue, cough, and loss of weight as manifestations of tuberculosis. In this sense, the delay may, indeed, be implicit in the disease itself.

Conversely, the long interval between onset of symptoms and diagnosis may be a medical responsibility. However, the diagnosis of active pulmonary tuberculosis is not a simple decision and may be equally troublesome for the family physician and for the medical specialist. This is true when tuberculosis is the only disease to be considered. How much more perplexing is the problem when the disease occurs in the course of other long-term illnesses. In this respect, also, the stage of the tuberculosis is the primary factor in the delay of diagnosis.

To remedy the delay in diagnosis, we must advocate repeated careful searching examination of the patient, with the possibility of tuberculosis constantly in mind. And for the patient, we urge earlier visits to the physician as soon as he is aware of ill health.

Because of our low tuberculosis rate, we must also emphasize case-finding measures which reach the groups with the highest prevalence of tuberculosis. Additional community control measures that may be applied are the X-ray screening of certain groups, such as transients, welfare department clients, old-age assistance beneficiaries, and persons interned in prisons and jails. The members of families and other close contacts of patients can be examined at regular intervals. As school populations are tuberculin tested, families and close associates of reactors may be similarly treated.

Perhaps the only major mechanism lacking for more complete case finding is the establishment of a "suspect registry." This registry would include all individuals who react to the tuberculin skin test, and all those who have suspicious, though stable, X-ray findings. Such a proposal is based upon the assumption that anyone who has had a tuberculous infection has within him the potentiality for subsequent active disease. With reporting centralized in a health department, these individuals could be followed at regular intervals by an official

agency. They could also be impressed with the importance of disclosing their status to the physicians whom they may consult for other reasons. Operation of this plan over a number of years would develop a vast group to be held under observation. The plan is feasible only in a population with a low incidence of infection. Many small communities and some entire States present such a situation today, and it is in these areas that tuberculosis case-finding techniques could be augmented by the addition of a tuberculosis suspect registry.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of **PUBLIC HEALTH REPORTS**, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

Not all our readers receive the journal on the delivery date. An official copy is trickled down to them through a series of other readers. Sometimes the trickle slows to a complete halt.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Health Departments And Seafood Conservation

By A. L. CHAPMAN, M.D.

FOR at least 50 years health departments have worked assiduously to provide sanitary water supplies. They have cooperated with the Food and Drug Administration to make foods safer to eat. As a result of these efforts waterborne epidemics rarely occur and food poisoning outbreaks usually are self-limited and localized.

Health departments have recognized the fact that the quantity and the availability of water is as important to the health of the Nation as the bacterial and chemical quality of water. The time would now seem propitious for health departments to evince the same degree of interest in the quantity and the availability of food.

Some interesting facts bear on this problem. Only about one-third of the world's estimated population of 2,200,000,000 people are well fed. The rest are either starving or they are living on substandard diets.

One of the principal reasons for this wholesale and worldwide dietary inadequacy is the fact that only a small portion of the earth's surface can be cultivated. Four-fifths of the earth's surface is covered with water. The other one-fifth is above the sea. Less than 12 percent of this land area of 36,800,000,000 acres is capable of producing food. A large part of the 88 percent of land not under cultivation is barren and few of these billions of barren acres ever can be made economically productive.

The Untapped Foodbasket

For many centuries the fertile elements of the soil have washed relentlessly down to the

Dr. Chapman is regional medical director of the Public Health Service, Department of Health, Education, and Welfare, Region II, New York City.

sea. Uncontrolled erosion caused a loss of top soil in which was mingled important nutritive elements. But the land's loss has been the ocean's gain. Even as the land became poorer, the oceans became richer. Nitrogenous substances and nutritionally valuable minerals leached from the soil became the fertilizer of the sea and supported luxuriant marine vegetation, generally food for the animal life of the sea.

Plankton pervade the ocean waters. They are to the sea what wheat and corn are to the land. They constitute the nutritional base of marine animal life. The waters of the earth contain billions of tons of planktonic materials that never have been harvested nor have they ever been used on any large scale to serve man's purpose.

By increasing the production and stimulating a higher consumption of fish and shellfish, at least indirectly we can tap that prolific foodbasket, which is the sea. The people of the United States are among the lowest per capita fish consumers in the world. This characteristic is not irreversible. Probably one of the best ways to reverse it would be to modernize shellfish production methods, more particularly the methods of oyster production.

Oyster Production

In one eastern seaboard State where a laissez faire attitude toward oyster production long existed, the annual oyster production dropped from 15 million bushels in 1883 to its present level of slightly more than 2 million bushels.

This drop in production in the oyster catch in one State represents a protein loss equivalent to 130,000 Hereford cattle. If this State had instituted a leasing policy in 1900, it is estimated that the current annual oyster yield, instead of being in the neighborhood of 2 million bushels, would approximate 20 million bushels. In several adjoining States the drop in oyster production, since the latter part of the 19th century, has shown a similar steady downward trend.

The reasons for this continuing decline in oyster production are known to marine biolo-

gists and to enlightened oystermen. Unfortunately, the nutritional importance of oysters and other shellfish has not been publicized sufficiently nor well enough to motivate health agencies to give sturdy support to the handful of scientists and conservationists who unsuccessfully have been trying to reverse the downward trend in shellfish production for many years. Oyster production in the North Atlantic States has dropped to negligible proportions for many reasons. Among the more important reasons are uncontrolled harvesting, failure to adopt scientific methods of oyster culturing, and increasing amounts of water pollution.

The oyster is a nutritious article of diet. It compares favorably with milk, poultry, eggs, and meat in its content of essential amino acids. Oysters, like milk, contain an abundance of calcium. They are iodine rich. They are excellent sources of thiamin and riboflavin. Local health officers in coastline counties often comment on the fact that no pellagra or beriberi is found among the members of families who have a pile of oyster shells in front of their shacks. Some nutritionists rank oysters and clams in the category of milk as an exceptionally well-balanced food. And oysters are very

must be remembered, too, that steers must be fed and watered if they are to grow and fatten; oysters feed and water themselves.

An oysterman who cultivates an oyster farm in accordance with sound principles of farm management can make more money than a dirt farmer. The cultivation of a good acre of oysters can be 10 times as profitable as the cultivation of an acre of potatoes and 17 times as profitable as the cultivation of an acre of wheat.

"Aquaculture"

In recent years, many dirt farmers, some 250,000 of them, have sensed the importance of fish and have constructed farm ponds in which fish are grown for food as well as for sport. The average yield of such ponds is about 200 pounds of fish per acre each year and well fertilized ponds can double that yield.

Congress recently recognized the importance of these ponds by providing special income tax exemptions for farmers who build them. It has been estimated that as many as 1,500,000 more ponds of this type could be wisely utilized.

In one of the coastal counties of a southern State, the maritime equivalent of a 4-H club

d fish culture in Java, Indonesia. The Javanese started raising fish for food about 1,200 or 1,400 years ago. United Nations photograph from "The Story of FAO."

istence except in the memories of a few old-timers.

Enough scientific research has been done to permit the rehabilitation of these barren oyster beds if oystermen would take the advice of conservationists. Recent developments in the

science of "aquaculture" makes it possible to culture oysters in such a way that "seed" suppliers do not have to depend upon the hit-or-miss methods of the past.

By the scientific analysis of such growing factors as salinity, turbidity, currents, and tem-

perature, the areas best suited to growing seed oysters can be selected. The seed oysters can then be planted in other selected areas where they will grow more rapidly to maturity. By skillfully dividing oyster farming into two distinct stages, the growing of seed oysters in some areas and the maturing of them in other areas, oyster farmers no longer need depend entirely upon chance to obtain good yields.

Important recent experiments at several biological laboratories along the eastern seacoast have demonstrated that seed oysters, which grow prolifically in warm southern coastal waters, can be transplanted successfully to cooler waters further north. There they can grow normally to toothsome maturity freed from the marine jungle competition into which they are born.

Health Department Interest

With many pressing public health problems on their way to solution, with human life expectancy approaching the 70-year mark, and with the world population steadily increasing, it is time to think much more seriously about the need to increase the world's and the Nation's

supply of food. The functions of health agencies are changing rapidly as the character of the health problems they face continue to change. In addition, then, to supervising the sanitary quality of water and food, would health departments be remiss if they became more actively interested in efforts that are being made to conserve and to expand the Nation's food supplies?

Can increased health educational efforts help popularize the wider use of fish and shellfish produced under sanitary conditions as dietary staples and thereby increase the demand for these products?

Can health departments help to increase the production of shellfish by encouraging marine conservationists to introduce more modern and more scientific methods of oyster culture?

Inevitably, the world's current population growth will generate the pressures needed to bring about an increase in our supplies of food.

Would it not be more in keeping with the leadership role of health departments to anticipate these pressures and attempt to moderate and perhaps guide them by participating actively in the rapidly developing though often lagging food conservation program?

PHS Staff Announcements

Assistant Surgeon General William H. Sebrell, Jr., director of the National Institutes of Health since 1950, retired on August 1, 1955, after 30 years of active duty as a commissioned officer of the Public Health Service. He has accepted appointment as research consultant for the American Cancer Society and will direct the society's research grants program.

Dr. Sebrell has earned worldwide recognition as a medical scientist, particularly through his studies on the B vitamins. In the 1920's, he was a member of the Public Health Service team that established the dietary origin, prevention, and treatment of pellagra. He discovered the causes and cure of ariboflavinosis and has made important contributions to research in the dietary causes and treatment of liver diseases, the effect of pantothenic acid deficiency on the adrenal glands, nutritional effects of sulfa drugs, and the cause and treatment of blood abnormalities.

Dr. James A. Shannon, formerly associate director of NIH, has succeeded Dr. Sebrell. Dr. Shannon is also chairman of the Public Health Service's Technical Committee on Poliomyelitis Vaccine. A commissioned officer of the Service since 1949, he was associate director in charge of research at the National Heart Institute prior to his becoming associate director of the Institutes in 1952. Dr. Shannon was awarded the Medal of Merit for his work in World War II malaria control programs.

Dr. Shannon received his medical degree from New York University in 1929. He also received a doctorate in philosophy from the same university in 1935. After teaching at the university, he became director of research at Goldwater Memorial Hospital in 1942. From 1946 to 1949 he was director of the Squibb Institute for Medical Research.

A Positive Control For Coccidioidin Complement Fixation

By FREDERICK W. BIEBERDORF, Ph.D.,
and KEITH WAYNE CHAMBLISS, Ph.D.

The use of complement fixation tests for diagnosis of coccidioidomycosis by laboratories in "fringe" and "nonendemic" areas is limited by lack of human antiserum for positive control of the coccidioidin. Lyophilized rabbit antiserum is suggested for this purpose.

...

THE VALUE of the complement fixation test in suspected and proved cases of coccidioidomycosis has been adequately discussed by Smith and co-workers (1, 2). Conant and associates (3) have also pointed out the value of complement fixation tests as an indication of the status of a coccidioidal infection. Schubert and associates (4) reported the results of their investigation with histoplasmin.

The continuous research on the use of complement fixation in the diagnosis of mycotic diseases emphasizes the value of this test as a diagnostic aid. As this value is recognized, the clinical laboratories will receive more requests for complement fixation tests. The serologist may properly interpret the results of any complement fixation test only if a positive control serum is used in each test.

In the endemic areas for *Coccidioides immitis* outlined by Smith (5), the clinical laboratories probably have little difficulty in obtaining an

adequate supply of positive human serum. However, the clinical laboratories located elsewhere encounter considerable difficulty in obtaining or maintaining a supply of this control serum. These laboratories may receive only two or three requests for this complement fixation test each year. At present there appears to be no commercial source of a control serum for laboratories outside the endemic areas.

With this problem in view, a preliminary investigation was made to determine whether rabbit antiserum could be used to replace human antiserum as a source of positive control serum.

Materials and Methods

Six young female white rabbits weighing from 5 to 7 pounds each were selected. Each of the rabbits was injected intraperitoneally with live spore mixtures of four strains of *Coccidioides immitis*. Ten days after this injection, 5 ml. of blood was removed from the ear of each rabbit, and the serum was tested for antibodies. Three of the rabbits showed high titer; all showed some titer.

As the rabbits were beginning to weaken from the intensity of the infection, they were bled approximately 50 ml. each by heart puncture on the 14th day after injection. The blood was permitted to clot, was centrifuged, and the serum separated. The serum of each rabbit was placed in a 50-ml. test tube and frozen until it could be tested. After each serum was again titered, the serums having similar titers were pooled and designated as serum pools 1 and 2. These two lots were dispensed in 10-ml. test tubes and refrozen until needed.

Autopsy of the rabbits revealed cysts, which were found to contain *C. immitis* endospores, in the peritoneal cavity.

Portions of the thawed serum pools 1 and 2 were dispensed into 2-ml. vials. The contents of the vials were frozen in a mixture of dry ice and isopropyl alcohol, desiccated, and sealed in vacuo. The vials of lyophilized serum were kept on the shelf at room temperature. When they were to be used, the serum solids

Dr. Bieberdorf, a mycologist, is research associate at the Southwest Foundation for Research and Education, Southwest Research Institute, San Antonio, Tex., and Dr. Chambliss is stationed at the Lackland Air Force Base at San Antonio.

of each vial were dissolved in 2 ml. (the original serum volume) of distilled water. The reconstituted rabbit serum was heated for 30 minutes in a 60° C. water bath just before use. The heated bath was used as described by Dr. John F. Kent, department of serology, Army Medical Service Graduate School, in a private communication. He has found that the bath is necessary to destroy the nonspecific anticomplementary activity in rabbit serum. Serial dilutions of the reconstituted serum were then prepared for the titrations.

Human serum from a case of disseminated coccidioidomycosis with a high titer (reported as 1:512 by the department of mycology) was used for comparative purposes. Portions of this serum were lyophilized along with the rabbit serum and sealed in vacuo. These serum solids were dissolved in distilled water, and this reconstituted serum was heated for 30 minutes in a 56° C. water bath just before use.

Serums from normal rabbits and normal human beings were used in the investigation as negative controls.

A coccidioidin antigen for use in these complement fixation tests was supplied by Dr. Charles E. Smith of the School of Public Health, University of California.

Crude antigen preparations were also made in the laboratories of Southwest Foundation for Research and Education from cultures of the same four strains of *C. immitis* used for injection of the animals in antibody production. These four strains had been isolated from active cases of coccidioidomycosis. They were grown on the asparagine synthetic medium used by Smith and associates (1) and by Schubert and co-workers (4) in their investigations. The cultures were incubated for 6 weeks at room temperature in Roux culture bottles.

The complement fixation procedures were adapted from procedures of Kent (6). Titrations of all reagents used in these procedures were carried out according to the procedures outlined in the Army Technical Manual (7). The complement solution used in these tests was twice as concentrated as designated in the manual, but only half the recommended volume was used. Thus the same number of units of complement were used; only the volume was changed.

In the complement fixation tests the materials were added to 10 by 75-mm. test tubes and mixed thoroughly after each addition. They were added in the following order:

1. 0.25-ml. antigen dilution.
2. 0.25-ml. serum dilution.
3. 0.25-ml. complement solution (containing 2 full units).
4. All tubes incubated at 4°–7° C. for 16 to 18 hours.
5. 0.50-ml. antishoop hemolysin (containing 2 units).
6. 0.50-ml. 2-percent sheep cell suspension.
7. All test tubes incubated for 30 minutes in 37° C. water bath.
8. All tubes were compared visually with synthetic standards freshly prepared in 10-percent hemolysis steps; hemolysis was estimated and recorded to the nearest 5 percent.

The titer of a serum was recorded as the highest dilution which would permit less than 70-percent hemolysis to be exhibited in this complement fixation test. A control tube containing all components except antigen was run with each serum dilution, and a control tube containing no serum dilution was run with each antigen dilution.

Results

Preliminary titrations were performed to determine the optimum dilution for each antigen. Serial dilutions of the antigen, varying by a factor of 5, for example, 1:1, 1:5, 1:25, and 1:125, were prepared, and each of these dilutions was used for the titration of the antiserum.

The data obtained in the "crosshatch" titration of rabbit antiserum pool No. 1 with the coccidioidin furnished by Dr. Smith is shown in table 1.

The experiment showed a serum titer of 1:64 when a 1:25 dilution of this coccidioidin was used. This 1:25 dilution of Dr. Smith's antigen was used later in the titrations of rabbit antiserum. The crude antigens prepared in this laboratory also showed maximum activity at a 1:25 dilution with rabbit serum pool No. 1 if the antigens showed any activity. In contrast to these results, Dr. Smith's coccidioidin showed a maximum activity at a 1:5 dilution when used for the titration of a positive human serum in a "crosshatch" procedure identical to that outlined in table 1.

Identical titrations were performed on samples of rabbit antiserum pools Nos. 1 and 2

Table 1. "Crosshatch" titration of Smith coccidioidin and rabbit serum pool No. 1, tabulated in percent hemolysis

Antigen dilution	Serum dilution				Saline control
	1:8	1:16	1:32	1:64	
1:1	5	15	ac	—	—
1:5	0	0	25	—	—
1:25	0	0	5	50	—
1:125	5	15	20	95	—
Saline	—	—	—	—	—

NOTE: Dash (—)=100 percent hemolysis; ac=almost complete hemolysis (greater than 95 but less than 100 percent).

which had been stored in the frozen state, and samples which had been lyophilized. The results of these titrations are shown in table 2, along with results obtained when a lyophilized

sample of pool No. 1 was titrated 6 months later. Table 3 shows the results of a similar titration of the one human antiserum available. The drop in titer from 1:256 to 1:16 on lyophilization could not be confirmed by repeating the experiment because no more of the human antiserum was available.

Discussion

There appears to be little difficulty in producing antiserum to *C. immitis* in rabbits. Although some rabbits develop a higher titer than others, standard immunological techniques can be used to follow the progress of the immunity reaction, enabling the worker to choose the animals showing the highest titers as a source of antiserum. As has been observed in other antiserum production, lyophilization destroys little if any of the antibody content. The lyophilized

products appear to be stable indefinitely at room temperature, which would permit shipment to, and storage by, small laboratories until needed.

The sharp drop in titer in the one human antiserum after lyophilization is not what would be expected. No conclusions should be drawn until additional human antisera are available for testing.

Further investigations must be carried out before a lyophilized rabbit anticoccidioidin is placed on the market as a standard reagent. The most important question to be answered is the one concerning the specificity of the antibodies produced by rabbits and humans. It is possible that the rabbit antibodies titrated in the above experiments were specific for one kind of molecules in the coccidioidin, the carbohydrates, for example, while the human antibodies were specific for an entirely different kind of molecules, possibly proteins, but not carbohydrates. Admittedly this example is an oversimplification. Nevertheless, some indirect evidence makes the possibility worthy of investigation. Martin (8) has shown that an alcohol-precipitated carbohydrate-like substance from *Blastomyces dermatitidis* antigens fixed guinea pig complement with rabbit antiserum but not with human antiserum although the protein portion of the *B. dermatitidis* cells did fix complement with the same human antiserum. Hassid and co-workers (9) have also shown that carbohydrate materials from coccidioidin failed to fix complement with human antiserum. The same human antiserum did fix complement with the original coccidioidin.

Of primary importance would be the comparison of the complement-fixing abilities of various purified fractions of coccidioidin with rabbit antiserum and with human antiserum. Additional investigations need to be accomplished; this is contemplated as soon as funds are available for this purpose. With such additional data, it appears possible lyophilized rabbit serum may become available to laboratories commercially.

Summary

Young female rabbits weighing 5 to 7 pounds were injected intraperitoneally with live spore

mixtures of *Coccidioides immitis*. Fourteen days following the injection the rabbits had developed a high titer of antiserum specific for *C. immitis*. This antiserum, when lyophilized and sealed in vacuo, was shown to be stable indefinitely at room temperature.

It is suggested that, after further investigation, such an antiserum preparation might be used as a positive control serum of known titer by laboratories which have no available source of supply of fresh positive human antiserum for *C. immitis*.

Problems which remain to be investigated are discussed.

1955 National Health Forum

AIR POLLUTION, mental health, chronic diseases, radiation, home accidents, and personnel shortages emerged at the 1955 National Health Forum, New York, March 23-25, as targets for the immediate future.

From the opening address by Ellsworth Bunker, president, American National Red Cross, to the 35th annual meeting of the National Health Council, the audience faced a series of challenges to the public health profession. Focusing on one of the challenges, Dr. Daniel Bergsma, State health commissioner for New Jersey, noted that although his State has been alert to the need for developing public protection against radiation, the swift pace of nuclear events finds current programs behind impending needs.

Mr. Bunker pointed out that, as the focus of health and welfare programs has shifted from relief of the sick and underprivileged to the improvement of the community as a whole, the need has grown to pool resources in comprehensive programs. He urged that volunteers support recruitment and training of health personnel; that they support education for improvement of mental health; that they cooperate in reducing the burden of handicapped or delinquent children; that they share in the immediate establishment of health plans for coping with national disasters; and that they encourage their neighbors to establish State and local health councils. Through such working partnerships, he said, "We can set an example of what can be done by free men to improve the welfare of the human race. This spontaneous association of men of good will can create a bridge of understanding among the nations which would overpass political antagonisms."

The probable changes in the economy, as a

basis for planning future health programs, were described by Dr. Dexter Merriam Keezer, vice president of the McGraw-Hill Publishing Co., with the specific provision that he assumed that his neat trend lines would not be disheveled by nuclear weapons. He also entered a reservation posed at an earlier date by Aristotle: "It is part of probability that the improbable happens."

By 1965, he forecast an American population of 190 million, an increase of 26 million above the present level, a number nearly twice the present population of Canada.

He pointed out that the population is not merely aging: It is growing more at the ends than in the middle. He forecast by 1965 an increase of 25 percent in the age group above 65. They would then be 9 percent of the total, as against 4 percent in 1900. The increase for children under 15 was forecast at 17 percent, as against 13 percent in the working-age group. But he predicted that rising productivity would permit the working-age population to carry the increasing burden of children and retired elders without strain. He also predicted a slight further gain in the minute excess of females over males. For this reason, he also forecast an increase in the number of women working in industry, with possible ill effects on female life expectancy.

He said the trend to move from farms, to urban or suburban areas would continue, with further aggravation of the problem of developing community health facilities in fringe areas.

Automation of many clerical jobs, he felt, would pose special mental problems for white-collar workers who place high value on the "continuity and stability of what they do." As a sample of things to come, he cited a data processing machine which with 10 man-hours does

Growth of population age groups and age groups as a percentage of the total population

This chart is based on the chart included in "Some Economic Factors in Forecasting the Nation's Health," the paper presented by Dr. Dexter Merriam Keezer at the National Health Forum, March 23, 1955.

work which formerly required 1,800 man-hours. The maintenance man for this machine requires a degree in physics.

On the whole, he foresaw great material gains in earnings and possessions, equivalent to an additional \$400 per person per year in present purchasing power. Moreover, he felt that these material gains would be shared broadly by most of the population.

Dr. Otis Anderson, chief of the Bureau of State Services, Public Health Service, questioned whether, without a marked change in public policy, there would be enough health personnel and facilities to permit the economy to expand as Dr. Keezer predicted. Without adequate health services, he suggested that productivity would suffer, and the incapacity of the older members of the family population would indeed be a burden on those of working age. He advocated as a measure to offset the rise in chronic diseases a medical form of DDT: Detection, Diagnosis, and Treatment. Facilities for care and treatment of older people, he emphasized, did not necessarily imply complete nursing care or elaborate hospital facil-

ities. A private home, properly designed and located, or household help would in many instances suffice. As to patterns of population movement, he asserted that tax structures, as broadly based as those of the typical health department, would be necessary to meet the rising demands for rural and suburban health services.

In view of the trend toward a broader distribution of income, Dr. Anderson cited figures demonstrating how protection against hospital, surgical, and medical expense has been extended to millions in the population. Most of this extension, he said, has come about since 1945, largely through collective bargaining between labor unions and management.

Dr. William A. Sawyer, consultant to the International Association of Machinists, emphasized that demands for health services are growing more rapidly than population. This is not a simple need for medical care, he said, but a need for better public health methods, a better distribution of health centers, and effective staff. The crucial question, he said, is not what economic trends will do to health

services but what health conditions will do to the economy. To emphasize this point, he reported that in West Virginia, 376 families on relief were rehabilitated at less than the \$225,000 spent annually on their maintenance, with the result that they now earn more than \$500,000 a year.

The rise in population, suggested Dr. James Perkins, managing director of the National Tuberculosis Association, might produce crowded housing conditions which would reverse the declining trend of tuberculosis. He expressed concern also with the prospect of population movements and growth in areas, certain western States and migrant labor camps,

which do not now provide adequate health services. The increased leisure predicted by Dr. Keezer would not, he said, necessarily improve mental health if we lack plans for utilizing such leisure. He stressed the point that spiritual leaders of all cultures have held that healthy minds and emotions are far more to be desired than material possessions.

At luncheon, delegates heard leaders in the field of communications discuss fundamentals of using magazines, newspapers, and broadcasting for effective health education and information.

Regulation of fluorides in public water supplies is a responsibility of the entire community, not that alone of the dentists, physicians, or,

Gains and losses to the medical profession

Chart prepared by the Division of Public Health Methods, Public Health Service.

If present trends continue, the net gain to the medical profession is expected to be about 3,500 in 1960. Deaths among physicians will probably rise to 4,100 in that year. Licentiate representing additions to the profession will be about 7,600. Of these, 7,100 will be graduates of approved medical schools in the United States.

the health workers, and the chief function of the health profession is to make facts available, according to a panel which included two members of the American Dental Association, Dr. J. Roy Doty, secretary of the Council on Dental Therapeutics, and Herbert B. Bain, director of the association's Bureau of Public Information. Also participating was Al Schottelkotte, reporter-columnist for the *Cincinnati Enquirer*, whose home city of Cincinnati rejected fluoridation by a referendum in 1953.

Dr. Bergsma's paper and excerpts from other addresses at the conference follow below.

In other action at the National Health Council meeting, Dr. Hugh R. Leavell, dean of the Harvard University School of Public Health, was installed as president, and Dr. Leona Baumgartner, health commissioner of New York City, was chosen president-elect.

The forum also heard a discussion of prospects for care of the long-term patient, analysis of the recommendations of the Hoover Commission on Organization of the Executive Branch of the Government, and comments on the recruitment of career workers in public health.

Radiological Health Services in New Jersey

The increasing use of more potent radiation sources, including radioactive isotopes, in this Nation and in the State of New Jersey, has already presented problems to those charged with responsibility for the preventive and constructive phases of public health administration.

Daniel Bergsma, M.D., M.P.H., commissioner, New Jersey State Department of Health, presented this paper at the 1955 National Health Forum of the National Health Council in New York City on March 23, 1955. Other papers from the forum follow in brief form.

Under the caption of "radiological health," there has developed a series of activities, unique in concept, with which official health agencies have begun to concern themselves.

Beginning in 1946, the Atomic Energy Commission permitted the distribution of an entirely new family of reactor-produced radioactive materials to authorized users for any purpose deemed by the Commission to be in the public interest. Contingent upon the sale of radioisotopes has been a series of requirements for radiological protection designed to safeguard individual and public health. We have tended to accept without comment this approach by the Atomic Energy Commission to the distribution of potentially hazardous materials. However, be assured that this is a remarkably modern concept and practice. This was possible because the Atomic Energy Commission was a governmental agency and was authorized by law so to do.

Major manufacturers of dangerous and toxic materials may label their products and indicate precautionary measures to be taken in handling the hazardous substances, but they could not take steps to reassure themselves that the precautions were being carried out.

If the control features used by the Atomic Energy Commission had been applied from the outset of the use of radiation, dating back almost 60 years, there would not now be the same uneasiness which exists in the minds of thinking individuals with respect to effects of radiation on public health.

The Atomic Energy Act of 1954, for the first time, opened the door for the development of the competitive use of private atomic energy within the United States. We can anticipate, I believe, that in a relatively short period, many of us will find in our respective jurisdictions, new users of nuclear energy.

The presence of nuclear power as a competitive process in the national scene has been stifled, in a sense, by the extreme caution necessary to provide adequate radiological health safeguards. This problem is very real. If we are to encourage the optimal growth of this awe-inspiring source of energy and simultaneously fulfill to the utmost our primary responsibilities as overseers of the environ-

mental well-being of the Nation, we must be capable of presenting a sympathetic but firm understanding of the problems generated by this expanding activity.

Many of us had our first introduction to atomic power by way of civil defense activities. The terms "radiation monitoring," "fission products," "radiocontamination," and so forth, have become increasingly familiar to us. The single exposure, lethal dose of 450 roentgens of whole body radiation became axiomatic. It took considerable reorientation in our radiological training to meet the first peaceful uses of atomic energy: radioiodine-131 and radiophosphorus-32 in clinical medicine, cobalt-60 in industrial radiography and cancer therapy, and strontium-90 in beta-thickness gauges. We have had to develop different concepts of instrumentation and shielding designed for a maximum permissible exposure level of 300 milliroentgens per week for industrial workers.

I certainly cannot advise on how to acquire these capabilities rapidly and yet in a practical manner. However, I can describe what has been done in the New Jersey State Department of Health to develop authority and competence.

It has been demonstrated that public health engineers, industrial hygienists, and public health physicians and nurses, already well versed in the intricacies of developing sound occupational health programs, are able to adapt themselves to this new science. There should be no hesitation in the future in asking that each such staff member prepare himself to understand and apply radiological health principles. The public health administration of these principles is no different from that of any other official health responsibility.

The New Jersey Program

Our experience in New Jersey suggests that certain factors are essential to the development and success of a radiological health program:

First is training for field and office personnel.

Second is supportive legislation in order to define the scope of authority to recommend radiological health controls wherever necessary. This legal base was brought about in New Jersey by the Public Health Council of the State of New Jersey exercising its existing power

with the adoption, effective December 15, 1952, of chapter VI, on radiation, as part of the State sanitary code.

This chapter is as follows:

"Regulation 1—Application of chapter.

"(A) X-ray machines and all other sources of radiation shall be shielded, transported, handled, used, and kept in such manner as to prevent all users thereof and all persons within effective range thereof from being exposed to excessive dosage of radiation. Owners or users of sources of radiation shall not expose themselves or permit others within effective range to be exposed contrary to regulations which may be promulgated by the State Department of Health relative to sources of radiation.

"(B) Every incident of exposure to radiation in violation of the aforementioned regulations or of this Chapter shall be considered a separate offense."

The simplicity and brevity of this chapter and its wide latitude for interpretation and enforcement make it a powerful instrument for radiological health control. Easily adopted departmental regulations that are amended readily, relating only to those sources of radiological health hazard demanding immediate attention, may be promulgated while the broader powers of the department in the entire field of radiological health remain unaffected.

To date the only departmental regulations which have been issued are those relating to fluoroscopic shoe-fitting machines.

Third is the preparation of a concise declaration outlining proposed activities in the field of radiological health. This is stated in New Jersey's radiological health program, formally approved on May 19, 1954. The findings of our earliest exploratory field activities were utilized to develop a realistic program.

Fourth is the ability to impart authoritative radiological health information and specialized advice to all interested parties.

Facing Up to the Problems

Now we must be prepared to operate in the realm of tomorrow and face the problems associated with nuclear power reactors, the most concentrated energy source thus far devised for peaceful purposes and, at the same time, poten-

has been a slowly evolving understanding of what we like to think are the fundamentals of radioactivity.

It was soon recognized that the radiations of radium were capable of killing living cells and that slowly developing degenerative changes of tissues exposed to these radiations could occur. The radiations of radium were applied to medical purposes and to a certain extent utilized in industry. The extraction of radium from its parent ore, pitchblende, was a laborious and costly process. The production was quoted in terms of milligrams, and a gram of radium with a radiation value which we now call a curie, cost about \$70,000. Over the years the stock of separated radium supply grew until finally about 1 kilogram had been separated.

Small as this total stock seems to be, the studies made of radium and other naturally radioactive elements led to the very fundamental knowledge on which our modern concepts of radiation protection are based. Furthermore there developed the technique of supplementing X-ray therapy with local implantations of radium and radon which have been of so much value in the treatment of many forms of cancer.

Significant as were these developments, the rate of progress was greatly increased by the development of accelerators of energy sufficient to induce nuclear reactions. The production of radioactive isotopes unknown in nature became possible for the first time, and these in turn were the keys that opened the doors to new knowledge in biochemistry and physiology. The fundamental studies of the physicists in turn led to the further great wartime accomplishments of the Manhattan Engineer District and the development of our present atomic energy program.

We now have in our hands modalities of research which only a few years ago were merely the ephemeral substance of dreams. Already there has occurred a tremendous revolution not only in the technology of biological and medical research but indeed in the concepts of the nature of material substance and the character of life itself. From that which already has transpired and has come into the field of human experience and knowledge, one may make certain predictions with reasonable confidence in

their reliability. We must never forget, however, that we merely stand on the threshold of a new era of knowledge. Phenomena and concepts, of which today we do not even speculate, surely lie in the future. With these qualifications and reservations arising from the sense of our intellectual limitations, I wish to discuss a number of specific topics.

Medicine

We are in the early period of great advances in biochemistry. These will surely have profound impact not only upon our knowledge of disease but also upon the methods of diagnosis. Reactions which may be brought about in the various physical states make it possible to introduce radioactive atoms as tracers into the most complex and delicate molecules. One can visualize that the diagnostic approach of the physician of the next 25 to 50 years will revolve around the quantitative measurement of the behavior of specific enzyme systems. The laborious and crude chemical techniques of today will be replaced by precise and rapid procedures of far more discriminating character through the introduction of radioactive atoms into highly specialized compounds of physiological importance. In our future medical schools, the teaching will of necessity emphasize the dynamic characteristics of intracellular reactions which can be observed in the living state without injury to the individual.

We may anticipate that within the next 50 years epidemics from infectious agents will have ceased to be a major threat to life and health. With the possibilities that are at present foreseeable we may anticipate that the scourges of parasitism of both animals and man that retard the development of tropical peoples will have been overcome.

This changing prospect with respect to infectious disease means that we must concentrate more and more attention on the understanding of the mechanisms of physiological deterioration with age and the specific diseases of the later decades. We may anticipate that through the combined efforts of the chemist and the radiologist we will be able to release powerful radiations within pathological cells to achieve either a cure or satisfactory sup-

pression of cells which have undergone neoplastic change.

While we may anticipate great improvement in the processing of atomic fuels, the same principles extend directly into such areas as the production of synthetic foodstuffs and the utilization of solar energy through the process of photosynthesis. Inherent are the prospects of new and greatly improved drugs for medical purposes and the production of compounds necessary to nutrition.

Public Health

It seems obvious that we are already in the midst of a profound change in the character of our public health problems. While the established concepts of epidemiology still hold, we see progressively greater preoccupation with substances which, in contrast to the living infectious agents, are not capable of multiplication but are capable of spontaneous transformation or transmutation. In the instant of release of radioactivity, the atom changes from one element to another which in some cases is capable of still further radioactive change. There is a consequent change in the behavior of the material in the chemical sense. It is a phenomenon remotely comparable to the sudden appearance of a mutation in a living cell line.

As the utilization of atomic energy for industrial and scientific purposes multiplies, as inevitably it will, the responsibility for insuring that the environment occupied by people, and by the biological systems upon which human life depends, shall not be contaminated to a level of population hazard. In general, this is equivalent to saying that the environmental contamination must be maintained at levels considerably below those considered significant as hazards to individuals.

The essentials of protection from dangerously radioactive substances are: time, distance, shielding, and containment. All radioactive substances decay and in time result in ordinary stable elements. The times required vary from minute fractions of a second to many years. The longest half-life of a fission product of any biological significance is approximately 20 years, although smaller amounts of elements of less biological consequence are formed that have

half-lives as long as 33 years. Consequently, inherent in considerations of environmental radioactive contamination is the element of time.

From the standpoint of external exposure to radiation, distance is extremely important as a protective measure. Intensity falls off as the square of the distance from the source, and to this there is a further reduction from attenuation by the air. A source which may be dangerous close up may be quite innocuous at a moderate distance.

All radiations may be stopped by appropriate and adequate shielding. The character of the material used for shielding and the amount of it are partly determined by the nature and intensity of the radiation concerned.

Containment is the fourth essential factor in radiation protection. Materials which would be hazardous if released to the environment in quantity may be held in storage until radioactive decay has taken place and the levels of radiation reached are acceptable in the disposal area. At Hanford large quantities of highly radioactive fission products are held in underground tanks for many years. Materials which might be hazardous are thus kept confined and do not enter the environment where they could be a risk to life.

As with all toxic substances, there are levels of exposure to radiation and various radioactive elements internally which can be said to be safe in the sense that no significant injury may be detected over the lifetime of the individual. These permissible or tolerance levels are determined through careful study of all available information derived from human experience and animal experimentation. In the United States the National Committee on Radiation Protection considers these matters and advises on the levels which may be accepted as permissible. Their recommendations are published from time to time by the United States National Bureau of Standards.

These developments mean that the sanitary engineer and the public health worker, not only now but especially in the years to come, must give increasing thought to the control of radioactive substances in the environment and the manner in which such substances may enter the various life cycles that constitute our food

chains. It requires diligence and a redirection of public health education.

That it is perfectly feasible to live and work with vast amounts of highly radioactive substances has already been demonstrated in the plants of the AEC itself. In some of these plants, the workers manipulate safely radioactive material equivalent to thousands of tons of radium. Not only has radiation injury been almost negligible in the atomic energy industry but the climate of radiological safety has resulted in better care with respect to hazards of all kinds so that the safety record of the AEC has merited special recognition. Difficult as the problems are, there is no occasion for fear that this record cannot be continued in the expanding atomic energy industry which may form one of the bases of our industrial and social structures within a comparatively few decades.

Manpower Potentials

PHR Many ways are being developed to overcome the economic barriers to good care which have existed in the past. While the quality and availability of health services is rapidly expanding, however, the population of the United States is growing.

Dynamic forces will increase the demand for health workers in the years ahead.

There are unmet demands today in medical education, public health, mental and tuberculosis hospitals, and rehabilitation. Many rural

By Howard A. Rusk, M.D., associate editor, New York Times; chairman, department of physical medicine and rehabilitation, New York University-Bellvue Medical Center; and chairman, Health Resources Advisory Committee, Office of Defense Mobilization.

areas and small towns are in need of practicing physicians. Hospitals in increasing numbers are resorting to the use of alien physicians with training which is less than adequate by our standards for house staff service. A civilian disaster of the magnitude possible today could put an incredible load on the available physicians.

It is often said that areas with lower physician population ratios are not economically in a position to utilize a greater number. However, the fact that in States with the poorest ratios, doctors report the longest workweek averaging 63 hours a week, and the highest average incomes, indicates that the demand for services in many of those areas is placing a heavy strain on the supply.

In dentistry, a parallel problem exists. Training facilities are being expanded. But this increase is not quite keeping up with the population, and by 1965 the ratio of dentists to population will be, we estimate, 57 per 100,000 as compared with 58 per 100,000 today.

The number of graduates of schools of nursing has been stabilized at 28,000 or 29,000 since 1951, but the number of entrants is now rising again.

The shorter patient stays and the emphasis in rehabilitation on getting the patient on his feet and returning him rapidly to a condition of independence all call for new emphasis in nursing care and have resulted in an intensification of nursing activities.

Efforts of the nursing profession to maintain the supply of professional workers and to improve their utilization have been outstanding, and there is indication that the supply situation in nursing is not as critical as it was a few years ago.

One aspect of better utilization is the increased employment of other workers for functions which do not require the nurse's special skills. The trend toward hospital staff nursing and away from private duty nursing means that more nurses are available for hospital employment.

The training of paramedical workers such as physical therapists and occupational therapists is likewise increasing although the numbers of these are still very small. But present levels

of training are not at all closing the gap between demand and supply.

For each of these professions there are probably over 3,000 vacant positions today.

The demand in these areas is continuing to grow rapidly, and though the supply of graduates is increasing there is every indication that the demand will continue to outrun the supply.

For the Future

This is the time then to take a long look at the educational opportunities which we are prepared to offer, both as to quality and quantity. First, curriculum: Most of the health professions today are looking seriously at their curriculum and weighing it in relation to the total job to be done. They are looking, although perhaps still not sharply enough, at the problem of training the workers in the many disciplines to work together for the patient, to orient their planning and activities so that the best thing is done for the patient rather than the best thing for the individual category of professional worker.

A real bottleneck in education today is salary scales. This is part of a general problem which plagues the Nation, that of obtaining enough teachers and good enough teachers from the kindergarten through the whole educational process.

Getting adequate facilities is another serious hurdle in providing for professional education. Schools of medicine and dentistry and nursing are seriously hampered by lack of facilities. Schools of the paramedical professions also suffer seriously from lack of basic clinical facilities and equipment.

Thus far, however, the attacks on these problems of curriculum, of faculty, and of facilities have been piecemeal and inadequate.

A basic across-the-board necessity is money. Medical schools, dental schools, schools of nursing, and the paramedical sciences are all hampered by lack of adequate funds in carrying out the objectives of their present programs, in recruiting and maintaining staff, in developing programs to meet changing needs, and in providing the best educational environment.

The spirit of rehabilitation is in itself a spirit

of dedication to the human welfare and dignity of man, regardless of his physical limitations.

In forecasting America's health, our efforts and the degree of success we achieve in developing improved health for the peoples of the world are a major factor. In our shrinking world of today, our own health—medically, emotionally, economically, and politically—is dependent upon the health of the rest of the world. To achieve that state of health, we could do well to adopt the slogan of an obscure but wise English philosopher who said 300 years ago, "If every man would but mend a man, the world would all be mended."

March of Medical Science

 The title of this program, "The March of Medical and Social Sciences," in itself reflects growing awareness that health is an inseparable element in social progress and that medical science does not and cannot function in isolation from the social, economic, educational, and cultural forces in our society.

Research Advances

The problems faced by medical science are tremendous in volume, scope, and complexity. When one looks back at what medical science has accomplished over a span of several decades, he can identify the items quite easily. When one looks at medical science today and tries to pick out the most promising work, he finds the task quite difficult. But when one attempts to anticipate what progress will have been made by, say 1975, his first inclination is to look for

By C. J. Van Slyke, M.D., associate director, National Institutes of Health, Public Health Service, Bethesda, Md.

cover, and his second is to generalize and digress, because the record shows that medical progress is replete with false hopes, pitfalls, and hypotheses that cannot be confirmed. The way to progress is long and difficult, and the specific advances are anticipated only by those who possess temerity and clairvoyance.

It is possible, however, to pick out several broad general areas and to project recent progress for several years, assuming that no new variables are brought into play. I will try to confine my speculations to areas which might have meaning in terms of planning health resources for the future.

It is reasonable to assume that there will be vaccines which will be largely effective in the prevention of influenza, poliomyelitis, and the minor upper respiratory infections, including the common cold.

There could be major advances against heart disease, featuring the prevention of rheumatic heart disease by the prevention of rheumatic fever; drugs to control hypertension; and some as yet unknown means to control the fatty deposits in the blood stream which lead to atherosclerosis.

There will be improvements in cancer diagnosis. Treatment of cancer will improve, too; in addition to X-ray therapy and surgery, there may well be chemical agents of particular value against the soft tumors.

There will be new drugs useful in the management of mental illness. We shall have better knowledge of prevention. But the hard core of the problem of mental illness will remain until training and education begin to yield the professional staffs that are so desperately needed, both to study mental illness and to care for the mentally ill.

There will be a series of new drugs, both natural and synthetic, useful in the treatment of arthritis and other rheumatic diseases.

We shall have the knowledge and methods to prevent several of the leading forms of blindness, particularly among children.

There may be fewer advances in the management of neurological disorders, such as cerebral palsy and muscular dystrophy. However, new rehabilitation techniques are in process which bring some of the victims of these diseases a measure of independent self-care.

The Medical Science Spectrum

As one studies the pattern of research activities in the medical and biological sciences, it becomes apparent that while a great deal of progress is being made toward relief or amelioration of the effects of disease, we are not making the same progress toward understanding of the basic underlying causes of disease. This is particularly true for the chronic illnesses. I raise this point only to emphasize the continuing need for fundamental studies, as distinct from target-applied research, which will yield the knowledge with which we can achieve the ultimate goal—prevention.

By these fundamental studies, I refer, in part, to clinical and laboratory investigations, but I also refer to those studies involving man in his environment, both normal and abnormal. If medical science applies the knowledge and techniques of epidemiology, statistics, economics, sociology, anthropology, and related fields to these fundamental investigations, it may find that such fields have as much potential for identifying the factors in disease causation as the clinical and laboratory studies.

Medical science has concentrated on understanding the nature and modes of action and interaction of progressively smaller things. Not too many decades ago, we were studying functions of whole organs or large sections of tissue. Gradually, we reduce the dimension of our studies to the cellular level. Now we are concerned with subcellular matters. We find that even within the cell, there are relations and interdependencies which materially affect the life processes. Scientists study, for example, the role of cytoplasm in genetics, the ability of viruses to destroy certain cells but live peacefully in others, or the factors that govern cell growth and multiplication.

I do not, of course, challenge the validity of the scientific method which seeks understanding of the processes of health and disease through this microscopic and submicroscopic approach. I stress, rather, that it is time for us to also give emphasis to the study of man as a "supramacroscopic" organism, if you will, and to study the whole man in relation to other men and to the environment in which they live.

By way of illustration, we are now conducting a study of a neurological disease known as amyotrophic lateral sclerosis, more commonly called "Lou Gehrig's disease." On the island of Guam, this disease is 50 times more prevalent than it is in the United States. That offers a golden opportunity for an epidemiological study. There is another study in Massachusetts, which has undertaken to follow a large population group in order to investigate and evaluate the factors involved in the development of hypertension and atherosclerosis. The investigators are not only physicians but also epidemiologists, biostatisticians, social workers, nurses, public health workers, industrial physicians, sociologists and psychologists, anthropologists, and historians—all those who can contribute to better understanding of what causes contribute to having or not having heart disease.

No Formula for Progress

Progress in medical science does not come easily. But I am convinced that it will continue in the future as it has in the past, and perhaps more abundantly. We have only to build intelligently on our experience.

The most serious threat to the ability of medical science to do the job it must do is the impending shortage of trained investigators of all kinds. Science teaching in the secondary schools has not kept pace with increasing needs. The preclinical sciences have suffered in the colleges and universities. And there are too few career opportunities in the basic sciences related to medicine and biology. We must do something immediately and constructively to resolve this issue.

Cooperative Effort

Another challenge of medical science is to achieve a more effective linking of institutions and agencies and organizations which together make up the health resources of our Nation.

I do not mean to oversell the value of coordination as such. There are times when I feel we spend so much time coordinating our efforts that the efforts themselves get almost obliterated, and coordination becomes merely entanglement. Cooperation, yes—knowledge of other

programs, ability to use them as resources, eagerness to work together where interests merge, respect for the objectives and methods of other groups, desire to avoid jurisdictional disputes—these are the essence of effective cooperation in health and related fields. For example, one city has a single telephone number to answer all health inquiries in order to assure appropriate referral to the proper health agency or agencies.

We need more of this kind of cooperation. For as we get larger and older as a Nation, the health needs of the people grow and the pattern of health services changes to meet these needs.

The General Outlook

Probably the largest single factor to concern those who plan civilian health programs in this country is our changing population.

Heart disease, cancer, mental and neurological disorders, arthritis and various metabolic problems such as diabetes, blindness, and dental disease will reach even greater proportions. The future will bring increased pressures upon society to prevent or cure these chronic diseases, to prolong the usefulness of man throughout the maximum portion of his allotted years.

The emphasis on chronic diseases should not obscure the fact that serious infectious diseases are with us, too—hepatitis, influenza, brucellosis—and that any relaxation of public health vigilance is an invitation for reappearance of smallpox, typhoid fever, and other scourges of the past. This work becomes all the more meaningful when one remembers that certain major chronic diseases may well have their origin in micro-organisms. Witness, for example, the several types of cancer in animals which are known to be caused by viruses.

Another problem for the future rests on the fact that this country has become predominantly urban. This trend increases the burden of State and local health departments to maintain sanitary, healthful conditions for our 160 millions. It brings to the fore such programs as city health planning, air and water pollution, accident prevention, sanitation, and cancer that may be of industrial origin.

I think I should make special mention of two problems of major significance: mental illness

and diseases of aging. Already the mentally ill occupy half of America's hospital beds and cost us well over a billion dollars in tax money alone. And the dimension of the problem is growing by \$100 million a year. We must certainly find better preventive methods and more practical and adequate means of treating these unfortunates.

Related problems are juvenile delinquency, drug and alcohol addiction, the gamut of self-injurious and antisocial behavior, to be approached through both the physical and the social sciences.

So we return to my earlier reference on the inseparability of medical and social science. It is all too obvious that we must do something about effective utilization of our older people, reexamining our whole social and economic structure to find ways to help them recapture their place as useful and productive and happy members of society.

Conclusion

In conclusion, this judgment seems germane to the forward march of medical science:

We must move simultaneously toward better application of what we now know about the prevention and control of disease; toward the acquisition of new knowledge; and toward making the necessary changes in today's health structure to be ready for tomorrow's challenges.

Social Processes at Work

Public health workers have two major interests: acquiring new health knowledge and applying known techniques and information. In different words, public health is committed to research and to practice. Social science can

By Benjamin D. Paul, Ph.D., lecturer on social anthropology, Harvard University.

aid in both. Examples from psychosomatic medicine, child study, and nutrition will indicate how social science can assist in basic health research.

Health Research

In the field of psychosomatic medicine, social scientists are exploring areas of social strain as possible determinants of ailments such as ulcers. Social mobility is one of the cardinal features of America's open class system. Striving for mobility may bring tangible benefits, but it also generates anxiety, and it is possible to study the role of mobility anxiety in ulcer formation. In recent decades ulcer has increasingly become a man's rather than a woman's disease. This may be related to men's steady loss of social status and security as a result of the ascending social position of women.

Social science is slowly building up information about, and fashioning tools for, studying personality formation. This is an important part of the field of child development, a field in which the health disciplines and the social science disciplines alike have a lively interest. Recently, for instance, Cornell, Harvard, and Yale have begun a joint study of parent-child relationships in five different villages located respectively in India, Okinawa, the Philippines, Mexico, and New England. Using nature's cross-cultural laboratory, this farflung research project is designed to test certain hypotheses concerning child training and its impact on child behavior, adult personality, and cultural values.

Still another example relates to nutritional research. Epidemiological studies and laboratory work have focused attention on the possibly critical role of certain vitamins, amino acids, and antibiotics in promoting normal growth. To test out some of these findings in the field, a nutritional research organization in Central America set up a series of experiments in five local villages. School children in each community were given a different combination of nutrients and food supplements. Periodically the nutritional status of the children was checked through blood sampling and other means. But in one of the vil-

lages the parents threatened to withdraw their children from the program, jeopardizing the conclusiveness of the ultimate research results.

To locate the sources of resistance, an anthropologist was sent into the community. These are some of the things he found out. Project personnel had unwittingly become identified with one of two hostile political factions; this led to the charge that the program was dangerously subversive. A local medical clinic and other services, intended to win village good will and cooperation, were causing more harm than good; they were not adjusted to local expectations. According to their lights, parents saw blood sampling as injurious to their children's health; they regarded blood as a non-regenerative substance. Moreover, they began to spread and credit rumors that the object of feeding children was to fatten them for export to the United States where they would be eaten; they now believed that the purpose of blood taking was to check scientifically whether the children were ready for shipment.

Once the sources of trouble were located, the anthropologist was able to suggest counter-measures to regain the villagers' confidence and allow the research program to run its full course. Here again, social science techniques furthered the cause of health research. However, social scientists are able to contribute even more perhaps to public health practice than to public health research.

Public Health Practice

The practice of public health emphasizes promotive and preventive medicine. Even more distinctively it is concerned with groups, populations, and communities, rather than with individuals in relative isolation. Social scientists by definition are equally concerned with groups and communities, although their primary urge is to acquire knowledge rather than put their knowledge to practical use; by inclination they prefer scholarship to a career of service. Yet their interest in understanding the community attracts them to action programs. By observing how communities respond to service programs they learn how communities work. Health programs in turn can improve their ap-

proach by taking advantage of the information the social scientists thus accumulate.

In working with health teams, social scientists probably cannot make their best contributions by engaging in direct service; their training doesn't usually fit them for social work. They can help in program planning, but perhaps their greatest contribution can be made in program assessment.

Assessment of Effect

Suppose a health agency is dedicated to changing a community's health habits. After a period of effort the agency wants to know: Did any change occur? Was the change the one we wanted? Were we the cause of the change?

Social scientists have techniques for supplying the answers. By means of interviews or questionnaires and using proper sampling methods, the health habits of a community are measured before and after the campaign.

In several Syrian villages it was found, for example, that hygienic habits had improved appreciably after 2 years of organized effort. Conceivably the improvement might have come about despite the health campaign and not because of it. Indeed control villages showed similar improvement during the same interval, thus making it difficult for the health workers to claim the credit for the change in their experimental village. We don't really know what happened. The answer would require use of a yardstick that measures process rather than effect alone.

Recently an interdisciplinary team engaged in an intensive campaign to alter attitudes toward the mentally ill in a fairly prosperous domestic community. Team members reasoned that an unfavorable attitude toward discharged mental patients was influencing the high rate of relapse and readmission to overcrowded hospitals. They established themselves in the town, gained the cooperation of influential persons, and used, as means and resources, motion pictures, pamphlets, books placed in the library, newspaper notices, broadcasts, speakers, small group discussions.

Before and after the campaign they collected several hundred questionnaires designed to re-

veal attitudes toward the mentally ill—conceptions of cause, curability, degree of personal responsibility for helping a sick relative, willingness to associate with a person discharged from a mental hospital. They twice administered the same set of tests in another town where no campaign of health education was attempted. As expected, the people there showed no significant change of attitude. But surprisingly, neither did those where the intensive campaign had been tried.

The reasons for this negative outcome were instructive. But to understand the reasons they had to investigate process rather than rest content with measuring effect.

Assessment of Process

In the mental health instance, the processes responsible for the negative outcome could be uncovered by combining various types of evidence, including data from intensive interviews and observed changes in people's reaction to the education and testing team.

One of the ideas the team had sought to communicate was that no sharp line divided the sane from the insane, that personality types fell along a continuum running from the fully nor-

mal to the fully abnormal, and that most released hospital patients were therefore not essentially different from other people and should be treated accordingly.

But people in the community clung hard to their black-and-white concept of normality and abnormality. Not always certain about their own sanity, they had erected a wall of defense that sharply divided the sane from the insane. In trying to undermine this popular conception, the educators were apparently arousing deep insecurities. Without good rational defenses against rational argument, the citizens responded by withdrawing their cooperation. They showed outward apathy, attempted to withdraw, and ultimately expressed open hostility toward the project personnel.

The lesson is clear. Before trying to change old health habits and ideas for new, it is wise to ascertain what the established habits and ideas are and what psychological and social functions these beliefs and practices perform. It is in this direction that social scientists can point the way. Ultimately their biggest contribution to health programs may lie in probing beneath cases of success and failure to unravel the hidden processes that are ever at work in the community.

Marshall A. Shaffer, 1899–1955

Marshall A. Shaffer, chief of the Technical Services Branch, Division of Hospital Facilities, Public Health Service, died suddenly on May 25. Mr. Shaffer, internationally recognized for his work, was responsible for the architectural engineering phases of the hospital survey and construction program since its inception. He entered the Public Health Service in 1941 and was commissioned as engineer officer in 1945.

After graduation from Pennsylvania State College in 1922, Mr. Shaffer worked for 11 years as an engineer in Central America, Mexico, and the southwestern United States. During this time

he studied and practiced architecture. He worked on the design of the Los Angeles General Hospital, the largest in the world, and won several competition awards. In 1933 he became consulting designer for the Federal Works Agency.

In 1951, Marshall Shaffer was given the American Institute of Architecture's Kemper award for "ensuring the conduct of the hospital building program in harmony with the highest ethical standards." That same year he was invited to represent the United States at the Building Research Congress in London. In 1952, he was a delegate to the Eighth Pan-American Congress of Architecture at Mexico City. At that time, he was elected president of the Plenary Session on Hospitals, the first American to be so honored.

The Internal Revenue Code of 1954 and Health Programs

By SELMA MUSHKIN, M.A.

OF SPECIAL INTEREST to public health personnel are changes in the new Internal Revenue Code of 1954 providing additional tax relief for those who become ill and incur large medical bills. Also of interest are provisions affecting health manpower, training, and research.

The new revenue code was designed primarily to remove inequities, clarify tax law, and bring the provisions of the taxing statutes in line with current economic developments. Although the new tax act involved a tax reduction of \$1.4 billion, it was designed as a reform and not a tax reduction measure.

Sick Leave Pay and Medical Costs

Two provisions of the Internal Revenue Code of 1954 are especially notable for their potential impact on health programs and voluntary health insurance. These provisions relate to sick leave pay or temporary disability benefits and the tax deduction allowed for medical expenses.

Employer Sickness Benefit Plans

In the last decade employer participation in employee health and welfare plans has expanded considerably. A combination of fac-

tors has stimulated employer interest in health plans. Increased recognition of such plans as an integral part of the labor-management programs, union emphasis on this form of protection in collective bargaining, the exemption of these plan benefits from restrictions of the wage stabilization program, and the indirect incentive of the excess profits tax have all contributed to this growth.

It has been estimated that employer contributions toward pension, health, and welfare plans reached \$5 billion in 1953 (1) and that employer contributions for health insurance plans alone exceeded \$750 million (2).

Considerable uncertainty developed under the earlier revenue laws concerning the tax liability of employer contributions toward sickness and health insurance of their employees. For some time before the enactment of the code of 1954, changes in Internal Revenue Service regulations were under discussion to clarify the employees' tax liability for these health and sickness insurance premiums. The new code specifies that premiums and contributions paid by employers under a plan to finance sickness and accident benefits are not currently taxed as employee income. Furthermore, employer payments and premiums to reimburse an employee for expenses incurred for the medical care of the employee, his spouse, and dependents are tax exempt, provided the employee does not claim a medical expense deduction for such expenses under his individual income tax.

Uncertainty also developed concerning the

Miss Mushkin is an economist with the Division of Public Health Methods, Public Health Service.

taxability of sickness benefits received by employees under plans operated by their employers (3). In general, amounts received as accident or cash sickness benefits were excluded from gross income under the earlier statutes and regulations, if the benefits were paid under an insurance contract. Benefits financed by an employer under a self-insured plan or a wage continuation plan were taxable. In the words of the Ways and Means Committee of the House of Representatives: "Very troublesome legal and administrative problems have arisen in determining whether particular plans, especially self-insured plans, which are financed by employers without the use of a carrier or insurance company, constitute insurance for purposes of the exemption" (4).

Although employer sickness benefit plans (including sick leave provisions for government employees) go back many years, provision of cash sickness benefits was stimulated considerably by the enactment of State temporary disability benefit laws, the Federal railroad cash sickness benefit provisions, and by collective bargaining agreements. Rhode Island adopted the first State temporary disability program in 1942. California, New Jersey, and New York also have enacted temporary disability statutes. In these three States, unlike Rhode Island, the benefits may be paid either from a State fund or under a private plan which conforms with State law. An approved private plan in these three States may be set up either in the form of a contract with an insurance carrier or on a self-insurance basis satisfactory to the States (5).

In 1953, cash sickness benefits under State law totaled \$231.8 million. Of this total some \$140 million was paid out through private plans, including about 8-10 percent which was paid out under self-insured plans. It has been estimated, furthermore, that in 1953 approximately \$975 million was paid in premiums for private insurance against loss of income during sickness, and the benefits paid out under this insurance amounted to about 60 percent of the premiums, or \$600 million (6). While there are no adequate current data on employer participation in the payment of these premiums, it has been estimated that employers are financing about 45 percent of the premiums paid.

In general, the new revenue code narrows the exemptions of these sickness benefits from taxable income by imposing a limitation on the maximum amount of sickness payments financed by employers which may be excluded from income. In testifying on the new revenue code, for example, Marion B. Folsom, Under Secretary of the Treasury, stated: "When the present law was put into effect giving tax exemption status to sick benefit payments under insured plans, very few insurance companies would write policies providing more than \$50 or \$75 a week benefits. But, in recent years they have cut off the maximum and now some of these insured plans provide almost unlimited benefits when people are out sick, for executives, as well as the rank and file. Under the present law, that is all tax exempt. Under our proposal, we would put a ceiling of \$100 a week on tax exemptions of any sick benefit plan" (7).

The new code clearly excludes from gross income the benefits an employee receives under a workmen's compensation act for sickness or accident incurred in the course of employment. It also excludes compensation paid under a workmen's compensation act to the survivors of a deceased employee. Similarly, damages received on account of personal injury or sickness (whether by suit or agreement) are clearly excluded. Full exemption is also granted for payments received for the permanent loss or loss of use of a member or function of the body or the permanent disfigurement of the employee, his spouse, or dependent provided such payments are not a continuation of wages for the period an employee is absent from work (8).

Payments received by an employee under an accident or cash sickness plan for wage loss resulting from illness or injury are exempt up to a weekly rate of \$100. However, such payments received during the first 7 days of illness are exempted from taxation only if the employee is hospitalized for at least one day during the period of illness. When the absence is caused by injury or accident there is no waiting period.

The exclusion from income, while narrowed for those receiving benefits under plans carried by insurance companies, is broadened to include payments under a self-insured plan and

amounts received as wages or in lieu of wages during a period of sickness. These payments, previously taxable, are now exempt within the \$100 weekly maximum to the extent they are employer financed. In general, the provisions of the new code follow the practices of many commercial insurance policies in length of waiting periods, in differentiating between hospitalized illnesses and other illnesses, and in distinguishing between accidental and other disabilities. The new tax provisions add another incentive to hospitalization and raise many complex problems similar to those involved in the administration of sickness benefit payments.

A notice of proposed regulations under the accident and sickness benefit provisions of the new code was released in the Federal Register on March 24, 1955. These regulations set forth rules for determining the amount of benefits attributable to employer contributions in cases in which contributory and noncontributory plans are combined. They clarify the basis of differentiating payments which are related to a period of work absence from other disability benefits. The regulations also spell out the rules for determining the proportion of wages which may be excluded under wage continuation plans, by defining both the basis for determining the weekly rate of pay and the period during which income attributable to illness may be excluded.

If the amount of wages or benefits received does not exceed \$100 a week, the full amount of the payment after the waiting period may be excluded from gross income without regard to the number of additional days of absence from work. If the wages exceed \$100 a week, the payment during the period of illness is prorated in proportion to the \$100 weekly maximum. For example, an employee earns \$120 a week. He is ill for the waiting period and an additional 3 days. He receives a total of \$192 during the period of illness. The \$120 pay for the first week would be counted as income. Sixty dollars of the additional \$72 in wages received for the 3 days of additional absence would be excluded from the employee's gross income. In other words, the exclusion would be in the ratio that the \$100 maximum is to the weekly wage of \$120.

Among the various problems of definition and interpretation in the new tax provisions is that of the definition of illness. The Internal Revenue Service under a recent ruling, for example, has determined that "payments received for a period of absence due solely to pregnancy may not be excluded from gross income. Pay for time missed for actual sickness during a pregnancy whether or not a result of the pregnancy, however, would be an exempt income amount."

It may be of interest to note that a provision of the new revenue code is especially addressed to the problem of equalizing the tax treatment of retirement pay on account of service-connected disabilities of the commissioned officers of the Public Health Service and of the Coast and Geodetic Survey with those of members of the armed services. For all these groups such payments are exempted from taxable income.

Medical Expense Deductions

A deduction for medical care expenses in excess of 5 percent of income was first introduced in 1942 along with the wartime increases in individual income taxes and reductions in personal exemptions. The Senate Finance Committee, in approving the deduction in that year, reported that "This allowance is recommended in consideration of the heavy tax burden that must be borne by individuals during the existing emergency and of the desirability of maintaining the present high level of public health and morale" (9). The deduction was modified by subsequent revenue acts. In 1944, the lower limit was changed from 5 percent of net income to 5 percent of adjusted gross income, that is, income before exemptions and allowed nonbusiness deductions. Other revenue acts raised the maximum amount of the deduction. A significant change was made by the Revenue Act of 1951 which permitted taxpayers 65 years of age and over to deduct medical expenses for themselves and their spouses without regard to the 5 percent of income minimum.

The new code makes three major changes in the medical care expense deduction. It allows deduction of medical expenses in excess of 3 percent instead of 5 percent of adjusted gross income. It limits the amount of drugs and medicine which may be included in medical care

Table 1. Number of taxable income tax returns with medical and dental deductions and amount of such deductions, 1950

expenses to sums in excess of 1 percent of income.

For example, a family with an adjusted gross income of \$5,000 may deduct medical expenses above \$150 instead of the amount in excess of \$250 previously allowed. However, this family can include in the deduction only the amount above \$50 that they paid for drugs and medicine. The maximum allowable deduction for medical expenses is increased from \$1,250 to \$2,500 per exemption. The overall limit per tax return for a married couple filing a joint return or a head of a household has been increased from \$5,000 to \$10,000. For a single person filing a return or married persons filing separately the maximum limit is raised from \$2,500 to \$5,000.

Other changes in the medical care deductions are also made by the new code. A new provision allows the expenses of a last illness to be deducted on the final return of a decedent, even if the expenses are paid after death. The definition of medical expenses is clarified by providing for the deduction of amounts paid for accident or health insurance and transportation expenses for travel prescribed for health reasons. Expenses for food and lodging during such travel are not deductible.

The Department of the Treasury at the time

of the hearings on the new revenue act estimated that about 8.5 million taxpayers would receive additional tax relief as a consequence of the changes in the medical care deductions and that the net cost to the Government in the form of tax loss would be about \$80 million.

In assessing the importance of the change in the medical care deduction provision, it is important to take account of the population represented on tax returns and the extent to which even large medical care bills fall within the limits of the so-called standard deduction option provided for all taxpayers (10, 11). An estimated 55 to 60 million tax returns were filed for the 1954 income year—80-85 percent estimated as taxable. The population represented on taxable returns has been estimated at between 65 and 70 percent of the total population. Those not taxable include, among others, persons drawing on their capital and assets for current living expenses, those with income less than \$600 per person supported by the family head, and those receiving a large portion of their income from nontaxable sources such as public payments and contributory annuities.

Even among the taxpaying group, however, a standard deduction is used far more frequently than are itemized deductions. The standard deduction, written into tax laws to

simplify administration, authorizes an average amount of deduction for all taxpayers for the deductible items of expenses—such as charitable contributions, property taxes, interest on indebtedness, and medical expenses. The standard deduction amounts to 10 percent of adjusted gross income, up to \$1,000 (\$500 for spouses filing separate returns). Accordingly, those with no deductions other than medical care costs—even costs amounting to as much as 15 percent of income—would tend, because of the greater simplicity, to use a standard deduction. Despite this fact, in 1950, the last year for which complete tabulated data are available, some 4 million taxpayers itemized their medical care deductions. In the aggregate, medical expenses of these taxpayers exceeded \$2 billion, or over \$500 per tax return. The amount of medical and dental deductions totaled \$1.3 billion (table 1). Almost half of the approximately 8.5 million taxpayers who itemized their deductions, instead of claiming a standard deduction, reported medical expenses in excess of 5 percent of income (table 2). The variation in the amount of average medical care expenses per return by income group and the percent of income spent for medical care are shown in tables 1 and 2. Table 3 indicates the proportion of total returns whether taxable or not

which reported medical and dental deductions for that year and the amount of these deductions by income groups.

The data derived in the operation of the revenue act may be compared with data available on the distribution of medical care costs for all families in the population. The Health Information Foundation, for example, in its recent study of voluntary health insurance and consumer expenditures for personal health services in the period 1952-53, found that 7 percent of all families—approximately 3.5 million—incurred medical care expenses in excess of \$495. Approximately 1 million families incurred medical care expenses equalling or exceeding one-half of their annual incomes, and about 500,000 families incurred medical expenses equalling or exceeding their annual income (12).

The national bill for medical care expenses in 1953 was approximately \$10 billion, or about 4 percent of personal income after taxes. The total by class of service as estimated by the Social Security Administration is shown in table 4.

During the course of the hearings on the change in the medical care expense deductions much testimony was offered on the need for special tax provision to give taxpayers incen-

¹ Adjusted gross income means gross income minus allowable trade and business deductions, expenses of travel and lodging in connection with employment, reimbursed expenses in connection with employment, deductions attributable to rents and royalties, certain deductions of life tenants and income beneficiaries of property held in trust, and allowable losses from sales or exchanges of property. Should these allowable deductions exceed the gross income, there is an adjusted gross deficit. The adjusted gross income classes are based on the amount of adjusted gross income, except that returns with adjusted gross deficit are designated "no adjusted gross income" without regard to the amount.

² Medical and dental expenses, reported on returns with itemized deductions, paid for the care of the taxpayer, his spouse, or dependents, not compensated by insurance or otherwise, which exceed 5 percent of the adjusted gross income. The deduction in 1950 could not exceed \$1,250 multiplied by the number of exemptions other than those for age and blindness with a maximum deduction of \$2,500, except on a joint return of husband and wife the maximum was \$5,000.

³ Percentages based on unrounded numbers of tax returns and dollar amounts in thousands.

⁴ Reported on returns with medical deductions. Does not include nondeductible medical expenses equal to 5 percent of adjusted gross income.

⁵ Adjusted gross income less adjusted gross deficit.

⁶ Adjusted gross deficit.

⁷ Persons with gross incomes below \$600 are not required to file returns. However, many such persons do file returns, chiefly for the purpose of claiming refunds of tax prepayments; and those returns are included in the tabulation.

tives for purchasing voluntary health insurance protection against large medical bills. At present, premiums paid for voluntary health insurance may be included as a medical care expense, but there is no special tax incentive for the purchase of this protection.

The American Hospital Association, through its Council on Government Relations, made known its view at the time of the hearings on the new revenue act. In a letter to the chairman of the Ways and Means Committee these views were stated as follows: "Hospitals recog-

nize that many hospital and medical expenses that impose severe financial burdens upon families and individuals are not deductible because they do not exceed 5 percent of income. Where an extensive illness occurs, it often seems that the maximum of \$1,250 hurts most the people who most need this help. But the problem cannot be solved by removing all limits. There are some economic implications in any complete removal of limitations which ought to be explored by the committee. As limits are lowered, there will be more deductions claimed and there

may need to be closer scrutiny of the nature and propriety of these deductions. Not all minor medical expenses are a handicap to income earning, and there is much to be said for limiting this form of relief to catastrophic situations, where these can be defined. . . . The American Hospital Association would generally favor (1) allowing the cost of voluntary health insurance to be deducted from taxable income without regard to fixed minimum percentage of income, and (2) some liberalization in medical expense deductions" (13a).

Health Manpower, Training and Research

The new revenue code contains a number of provisions affecting training and research expenditures. Among these provisions are the broadened definition of dependents, the clarification of the tax status of scholarships and fellowships, the liberalized deductions for contributions to hospitals and educational institutions, and special deductions for care of dependents.

Definition of Dependents

Although the Congress rejected proposals for tax deductions for higher education expenses, the new revenue code gives some recognition

to the costs to parents of financing students through long periods of academic training and to the current levels of even sporadic earnings of full-time students. The American Council on Education, in testifying before the Ways and Means Committee, described the problems imposed by the earlier revenue provisions as follows: "It means that hundreds of thousands of students spend a considerable portion of their free time in enforced idleness. It places heavy financial burdens on their parents at a time when they can least afford to meet them. It makes it impossible for many poor, but worthy students, to attend institutions of higher learning because of the monetary limitation" (13b).

Before the enactment of the code of 1954, a \$600 exemption was granted a taxpayer for a dependent if the dependent had a gross income of less than \$600 a year. The new revenue act liberalizes this provision by permitting children to be counted as dependents for purposes of exemptions even though they earn income in excess of \$600 a year. The children for whom an exemption may be claimed must be under the age of 19 or full-time students at an educational institution. Moreover in determining whether an exemption may be claimed for a child—that is in determining whether the taxpayer provides half or more of the support of the child—the new code permits any scholarships received for study at an educational institution to be ignored in applying the support test.

The problem of dependency credits for students attending medical or dental schools is especially significant because of the extended period and high cost of training and the proportion of students who work. Counts and Stalnaker, in a recent study on the cost of attending medical school, point out that, on the average, students spend \$1,500 a year in addition to tuition and fees. Tuition at the schools included in their special study averaged (median value) \$800, making the total cost for a student year about \$2,300—or a total cost of \$9,200 for the completion of 4 years of medical training. Counts and Stalnaker found in their questionnaire survey of 6,251 medical students from 26 selected medical schools that parents were the most important source of income for the majority of students. Approximately 59 percent of the students financed their way by help (other

than loans) from parents. The median amount of income from parents was \$1,300 (14).

About 3 out of each 4 students reported income from vacation earnings, the median amount being \$550. In addition, about one-fourth of the students were employed other than during vacations and received cash payments for their work. A few of the students received services such as board, room, or laundry. Although some of the students were employed at the university where they were attending medical school, the majority had jobs outside the medical school. The median amount of earnings—other than vacation earnings—was \$450.

Parents of medical or dental students who are providing half or more of the support of their children will now be permitted to claim the student for purposes of personal exemption even though he earns more than \$600 a year. Although the student would be required to file a return, he could also claim a personal exemption of \$600. At the lowest income tax bracket, this change would mean a tax saving to the parent of \$120 a year. The reported income for parents in the study just cited averaged approximately \$7,000, which might make the average tax saving somewhat higher (14).

Scholarships and Fellowships

Under earlier tax law there was no special provision regarding the treatment of scholarships and fellowships. The basic ruling of the Internal Revenue Service stated that the amount of a grant or fellowship was includible in gross income unless it could be established to be a gift. The ruling created considerable ambiguity.

The 1954 revenue bill adopted by the House of Representatives excluded scholarships or Federal grants from gross income, but severely limited the types of grants which could be excluded. For example, the House bill specified that postdoctoral fellowships and scholarships could be excluded only if the annual amount of the grant, plus any compensation received from a previous employer, was less than 75 percent of the recipient's earnings in the year preceding the grant.

The American Cancer Society, through its executive vice president, testified that under

earlier law their fellowship stipends were ruled by the Internal Revenue Service to be gifts. Although they were not taxable earlier, under the bill as passed by the House the stipends granted by the American Cancer Society would have become taxable because the minimum grants were usually more than 75 percent of the pre-fellowship earnings. The Senate committee, to take account of the problems raised, adopted an exclusion of \$300 per month of postdoctoral grants as a substitute for the 75 percent rule in the House bill.

The new revenue code excludes scholarship and fellowship grants from gross income with certain limitations. The exclusion extends to the value of services and accommodations, such as room, board, and laundry, which are received as part of the grant. It also extends to the amount received for travel, research, clinical assistants, or equipment to the extent that the sums are spent for these purposes.

The exclusion of grants to candidates for degrees does not apply to that portion of any amount received which represents payment for teaching, research, or other services in the nature of part-time employment required as a condition for receiving the grant. However, services required for all candidates for a particular degree are not to be considered part-time employment. For individuals who are not candidates for degrees, such as those receiving postdoctoral fellowships, the exclusion is limited to \$300 a month for a maximum period of 36 months. Moreover, the grant may be excluded only if the grantor is a tax exempt organization or a Government agency.

The National Institutes of Health has prepared a summary statement on Public Health Service research fellowships for persons interested in applying for these fellowships. The provisions of the Internal Revenue Code of 1954 as they relate to fellowship awards are included in this summary statement (15). In general, postdoctoral awards would not be taxable under the new code because the amount of the awards is below the \$300 a month maximum.

Charitable Contributions

The principle of providing an incentive to taxpayers to contribute to charitable causes has long been recognized in income-tax law. In

1952 the maximum allowed deduction for total charitable contributions was raised from 15 to 20 percent of income. The 1954 revenue code allows this limit to be exceeded to the extent that this excess represents contributions to hospitals, educational institutions, or churches. However, this excess may itself in the aggregate not exceed 10 percent of adjusted gross income. In addition, corporations that are limited in their deductions for charitable contributions to 5 percent of taxable income may carry over to the succeeding 2 taxable years any contributions in excess of the 5-percent limit.

In explanation of the changes, the House Ways and Means Committee reported: "This amendment by your committee is designed to aid these institutions in obtaining the additional funds they need in view of their rising costs and the relatively low rate of return they are receiving on endowment funds" (4a).

A number of groups appeared in support of continued Federal recognition of the role of voluntary nonprofit health organizations and education institutions through provision by the tax deductions of incentives to contribute to charitable causes.

Child Care Expenses

During the course of consideration by the House Ways and Means Committee of deductions for child care, the American Nurses Association presented its position in support of allowing working women to deduct the amount spent for child care for income tax purposes. In the course of the testimony Julia Thompson, representing the American Nurses Association, indicated that approximately 20 percent of the Nation's 335,000 active nurses would be immediately affected by this legislation. Miss Thompson also pointed out that of the 220,000 inactive nurses, approximately 58 percent have dependents under 18 years of age.

"The American Nurses Association believes that there are many of these inactive nurses—highly trained women greatly needed in hospitals and health agencies—who are willing and able to take nursing jobs but cannot do so because they will not earn enough to pay for help to take care of their children while they work. . . . It would seem that the proposed amendment to the Internal Revenue Code

would help relieve the situation by enabling inactive nurses with children to return to their profession on an economical basis" (13c). Dr. William S. McNary of the American Hospital Association, in a letter to the chairman of the committee, also indicated the potential effect of the income tax change on hospital manpower resources.

. In recognition of the special problems of expenses for child care a new deduction was introduced by the 1954 revenue code. A deduction up to \$600 is allowed for expenses paid by a workingwoman or widow for the care of a dependent child or stepchild under 12 years of age or for the care of any dependent who is physically or mentally incapable of caring for himself. The care must be for the purpose of enabling the taxpayer to be employed.

The deduction is limited, moreover, in the case of a working wife. In such cases the deduction is allowed only if she files a joint return with her husband, and the deduction is reduced by the amount by which the combined adjusted gross income of both husband and wife exceeds \$4,500, except where the husband is incapable of self-support because physically or mentally incapacitated.

The revenue bill as it passed the House restricted the allowable deduction of workingwomen to widows or those with incapacitated husbands and to expenses for the care of a child under 10 years of age. Various groups testified before the Senate Finance Committee on the need for liberalization of the deduction. Among those supporting liberalization were the United Cerebral Palsy Association and Dr. George G. Deaner of the Institute of Physical Medicine and Rehabilitation. The Senate Finance Committee, in reporting out changes in the House bill which were later voted by the Senate and accepted by the Conference Committee, stated: "Your committee's action in extending the deduction recognizes that similar financial problems may be incurred by taxpayers who, if they are to be gainfully employed, must provide care for physically or mentally incapacitated dependents other than their children. Moreover, it is recognized that in many low-income families, the earnings of the mother are essential for the maintenance of minimum living standards, even where the

father is also employed, and that in such situations the requirement for providing child care may be just as pressing as in the case of a widowed or divorced mother" (16).

Definition Problems Ahead

This brief summary of selected provisions of the new revenue code suggests the number and variety of health and medical care questions on which tax decisions will be required. Earlier revenue statutes involved determinations of medical care cost items—what types of expenses are medical care expenses and which of the expenses fall outside of medical care costs. The extra personal exemption for the blind necessitated definitions of blindness.

The new code, however, goes further in the direction of tax relief for hardship cases involving disability and illness. Many additional questions of definition are involved. The new tax deduction provisions for employer-financed compensation for injuries or sickness require differentiation of payments for permanent injury and wage continuation payments for illness. They also require definition, for example, of "permanent loss or loss of use of a member or function of the body," of "sickness," of a period of hospitalization and of continuous illness. The new deduction for expenses for care of dependents requires differentiation of expenses for "drugs and medicine" from other medical care costs as well as definition of "drugs and medicine." The additional deduction for designated types of charitable contributions requires definition of a "hospital." Problems of definition are currently being explored by the Internal Revenue Service, and clarifying regulations are being issued from time to time. Determinations in application of these definitions to individual cases will be the task of that administrative agency in the period ahead.

The American Diabetes Association

By JOHN A. REED, M.D.

PROFESSIONAL education, patient education, public education and case finding, and research are the four major interests of the American Diabetes Association, which was established and incorporated as a medical organization in 1940. The association is a nonprofit membership organization and the only national nongovernment or voluntary group in the field of diabetes in the United States.

During its early years, the American Diabetes Association was concerned largely with clinical investigation and basic research pertaining to the problems of diabetes mellitus. Recently, however, it has carried out many of the functions of a voluntary health agency, although it has maintained its identity in structure as a medical organization.

The broad objectives of the association, in the language of its constitution and bylaws, are "to further the general welfare through acquisition and dissemination of useful and accurate knowledge and information regarding diabetes mellitus and to undertake in the public interest such activities as will improve the physical welfare of persons having that disorder." To these ends, the association strives:

- To promote among physicians and others the free exchange of knowledge with respect to diabetes mellitus.
- To improve the standards of treatment.
- To promote medical research by individuals, hospitals, clinics, universities, and other institutions.
- To educate the public in the early recognition of the disease and in the importance of medical supervision of its treatment.
- To distribute accurate information to the general public by literature, meetings, and other appropriate means.
- To develop educational methods designed to give diabetic patients a better understanding of their disease.
- To encourage the formation of subsidiary groups which will cooperate actively with the association in its program.

The active membership of the association consists of about 2,000 physicians and persons in related scientific fields whose primary interest is in diabetes mellitus. In addition, there are associate, honorary, and corporate members, who assist in the organization's work but are not entitled to vote.

The affairs of the association are managed by a council, which is composed of 18 persons elected by and from the active membership, the 5 principal officers of the association, and the 3 most recent living past presidents.

Financial support for the organization comes from membership dues; self-supporting projects, such as a professional journal, a magazine for diabetic patients, and a series of postgraduate courses; voluntary contributions by individuals, primarily diabetic patients; and

Dr. Reed, who served for 6 years as secretary of the American Diabetes Association, was elected second vice president of the association in June 1955. He is also an assistant clinical professor of medicine, George Washington University School of Medicine, and has served as a member of the National Advisory Arthritis and Metabolic Disease Council, National Institutes of Health, Public Health Service.

well as to provide for them ordinary camping experiences. The affiliates also promote professional and nonprofessional education in diabetes in their own communities through lectures and public forums, and they are a major force in the conduct of the annual diabetes detection drive.

Toward Early Control

Because of the degenerative complications which develop in a high percentage of diabetic patients, it is of utmost importance that control of the disease be established early and maintained. It is generally accepted that good chemical control of the disease prevents the disabling complications to a great extent. With proper treatment, a person with diabetes can work efficiently and with no more loss of time from the job than a person who does not have

this ailment. It has been estimated that there are now nearly 200,000 diabetic patients in the labor force.

Diet is the essential part of control, but insulin in addition to diet is necessary in about 50 to 75 percent of the cases. Through close cooperation between the patient and the physician, good diabetic care can be achieved. The life span of the diabetic patient today can be practically normal.

Over and above the current program, a great deal must be done to accomplish the American Diabetes Association's four major objectives. For the immediate future, the association will seek an increase in the number of affiliate associations; an extension of the postgraduate course series, especially to regional and State levels; expansion of the diabetes detection drive; and an increase in the number of fellowships for research work.

National Sanitary Engineers' Register

At the request of the Office of Defense Mobilization, the Public Health Service is developing a National Register of Sanitary Engineers, as a phase of the program of the National Science Foundation.

In 1949, the American Public Health Association prepared a National Roster of Sanitary Engineers for the National Security Resources Board. Maintenance of that roster was discontinued a few years ago. The Public Health Service used that list and drew on the association's experience.

The American Public Health Association, the American Society of Civil Engineers, the American Water Works Association, the Federation of Sewage and Industrial Wastes Association, the Conference of Public Health Engineers, the Conference of State Sanitary Engineers, and the registration boards in each State have supplied their membership lists. A master mailing list of over 10,000 names of sanitary engineers has been developed from these and other sources.

A 1-page information sheet, prepared in cooperation with the Engineers' Joint Council and the National Science Foundation, will be sent to each engineer whose name is on this list. A letter from Assistant Surgeon General Mark D. Hollis, chief engineer of the Public Health Service, to accompany the information sheet, will ask each recipient to read the National Research Council's definition of a sanitary engineer before transmitting his reply. By this means, details on the engineer's education, his professional experience, and his sanitary engineering specialty will be recorded on the register.

grants by corporations and foundations. The association does not engage in any general public fund-raising campaigns.

Public Education and Case Finding

Education of the public concerning the prevalence of diabetes mellitus and the necessity for early discovery of the disease is of major importance. The number of diabetic patients now under medical care has been estimated to be well over one million, and there is probably an almost equal number of persons who have the disease but are unaware of it. Diabetes stands eighth in the list of known causes of death.

A program of public education and case finding, known as the diabetes detection drive, was established about 7 years ago for the purpose of finding persons with undetected diabetes. The drive is directed through local affiliates of the American Diabetes Association and the committees on diabetes of county and State medical societies, with assistance from public health groups and various local organizations. Activities are conducted throughout the year, but the greatest effort is made in observance of Diabetes Week, which is the third week of November.

The American Diabetes Association uses all mass communications media to focus the attention of the public on the detection drive, while the local affiliates and the committees on diabetes of county and State medical societies obtain the support of newspapers and radio and television stations in their areas.

Any public or voluntary health group which desires to cooperate in the diabetes detection drive, and especially in Diabetes Week activities, may do so through a local affiliate of the ADA. In areas where there is no ADA affiliate, proposed plans may be channeled through the committee on diabetes of the county or State medical society, which, in the absence of an ADA affiliate, assumes full responsibility for the drive. Many health departments, of course, are also undertaking diabetes detection programs.

Other ADA activities in public education include the showing of an exhibit entitled,

"What is Diabetes?" This exhibit, which was prepared by the association in 1954, has already been shown at county fairs and medical centers in 17 cities. Ten sets of the exhibit are now in circulation.

Professional Education

Although the American Diabetes Association is one of the younger medical groups, it already has developed a broad program of professional education for its members. This program includes annual scientific meetings; an annual postgraduate course in diabetes and basic metabolic problems; publication of the monthly professional journal *Diabetes*; publication of the Diabetes Guide Book for the Physician, of which more than 150,000 copies have been distributed; preparation and showing of exhibits; and community meetings of the physician membership of the local affiliates.

The postgraduate course, which has been offered yearly since 1953, provides refresher and review training for persons engaged in the clinical practice of diabetes mellitus and for those preparing for American Board of Internal Medicine examinations. The American Academy of General Practice allows 20 hours of postgraduate credit to persons who attend the course. The course is under the direction of the association, and the faculty consists of outstanding men in the fields of clinical metabolism and experimental metabolism. The third in the series was presented January 19 through 21, 1955, at the Lankenau Hospital, Philadelphia.

To date, the association has prepared three exhibits for use in professional education: "Diabetes Detection by the Physician," "Vascular Complications of Diabetes," and "Management of Diabetes Mellitus." These are shown regularly at the annual meetings of the American Medical Association and the American Academy of General Practice, and at State and regional medical meetings throughout the United States.

Patient Education

Patient education is a phase of the association's program which is almost limitless in its

Affiliate Diabetes Associations

To assist the American Diabetes Association in fulfilling its objectives, local affiliate units have been established throughout the United States. As of June 5, 1955, there were 39 such affiliates. Each of these has a clinical society, and many of them also have lay societies composed of diabetic patients, their relatives, and their friends.

The members of the committee on diabetes of the county or State medical society are usually members, and sometimes officers, of the local affiliate. In fact, before an affiliate of the American Diabetes Association is formed, prior official endorsement must be obtained from the appropriate medical society through its committee on diabetes. This close cooperative effort provides a firm foundation on which to build an affiliate.

The affiliate serves the community by bringing together the physicians who are primarily interested in the disorder and the diabetic patients, their families, and their friends. In order to strengthen the ties between the national organization and the affiliate, the council of the ADA has set up a Board of Governors, composed of a representative from almost each State and two from some of the larger ones. The governor functions as a liaison between the national organization and the local groups. He will participate in the development of all phases of the ADA program, particularly the strengthening of existing affiliates and the formation of new ones. Because of his awareness of the local situations, the governor is in an excellent position to serve in the capacity of adviser.

The governor also serves as senior delegate from his respective State to the ADA Assembly of Delegates, which is an advisory body to the ADA Council. Each affiliate also elects one physician and one layman, if there is a lay society, to the Assembly of Delegates.

One of the projects of great interest in the affiliates is the support of camps for diabetic children. At the present time, there are 24 such camps, most of which are owned or sponsored by affiliates. These camps afford opportunities to educate the children in the maintenance of proper control of their condition, as

scope. One of its most far-reaching activities is the publication of a bimonthly magazine for diabetic patients, the *ADA Forecast*, which is now 8 years old. Written and edited for diabetic patients, it contains contributions by medical authorities and many articles by patients themselves. In response to requests from patients and their families, reprints have been made available of a large number of informative articles selected from back issues of the publication.

Answering inquiries from diabetic patients and their families is another activity of importance. Each year, the association receives several thousand letters asking questions about diabetes mellitus. Some can be answered with printed materials, but those asking specific questions receive the careful attention of competent medical men.

For use in teaching diabetic patients about their ailment and its control, the association has cooperated with the Public Health Service in producing an audiovisual kit. Also, it has cooperated with the Public Health Service and the American Dietetic Association in the publication of food exchange pamphlets and food lists for use by patients.

The ADA Committee on Employment has set up standards of employment for persons with diabetes. These standards have been of considerable value to employers and patients alike. In addition to these activities, many of the local affiliates have formed societies of laymen for the purpose of providing mass instruction and general discussion on diabetes for patients and other interested persons.

Through special gifts and grants, research funds have been established for the purpose of widening the knowledge of diabetes mellitus and its control. At the present time, the research program is limited to the granting of fellowships. Dr. Charles H. Best, co-discoverer of insulin, is chairman of the association's Committee on Research and Fellowships, which includes eight eminent investigators and clinicians.

Research

well as to provide for them ordinary camping experiences. The affiliates also promote professional and nonprofessional education in diabetes in their own communities through lectures and public forums, and they are a major force in the conduct of the annual diabetes detection drive.

Toward Early Control

Because of the degenerative complications which develop in a high percentage of diabetic patients, it is of utmost importance that control of the disease be established early and maintained. It is generally accepted that good chemical control of the disease prevents the disabling complications to a great extent. With proper treatment, a person with diabetes can work efficiently and with no more loss of time from the job than a person who does not have

this ailment. It has been estimated that there are now nearly 200,000 diabetic patients in the labor force.

Diet is the essential part of control, but insulin in addition to diet is necessary in about 50 to 75 percent of the cases. Through close cooperation between the patient and the physician, good diabetic care can be achieved. The life span of the diabetic patient today can be practically normal.

Over and above the current program, a great deal must be done to accomplish the American Diabetes Association's four major objectives. For the immediate future, the association will seek an increase in the number of affiliate associations; an extension of the postgraduate course series, especially to regional and State levels; expansion of the diabetes detection drive; and an increase in the number of fellowships for research work.

National Sanitary Engineers' Register

At the request of the Office of Defense Mobilization, the Public Health Service is developing a National Register of Sanitary Engineers, as a phase of the program of the National Science Foundation.

In 1949, the American Public Health Association prepared a National Roster of Sanitary Engineers for the National Security Resources Board. Maintenance of that roster was discontinued a few years ago. The Public Health Service used that list and drew on the association's experience.

The American Public Health Association, the American Society of Civil Engineers, the American Water Works Association, the Federation of Sewage and Industrial Wastes Association, the Conference of Public Health Engineers, the Conference of State Sanitary Engineers, and the registration boards in each State have supplied their membership lists. A master mailing list of over 10,000 names of sanitary engineers has been developed from these and other sources.

A 1-page information sheet, prepared in cooperation with the Engineers' Joint Council and the National Science Foundation, will be sent to each engineer whose name is on this list. A letter from Assistant Surgeon General Mark D. Hollis, chief engineer of the Public Health Service, to accompany the information sheet, will ask each recipient to read the National Research Council's definition of a sanitary engineer before transmitting his reply. By this means, details on the engineer's education, his professional experience, and his sanitary engineering specialty will be recorded on the register.

The Specific Heat of Garbage

By E. ROBERT BAUMANN, Ph.D., and CHARLES S. OULMAN

LAWS or regulations in 45 States now require that garbage intended for animal feed be cooked to destroy pathogenic organisms. Most States require that the garbage be heated to a temperature of 212° F. and be held at this temperature for at least 30 minutes. To comply with these laws (1), hog feeders have built a wide variety of equipment for cooking garbage. Some of the garbage cookers show considerable ingenuity, but ingenuity alone is not enough for an efficient design. To evaluate the factors involved in the design of suitable equipment for the heat treatment of garbage, two research groups at Iowa State College have recently undertaken a project titled "Survival of Swine Disease Organisms in the Heat Treatment of Garbage." This study is being conducted by the Iowa Engineering Experiment Station and the department of veterinary medicine of Iowa State College under grant RG 3985 (C) from the National Institutes of Health.

One of the major factors to be considered in the design of a garbage cooker is the amount of heat required to destroy pathogenic organisms. The size of the burner used with direct-fired kettles and the amount of steam required for steam-injection cookers depends on the amount of heat that must be available to raise the tem-

perature of the garbage to 212° F. The heat required to raise the temperature of the garbage without considering heat losses may be calculated by the following formula:

$$W \times \Delta T \times C_{pg} = \text{B.t.u. required}$$

when W = weight of garbage in pounds.

ΔT = 212° F. minus the temperature of garbage before cooking, degree F.

C_{pg} = specific heat of garbage in B.t.u. per pound per degree F. temperature rise.

B.t.u. = British thermal unit, the quantity of heat required to raise the temperature of 1 pound of water 1° F. at or near its point of maximum density.

Specific heat may be defined as the number of B.t.u. of heat required to raise 1 pound of a material 1° F. The specific heat of water is 1.0. The specific heat of almost all other materials, including garbage, is less than 1.0. The specific heat of garbage is not constant but will vary with the moisture content and the composition of the garbage solids. Since the moisture content of garbage will usually be between 65 percent and 85 percent (2-4), many engineers (5) have used a garbage specific heat of 1.0 for purposes of calculating heat requirements. Others, on the other hand, have based their calculations of heat requirements for garbage on specific heat values varying from 0.50 to 0.90 (6). No reliable bases for these assumptions have been reported in the literature.

In the study of the survival of swine disease organisms being conducted at Iowa State College, numerous types of equipment and cooking methods are being employed. Routine observa-

Dr. Baumann is associate professor of civil engineering, Iowa State College, Ames, Iowa, and Mr. Oulman is a student assistant.

tions are being made of heat losses and heat transfer coefficients obtained with each piece of equipment. A more accurate value of specific heat of garbage should be used to calculate these data with a reasonable degree of accuracy. The purpose of this paper is, therefore, to present a method for estimating the specific heat of garbage with sufficient accuracy for design purposes.

Specific Heats of Foods

Garbage fed to hogs is usually commercial garbage (1). Commercial garbage is obtained from restaurants, cafeterias, hospitals, hotels, and other public eating places. It is primarily waste food, and as such, the specific heat of the garbage should be very nearly the same as that of the food products that it contains.

The specific heats of many foods have been reported in the literature (7-9). For the most part, the specific heats vary approximately directly with the moisture content. When heated, food may be assumed to behave as a mechanical mixture of food solids and water (10). Some research workers have found that this assumption is in error for temperatures in the freezing zone, but the assumption will give good results for temperatures above 40° F. (10). The specific heat of food (and garbage) may be determined, then, by a weighted average of the

specific heats of the food solids and of the water. On the basis of this assumption, specific heats, (C_p) of the solid portion of various foods were determined as follows:

EXAMPLE 1

Broccoli¹ (90 percent water, 10 percent solids)
 Specific heat due to water----- $0.90 \times 1.00 = 0.90$
 Specific heat due to solids----- $0.10 \times C_p = \text{---}$
 Specific heat of broccoli (C_f)¹ = .93
 Specific heat of food solids (C_p) = $\frac{0.93 - 0.90}{0.10} = .30$

¹ Reference 7.

Table 1 lists average values and ranges of values of percentage of moisture and specific heats for representative types of food products calculated from data reported by others (7-9).

The specific heats of most food solids vary from 0.15 to 0.45, with an average value of about 0.33. This rather wide variance in values can be explained by the high moisture content of food and the low specific heat of the food solids. On the average, the moisture content of food is about four times as great as the food solids content, and the specific heat of this water portion is about three times as great as the specific heat of the solids. Therefore, a relatively small variance in the determination of the moisture content of the food can produce a rather large variance in the determination of the specific heat of the food solids.

Table 1. Specific heats of foods

Food	Average values			Range of values		
	Percent moisture	C_f ¹	C_p ²	Percent moisture	C_f	C_p

¹ Reference 7.

Conversely, values of the specific heat of food solids that are considerably in error may be used without introducing an appreciable error in the value computed for the specific heat of the food. Table 2 lists nine foods and their respective specific heats. The specific heats of the foods in this table, as computed by using an average value of specific heat of 0.33 for the food solids, are compared with the specific heats that were reported by others (7-9). Two conclusions may be drawn from table 2. First, the variance in the calculated value of specific heat for a food is small when the average value (0.33) is used for the specific heat of the food solids. Second, the variances are smallest if the water content of the food is high.

Table 2. Variations in specific heats of foods

Food	Percent moisture	Specific heat of food	Computed specific heat of food	Percent variance
Beef, boiled ¹ -----	57	0.73	0.71	2.7

Specific Heat of Garbage

The water content of garbage ordinarily varies from 65 percent to 85 percent (2-4). Since garbage solids are food solids, the specific heat of garbage solids may be expected to approximate 0.33, the average specific heat of food solids. It is proposed, therefore, that the average specific heat of garbage be calculated as shown in example 1, using a specific heat for

the water of 1.0 and a specific heat for the solids of 0.33. Table 3 shows the relationship that exists between the percent of moisture in the garbage and the specific heat of the garbage if this assumption is made. The variances resulting from using the average value of specific heat for the food solids in the garbage should be rather small. The chart illustrates the variances resulting from using this average value for estimating the specific heat of a garbage for moisture contents of 65 percent and 85 percent. It also shows the variance in moisture content that will produce the same variance in the specific heat of the garbage.

EXAMPLE 3

The average value of specific heat of food solids, 0.33, is used to calculate the specific heat of a garbage whose actual moisture content is 85 percent. The calculated specific heat of the garbage would be 0.90. If the actual specific heat of the food solids is 0.218, the specific heat of the garbage would be 0.883.

Variance in specific heat of food solids, 51 percent.

Variance resulting in specific heat of garbage, 1.9 percent.

Variance in moisture content which would cause an equivalent variance in specific heat of the garbage, 3.0 percent.

(This would result if a moisture content of 82.4 percent were used instead of the actual value of 85 percent.)

In most estimates of specific heat, the use of an average value of specific heat for the food solids should be sufficiently accurate. However,

Table 3. Relationship between moisture content and specific heat of garbage ¹

Percent moisture	Specific heat of garbage	Percent moisture	Specific heat of garbage
100-----	1.000	74-----	0.826
95-----	.97	73-----	.82
90-----	.93	72-----	.81
85-----	.90	71-----	.806
84-----	.89	70-----	.80
83-----	.886	69-----	.79
82-----	.88	68-----	.786
81-----	.87	67-----	.78
80-----	.866	66-----	.77
79-----	.86	65-----	.766
78-----	.85	60-----	.73
77-----	.846	55-----	.70
76-----	.84	50-----	.665
75-----	.83		

¹ Specific heat of water, 1.0; specific heat of garbage solids, 0.33.

if the makeup of the garbage is known, additional accuracy might be attained by computing a specific heat of solids for that particular garbage. Values of the specific heat of food solids can be used for computing this value if the approximate solids composition and moisture content of the garbage are known.

EXAMPLE 4

For a garbage known to contain :

Food	Amount	C_p^1
White bread.....	$0.30 \times 0.375 = 0.11$	
Potatoes.....	$.30 \times .350 = .11$	
Parsnips.....	$.15 \times .333 = .05$	
Peas.....	$.10 \times .423 = .04$	
Beef.....	$.05 \times .372 = .02$	
Milk.....	$.05 \times .360 = .01$	
Ice cream.....	$.03 \times .394 = .01$	
Butter.....	$.02 \times .407 = .01$	
		Average $C_p = .37$

¹ C_p = Specific heat of food solids.

For a moisture content of 75 percent :

Specific heat due to water	----	$(0.75 \times 1.00) = 0.75$
Specific heat due to solids	----	$(0.25 \times 0.37) = .09$
		<hr/>
		Specific heat of garbage = .84
Calculated specific heat of the garbage		= .83

Because the makeup of different lots of garbage from the same source will vary considerably, the use of an average specific heat of food solids in calculating the specific heat of garbage

will probably give results as good as any that might be computed for it on the basis of its assumed makeup.

Laboratory Studies

To verify the accuracy of the calculated value of the specific heat of garbage, some experiments were run in the laboratory to determine the specific heat of several samples of garbage. In these tests, garbage samples were homogenized in a blender and tested in a homemade calorimeter. The laboratory tests were found to give a value of garbage specific heat within about 3 percent of the specific heat calculated on the basis of the proposed method. The proposed method should be checked, however, using a food calorimeter of the type in operation at the University of Texas (10).

Conclusions

1. The specific heat of garbage may be calculated with reasonable accuracy when the water fraction of the garbage is assumed to have a specific heat of 1.0 and the solids fraction is assumed to have a specific heat of 0.33.

2. The specific heat of garbage will normally range between 0.77 and 0.90 for moisture contents of 65 percent and 85 percent, respectively.

3. For determining the amount of heat re-

quired for cooking garbage, the specific heat should be assumed to be 1.0 if heat losses are not considered and 0.9 if heat losses are considered.

• • •

Tabulated values of moisture contents and specific heats for various foods may be obtained from the authors on request.

To Develop Cancer Drugs

A national voluntary program of cooperative research and development to find and produce effective drugs for the treatment of cancer has been launched under sponsorship of the American Cancer Society, Atomic Energy Commission, Damon Runyon Memorial Fund for Cancer Research, the Veterans Administration, the Food and Drug Administration, and the Public Health Service National Cancer Institute.

General guidance of the program will come from the Cancer Chemotherapy National Committee, established May 14, 1955, as the top policymaking body. The committee will define the scope of the program, develop general policies, assist in obtaining financial support for the work, coordinate the activities of the sponsoring organizations, and observe the rate of progress of the entire effort.

The committee will be headed by Dr. Sidney Farber, scientific director of the Children's Cancer Research Foundation in Boston and also chairman of the Chemotherapy Committee

of the National Advisory Cancer Council, Public Health Service.

Dr. Kenneth M. Endicott, National Cancer Institute, is executive secretary of the committee and in charge of the small full-time staff provided by the sponsoring agencies to administer the program, organize an information exchange, and give needed assistance to research scientists. Staff headquarters will be at the Cancer Chemotherapy National Service Center, National Institutes of Health, Public Health Service, Bethesda 14, Md.

Members of the committee are: Dr. Charles L. Dunham, Atomic Energy Commission; Mrs. Albert D. Lasker, National Advisory Cancer Council and American Cancer Society; Dr. Theodore S. Moise, Veterans Administration; Dr. C. P. Rhoads, Memorial Center for Cancer and Allied Diseases; Robert S. Roe, Food and Drug Administration; Dr. Antonio Rottino, Damon Runyon Memorial Fund; Mefford R. Runyon, American Cancer Society; and Dr. Leon A. Sweet, Parke, Davis and Company.

A comparative study of the efficiency of dry heat, dry heat and formaldehyde, and formaldehyde in a moist atmosphere for the sterilization of used bedding.

Efficiency of Dry Heat and Formaldehyde in Sterilizing Used Bedding

By ROBERT S. LLOYD, M.S., and MILTON J. FOTER, Ph.D.

DRY HEAT alone or in combination with formaldehyde is among the methods recommended for the sterilization of bedding materials by a number of State and local government agencies. This method, however, is subject to many procedural variations.

Little information has been published on the commercial sterilization or disinfection of bedding materials by heat or by heat and formaldehyde. Sprague (1) used formaldehyde gas to sterilize hair and feather pillows, mattresses, and blankets. He reported that the presence of moisture and the evacuation of the sterilizing chamber prior to the introduction of formaldehyde gas enhanced the effectiveness of formaldehyde on porous materials. He also recommended the use of at least one-fourth as much formaldehyde solution as the liter capacity of the chamber. Nordgren (2) stated that the sterilization of porous materials by formaldehyde gas could be attained only through previous evacuation of the sterilizing chamber.

Gibbons and associates (3) reported that hot, moist air at 275° F. for 24 to 30 hours disinfected mattresses, and that the vaporization of 80 pounds of formalin per 1,000 cubic feet of capacity was more effective for sterilizing mattresses in an evacuated chamber than in a chamber under atmospheric conditions. The American Standards Association, Inc., Subcommittee on Bedding Sterilization (4) reported that only surface sterilization was achieved in mattresses exposed to 230° to 270° F. for 1½ to 2 hours and that the combination of dry heat and formaldehyde at atmospheric pressure did not produce complete sterilization of mattresses even at elevated temperatures for prolonged exposure times.

Other methods of sterilization which have been considered include the use of ethylene oxide or mixtures of ethylene oxide and carbon dioxide (5), methyl bromide (6), and dielectric heat (7).

Methods and Materials

Escherichia coli, *Staphylococcus aureus*, *Mycobacterium phlei*, and spores of *Bacillus globigii* and *Aspergillus niger* were employed as test organisms for bedding contamination. The nonsporulating species were grown in a liquid nutrient medium at 98.6° F. for 24 hours.

Mr. Lloyd is bacteriologist with the Milk and Food Protection Laboratory, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati, Ohio. Dr. Foter is chief of the Aerobiology Unit, Bacteriology Section of the center.

B. globigii and the mold species were grown in or on a special spore medium at 98.6° F. and 86.0° F., respectively, for 4 to 5 days. Filter paper strips (Whatman No. 3, 2¾ by ½ inches) were inoculated with 0.5 ml. of a cell or spore suspension. The culture strips were dried at room temperature and viable counts of the organisms on several strips picked at random were determined by agar plate procedure. The strips were then transferred to 4 by 2½ inch paper or cloth envelopes which were inserted in or on the bedding surface for exposure tests.

The presence of viable cells in the bacterial culture strips after exposure was determined by transfer from the envelopes to tubes containing tryptose-phosphate broth and glycerol broth, and the mold spore-inoculated strips were placed in neopeptone-dextrose broth. The tubes were then incubated for 1 to 2 weeks at the optimum temperature of the test organism. Subcultures of the exposed culture strips exhibiting growth were examined microscopically for identification of the surviving organism. Inoculated but unexposed culture strips were subcultured as controls. Test results were recorded as the survival or nonsurvival of the exposed organisms in the culture tubes after subculturing. Percentage survival of the exposed organisms was not determined.

Untreated, used cotton-felt and spring mattresses and specially made cotton-felt and spring mattress sections enclosed in zippered

Figure 1. Electrically heated sterilizing chamber with 300 cubic feet capacity.

Figure 2. Nonpressure chemical sterilizing chamber with 300 cubic feet capacity.

mattress ticking were employed in the field studies. Samples of cored and uncored foam rubber (8½ by 4 by 1½ inches) wrapped in commercial mattress ticking were used in the laboratory studies. These materials were furnished by the Indiana State Board of Health, Indianapolis, Ind., and the Rubber Manufacturers Association, New York, N. Y.

Field Investigations

The major part of the field studies were conducted in commercial, nonpressure, mattress sterilizing chambers of approximately 300 cubic feet capacity (figs. 1 and 2). Air temperatures at several positions within the chambers were registered by recording thermometers. Temperatures on the surface and inside the bedding were measured by thermocouples.

Dry Heat

A number of the untreated, used mattresses and the zippered cotton-felt and spring mattress sections were placed horizontally on a mattress rack. Envelopes containing the inoculated and dried culture strips were attached to the surface of the top, middle, and bottom mattresses and inserted inside the zippered mattress sections. Additional thermocouples were also placed in these same locations to obtain temperature readings of the exposed bedding materials. The rack was transferred to a gas-heated chamber, which was equipped with a fan for circulating the air. Heat was introduced

until the desired test temperature, as recorded with a thermocouple unit, was reached inside the zippered spring mattress section. The exposure period was calculated from this point. Temperatures and exposure periods ranging from 230° F. for 2 hours to 270° F. for 1 hour were studied in these tests.

Dry Heat and Formaldehyde

In these studies, untreated, used cotton-felt and spring mattresses were suspended vertically from the mattress rack. Thermocouples and envelopes containing test culture strips were placed inside and on the mattress surfaces. The rack was then transferred to an electrically heated chamber, which was also equipped with a fan for circulating the air. Gaseous formaldehyde was generated by heating a liquid so-

lution of 37 percent formaldehyde contained in a shallow dish on the chamber floor. Temperatures ranging from 230° F. to 250° F. for 1½ to 2¼ hours and quantities of formaldehyde ranging from 1 pint to 1 quart per 1,000 cubic feet were tested.

To ascertain the formaldehyde concentration during the exposure periods, air samples were collected from the chamber at various intervals during the exposure period. Gas washing bottles, containing fritted glass disks and 100 ml. of 5 percent sodium bisulfite, were used to collect the chamber air from sampling ports located on one side of the chamber near the top, in the middle, and just above the chamber floor. The samples, collected at a rate of 8 liters per minute for 10 minutes, were analyzed for formaldehyde by the sulfoxylate method (8).

0=No growth after subculturing and incubation for at least 1 week.

+ =Growth after subculturing and incubation for at least 1 week.

The experimental commercial chambers for the study were made available by James Miller, Fred Franke Co., Louisville, Ky. and Otis Auer, Docona Associates, Glen Ridge, N. J. Technical assistance in gas sampling and analysis and in the development of operational procedures was given by H. G. Porter and Bruce Turney, Indiana State Board of Health, Indianapolis, Ind. and John Perkins of the American Sterilizer Co., Erie, Pa.

Laboratory Investigations

Because of the increased use of foam rubber in bedding materials, laboratory tests were made to determine the physical effects of steam under pressure (248° F. at 15 pounds per square

inch), dry heat (230° F.), and heat and formaldehyde in a humid atmosphere on foam rubber. Cored and uncored foam rubber samples, wrapped in mattress ticking, were employed in these tests. Unwrapped samples were also used for comparative purposes. Culture strips, containing the test organisms, were inserted in the samples to determine the bactericidal efficiency of formaldehyde and heat under moist conditions.

A standard laboratory hot air oven and an autoclave were employed in the heat and steam under pressure studies. The formaldehyde tests were conducted in a 1.5 cubic foot laboratory chamber in which liquid formaldehyde was vaporized from a shallow dish placed on the chamber bottom. Outlets were provided for

until the desired test temperature, as recorded with a thermocouple unit, was reached inside the zippered spring mattress section. The exposure period was calculated from this point. Temperatures and exposure periods ranging from 230° F. for 2 hours to 270° F. for 1 hour were studied in these tests.

Dry Heat and Formaldehyde

In these studies, untreated, used cotton-felt and spring mattresses were suspended vertically from the mattress rack. Thermocouples and envelopes containing test culture strips were placed inside and on the mattress surfaces. The rack was then transferred to an electrically heated chamber, which was also equipped with a fan for circulating the air. Gaseous formaldehyde was generated by heating a liquid so-

lution of 37 percent formaldehyde contained in a shallow dish on the chamber floor. Temperatures ranging from 230° F. to 250° F. for 1½ to 2¼ hours and quantities of formaldehyde ranging from 1 pint to 1 quart per 1,000 cubic feet were tested.

To ascertain the formaldehyde concentration during the exposure periods, air samples were collected from the chamber at various intervals during the exposure period. Gas washing bottles, containing fritted glass disks and 100 ml. of 5 percent sodium bisulfite, were used to collect the chamber air from sampling ports located on one side of the chamber near the top, in the middle, and just above the chamber floor. The samples, collected at a rate of 8 liters per minute for 10 minutes, were analyzed for formaldehyde by the sulfoxylate method (8).

temperature measurements, air sampling, and internal pressure readings. The air samples, collected at 2 liters per minute for 3 minutes through fritted disk gas washing bottles containing 5 percent sodium bisulfite, were analyzed for formaldehyde by the method previously indicated.

Results

Dry Heat. Results of the commercial sterilization of bedding by dry heat are shown in table 1. Spores of *B. globigii* survived exposures of 230° F. to 270° F. for 1 to 2 hours except when the culture strips were located on

the mattress surface near the top of the chamber. Nonsporulating cultures placed on mattress surfaces were destroyed under the test conditions. All cultures placed inside the cotton-felt mattress survived exposure at 230° F. for 2 hours.

Representative temperature data illustrate the elevation of temperatures at various locations in the chamber and in the mattresses (fig. 3). Temperatures of the chamber air and surface temperatures of mattresses placed near the top and in the middle of the rack increased rapidly to about 300° F. during the initial heating of the chamber. Surfaces of mattresses placed near the bottom of the rack required approxi-

mately 2 hours to reach the desired test temperatures. The desired test temperatures were never attained inside the cotton-felt mattresses exposed in the conducted tests.

No physicochemical tests were conducted to determine the effects of dry heat on exposed mattresses. Scorching was visible on the ticking of mattresses located near the top of the chamber where temperature readings ranged from 280° F. to over 300° F., which in most cases were considerably above the desired test temperatures. This indicated an uneven distribution of heat within the chamber during the exposure period.

Dry Heat and Formaldehyde. Spores of *B. globigii* survived in all the tests (table 2). The nonsporulating organisms were killed in all but one test when located on mattress surfaces but survived in some instances when placed inside spring mattresses.

Formaldehyde concentrations of the chamber air ranged from 30 to 90 mg. per cubic foot. Temperature readings during these studies were essentially the same as those shown in figure 3.

Results of Foam Rubber Tests. Discoloration, hardening and loss of elasticity and tensile strength were found in the foam rubber samples subjected to steam under pressure for a total of 3 hours or to dry heat at 230° F. for a total of 11 hours. Discoloration, brittleness, and drying of the mattress ticking were also noted.

No adverse effects were found in the foam rubber samples wrapped in mattress ticking and subjected for a total of 85 hours to formaldehyde gas (74 to 566 mg. per cubic foot) and heat (122° F. to 158° F.) at pressures of 0.56 to 4.1 pounds per square inch and at an indicated average of 50 to 90 percent relative humidity. Also no adverse effects were found in unwrapped samples of foam rubber exposed to approximately the same conditions.

Nonsporulating organisms and spores of *A. niger*, placed inside wrapped samples of foam rubber, were killed in 3 hours in the presence of about 440 mg. formaldehyde per cubic foot at 158° F. and an indicated average of 55 to 65 percent relative humidity. *B. globigii* spores survived. All test organisms were killed in 6 hours in the presence of 370 to 375 mg. formaldehyde at the same temperatures and relative

humidity. The efficacy of formaldehyde in a heated, moist atmosphere currently is being studied in a gas-tight commercial, mattress sterilizing chamber of approximately 280 cubic foot capacity.

Summary and Conclusions

Results of an investigation have been presented comparing the efficiencies of dry heat, dry heat and formaldehyde, and formaldehyde in a moist atmosphere in the sterilization of used bedding materials under field and laboratory conditions using *Escherichia coli*, *Staphylococcus aureus*, *Mycobacterium phlei*, and spores of *Bacillus globigii* and *Aspergillus niger*.

Except for the organisms inside cotton-felt mattresses, dry heat at 230° F. for 2 hours in a commercial sterilizing chamber killed all nonsporulating test cultures. Spores of *B. globigii* survived all temperatures and exposure periods tested.

Considerable temperature variations were found in the bedding and in the chambers when the chambers were heated to the desired test temperatures.

The addition of formaldehyde in quantities of 1 pint to 1 quart per 1,000 cubic feet of chamber space did not enhance the sterilizing effects of dry heat alone.

Marked effects were noted in foam rubber when subjected to dry heat at 230° F. and steam under pressure (248° F. at 15 pounds per square inch). No adverse effects were observed when foam rubber was subjected to heat at 122° to 158° F. and formaldehyde in a moist atmosphere. No viable organisms were recovered from artificially contaminated foam rubber exposed to an average of 376 mg. formaldehyde per cubic foot for 6 hours at 149° to 158° F. and an indicated average of 60 to 65 percent moisture.

technical publications

Directory of Full-Time Local Health Units, 1954

Public Health Service Publication No. 118. Revised 1954. 58 pages. 25 cents.

Revised July 1954, this directory brings up to date the listing of full-time health units serving local areas, together with the name of the health officer, or other designated administrative head, of each unit. The local units are listed by State, giving in each instance the health area jurisdiction, the post office address, and the health officer's name and his official title.

When the Migrant Families Come Again

A Guide for Better Community Living

Federal Interdepartmental Committee on Children and Youth publication. 1955. 27 pages; illustrated. 15 cents.

Addressed primarily to citizens in communities where there is a large annual influx of migratory farm and food processing workers, this pamphlet offers suggestions for building community programs to offer to the migrant worker and his family the basic things available to the average family—housing, good food,

churches, schools, recreation facilities, and store services. It describes what some community groups have done to help meet the health, education, and welfare problems arising during the season the migratory workers and their families are in the areas. Health agency personnel and community leaders will find in the pamphlet information to stimulate program planning to fit their community's specific needs.

The Clinical Center

Current Studies and Patient Referral Procedures

Public Health Service Publication No. 284. Revised 1954. 24 pages. 10 cents.

Useful primarily to physicians, this leaflet describes briefly the principal research projects to which patients are currently being admitted for study and therapy at the Clinical Center of the National Institutes of Health, Bethesda, Md. The procedure for referral of patients and the eligibility requirements are also explained.

The Clinical Center is a modern facility shared by all seven of the institutes of health concerned with basic laboratory investigations and research in the fields of cancer, cardiovascular disease, mental health, neurological diseases and

blindness, arthritis and metabolic diseases, microbiology, and dental health.

National Institutes of Health Annual Lectures, 1953

Public Health Service Publication No. 388. 1954. 102 pages. 45 cents.

Five lectures delivered in 1953 at the National Institutes of Health, Bethesda, Md., are published in this booklet: Tricarboxylic Acid Cycle—Enzymatic Mechanisms, by Seyero Ochoa; Philosophy of the Clinical Trial, by A. Bradford Hill; Changes in the Vulnerability of Tissue—An Aspect of Man's Response to Threat, by Harold G. Wolff; Regulation of ACTH Secretion, by C. N. H. Long; and The Gold-Headed Cane in the Laboratory (the third R. E. Dyer lecture), by René J. Dubos.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

| *Studies of bacteria with acquired resistance to drugs throw light on the mechanism of the resistance phenomenon.*

Genetic Basis of Acquired Drug Resistance

By M. DEMEREC, Ph.D.

UNTIL a very few years ago many biologists still questioned whether the hereditary mechanism that had been so effectively analyzed in *Drosophila*, maize, *Datura*, and mice, and found to apply to all the higher organisms, was also operative in lower organisms. Bacteriologists in particular were highly skeptical on this subject, probably because they considered it unlikely that such a simple mechanism, if it existed in bacteria, could have escaped detection in the course of their extensive physiological and clinical studies.

Within the past decade, however, there has been a striking change in the thinking of scientists about heredity in micro-organisms. About 10 years ago geneticists started to work with these organisms, and they developed for their

research special methods utilizing a broad background of information derived from studies of higher organisms. Their results have been spectacular.

Hershey (1) and Delbrück and Bailey (2) in 1946 found that crosses could readily be made between bacterial viruses (bacteriophages), and experiments by Visconti and Delbrück (3) in 1953 indicated that the transmission of paternal characteristics to the offspring of such crosses is in accordance with expectation based on Mendel's law. These findings mean that the basic genetic mechanism operating in the lowest and smallest of known living beings is similar to that operating in the higher organisms, and they suggest that the fundamental laws of heredity are general and apply to all life. They do not necessarily mean that the mechanism of heredity must be identical in all details throughout the living world, nor, in particular, that chromosomes, which have been established as the carriers of the determiners of heredity (genes) in higher organisms, must be present in the same form in all organisms. Indeed, we have good reason to believe that such chromosomes do not exist in bacterial viruses. It does seem very probable, however, that the basic threadlike structure of the chromosome, the chromonema, is similar in all organisms, but that the envelope surrounding the chromonemata may be absent in the lowest organisms, such as viruses, and present in a different form in some others.

Dr. Demerec is director of the department of genetics, Carnegie Institution of Washington, and director of the biological laboratory, Long Island Biological Association, in Cold Spring Harbor, N. Y. Numerous reports of his research dealing with studies of gene structure and gene mutations have appeared in the literature. This paper was delivered at a symposium on the nature of acquired microbial resistance to drugs, which was organized by the American Society for Pharmacology and Experimental Therapeutics, at the 39th annual meeting of the Federation of American Societies for Experimental Biology in San Francisco, April 14, 1955.

Whereas a single chromonema is extremely slender and very probably below the level of optical visibility, the envelope makes up the bulk of a chromosome and is responsible for its characteristic appearance as observed at certain stages in dividing cells.

The discovery that bacterial viruses possess a genetic mechanism similar to that operating in higher organisms would in itself have justified the assumption that such a mechanism is present also in bacteria, for it would be remarkable, indeed, if bacteria were set apart in a class by themselves as far as heredity is concerned. In addition to this indirect evidence, however, there is a considerable body of direct evidence about the genetic mechanism in bacteria, proceeding especially from the genetical work of Lederberg and his collaborators, and from cytological studies by Robinow (4) and DeLamater (5). Thus, we are now able to say with a fairly high degree of certainty that bacteria are not essentially different from other organisms with respect to the genetic mechanism, that is, that they possess genes and chromosomes.

In the early days of genetics, and in some quarters even recently, the opinion prevailed that biologically unimportant characteristics, such as body color, shape of various organs, and the presence or absence of hairs and bristles, were determined by genes, whereas biologically important and fundamental properties, such as taxonomic differences, fertility, and the functions governing development, were determined by some other, unidentified mechanism. But with the progress of genetic research the number of such "fundamental" properties that can be supposed to depend on some extragenic mechanism has rapidly decreased, and at present there is ample evidence to indicate that genes play a major role in the transmission of almost all hereditary traits.

For example, the results of early studies by Ephrussi and his collaborators indicated that cytoplasmic constituents were responsible for the inheritance of a "petite" colony type in yeast, but later these workers were able to show by ingenious tests that genes also play a decisive role. In this yeast, treatment with euflavine suppresses synthesis of the enzyme, cytochrome oxydase, by eliminating from the

cells the specific cytoplasmic components (mitochondria) that presumably produce the enzyme. The rate of multiplication of such cells is affected so that they form small colonies rather than colonies of normal size; and this pattern of growth is transmitted to the offspring. Thus, the character appears to be determined by the cytoplasmic units, mitochondria. Crosses made between these small-color cells and normal cells from another strain of yeast, however, showed that the synthesis of respiratory enzymes requires the simultaneous presence of a cytoplasmic factor and a dominant nuclear gene. The cytoplasmic factor appears to be dependent on the nucleus in its function although independent of it in its reproduction (6).

Origin of Resistance

With this brief introduction, in which I have stressed the likelihood that the same kind of genetic mechanism operates in all living organisms and that it plays an important role in the hereditary transmission of almost all characteristics, I shall now take up the problem of the genetic basis of acquired drug resistance. The following are well-established facts: (a) Bacterial strains more resistant to a certain drug than the original strain can be isolated, sometimes with great ease; (b) the degree of resistance may vary from slight to complete; (c) as a rule, the resistance is retained through a large number of transfers; and (d), again as a rule, the degree of resistance is not affected by many transfers. Thus, it is demonstrated that bacteria of such resistant strains have acquired a new property, which they transmit to their offspring, in other words, that we are dealing with a heritable characteristic.

With this information available, a geneticist would assume a priori that changes in genes—that is, mutations—are responsible for the origin of resistances, since it seems very improbable that some other mechanism could account for such a clear-cut and comprehensive change in properties. Substantial grounds for this assumption have been provided by experimentation carried out in several laboratories. The combined results have shown clearly: (a) that resistance is not induced by the presence of

drug but appears spontaneously, as one would expect if it is caused by gene mutation (7-14); (b) that crosses made in studies of resistance to streptomycin (15-18), chloramphenicol (19, 20), azide (21), terramycin (12), and furadroxyl (Nelson, quoted in reference 22) have given rise to Mendelian segregation and linkage, as expected in genic inheritance; (c) that in transduction experiments streptomycin resistance is transferred in the same manner as other genic characters (23); and finally (d) that in transformation experiments both penicillin resistance and streptomycin resistance are transferred like other genic characters (24-26). Thus, in manner of origin and in behavior in crosses, transduction, and transformation, the characters conferring bacterial resistance to drugs conform to the type of reaction usually observed in studies of gene-determined traits.

Within the past decade another important aspect of genic reaction has been explored. It has been found that not only radiations but also a considerable number of chemical compounds are able to induce mutations in genes, and—the significant point for our consideration here—that in every known instance the effect has been nonspecific; that is, in no case studied so far has a chemical been able to induce mutations only in a certain gene or only in genes affecting one particular property. Therefore, again, it would be very surprising indeed to find that treatment of bacteria with a drug had a specific effect on the gene or genes determining their sensitivity to that drug—a postulate implied by those who claim that bacterial resistance to a drug is induced by the drug itself. Fortunately, no such assumption is necessary to account for the observed fact that resistant bacteria invariably appear after exposure of cells to certain concentrations of a drug. This result is to be expected under circumstances that are well known to students of population genetics, namely, when a strong selection pressure acts on a large, nonhomogeneous population in which many genotypes are represented. A bacterial culture or a bacterial infection is just such a population. Since bacterial cells are very small, a tremendous number of individuals can be present in a relatively small volume. For example, 1 cubic millimeter would hold about 10^9 (a billion) cells of *Escherichia coli*. From

what is known about the frequency with which spontaneous mutations to drug resistance occur, it is to be expected that a population of that size would include mutants representing almost all the genes instrumental in resistance, and consequently that some bacteria resistant to any particular drug would be present. Treatment with a drug, then, would inhibit or eliminate the large body of sensitive individuals and thus would make it possible for the few resistant bacteria to multiply freely and produce a strain resistant to the drug used in treatment.

Patterns of Resistance

Studies of resistance to different drugs have shown that in the great majority of cases a high degree of resistance is attained only "stepwise," that is, through the occurrence of several consecutive mutations. From a sensitive strain we can isolate a mutant strain that is only slightly resistant (first-step resistance); another mutation occurring in such a strain will produce an increased degree of resistance (second-step resistance); and so on. With a few drugs, however, it is possible for some first-step mutants to possess a high degree of resistance. Thus, effective resistance either may be built up in several steps, or it may be attained through a single mutational event. The stepwise pattern of resistance development has been called the penicillin pattern, and the single-step pattern, the streptomycin pattern, after the drugs first used in analyzing the patterns (8). It is interesting to note that, as a rule, the resistance pattern is specific for the drug, in other words, that the origin of resistance to a certain drug follows the same pattern in all strains and species of bacteria.

Pattern of resistance has a very important bearing on the effectiveness with which physicians can avoid the development of highly resistant strains in clinical practice. The use of drug concentrations high enough to eliminate all first-step resistant organisms will preclude the buildup of high resistance where the stepwise pattern of origin is concerned, but no single treatment will be effective in preventing the origin of highly resistant individuals when one is dealing with the single-step pattern. Fortunately, only a small number of known drugs

elicit this single-step pattern of resistance—streptomycin, isoniazid, sodium *p*-aminosalicylate (PAS), erythromycin, and cinnamycin (27); all others are associated with the stepwise pattern.

Theoretically, it should be possible to avoid the development of strains resistant to the single-step pattern drugs by administering these drugs in combination with other drugs which act independently of them. In dealing with the stepwise pattern, also, the clinical use of combinations of drugs should still further reduce the chances for development of resistance. The reasoning on which this expectation is based can be outlined as follows. If the frequency of origin of mutant bacteria resistant to either drug A or drug B is 1 per 10 million (1×10^{-7}), and if mutants resistant to drug A are sensitive to drug B and vice versa, then the expected frequency of bacteria carrying both resistances is 1 per 10^{14} . Since only "double" mutants of this kind could survive appropriate treatment with a combination of drugs A and B, and thus become the progenitors of a resistant strain, the chance that resistant strains will develop is tremendously smaller when a combination of drugs is used in treatment than when a single drug is used. Laboratory experiments, the results of which are consistent with this theoretical expectation, have been reported by Szybalski and Bryson (28).

In clinical application of drugs, however, other factors than resistance may play a role in the survival of bacteria. Some cells may survive because they are located where they cannot be reached by a full concentration of the drug; others may be in a physiological state that confers a temporary immunity to its action. Under certain circumstances these factors may favor the selection of resistant mutants and result in the development of resistant strains in spite of treatment that theoretically should prevent such development.

In the present discussion I have emphasized the genetic mechanisms that participate in the origin of bacterial resistance to various drugs and have omitted any consideration of complicating factors, such as synergism, cytoplasmic constituents, and physiological aspects. A full discussion of these problems has been ably

presented in a comprehensive review by Bryson and Szybalski (27).

Trichophyton tonsurans Ringworm Spreading

A northeastern Michigan outbreak of ringworm infection caused by *Trichophyton tonsurans* was reported in the *Journal of the Michigan State Medical Society*, June 1955, pp. 687-690 and 727, by Eugene A. Hand, M.D., Saginaw, Mich., and Lucille K. Georg, Ph.D., Public Health Service mycologist.

The disease, previously almost unknown in the area, was reported endemic in both rural and urban sections of Michigan where there is a growing community of persons who have come from endemic areas in Mexico.

The Michigan outbreak is indicative of the spread of the disease on the North American continent, according to the Mycology Unit of the Public Health Service Communicable Disease Center.

Within the past 6 to 8 years, *T. tonsurans* infections of the scalp, glabrous skin, and nails have become endemic in New York and in the southwestern States, especially in Texas and southern California. Scattered cases have been reported from 13 States and Canada. Ringworm infections caused by this endothrix fungus have been common in Mexico and Puerto Rico for many years, whereas *Microsporum audouinii*, the common agent of ringworm of the scalp in the United States, is rare in those countries.

Public Health Service mycologists foresee the possibility that *T. tonsurans* ringworm may constitute a health problem in the United States similar to epidemic ringworm caused by *M. audouinii*. They point out, however, that the problem will be more difficult because the infections occur in both children and adults. The infections are harder to detect and usually are more refractory to treatment. Roentgen ray epilation is considered the treatment of choice.

The problem of *T. tonsurans* ringworm was previously presented in detail in *Public Health Reports*, January 1952, pp. 53-56.

State and Territorial immunization policies contain both useful variations and needless and confusing differences. Agreement on standards is advocated.

Variations in State Immunization Policies

By JOHAN W. ELIOT, M.D.

THE planning of a revision of immunization policies by the Arkansas State Board of Health in 1954 prompted a comparison of Arkansas' policies with those of the other States. Each State and Territory was therefore requested to furnish its current immunization policies to the Arkansas State Board of Health. Very helpful replies were received from all States.

Some of the States submitted their current policy statements with the understanding that revision was in process or planned. The District of Columbia and Washington preferred to wait until their revisions were completed before submitting material. Information on the two is therefore not tabulated.

Nine States, two Territories, and the District of Columbia are currently revising or planning revision of their immunization policies, and 15 States and 1 Territory have revised their policies within the past 2 years (table 1). Older policies are not necessarily out of date, as, for example, Oregon's thoughtful and thorough manual of 1950.

An increasing number of States are making

use of the Report of the Committee on Immunization and Therapeutic Procedures for Acute Infectious Diseases of the American Academy of Pediatrics (1). Eighteen States and three Territories used this report either in whole or in part, or are making it a basis for forthcoming revisions (fig. 1).

Compulsory Immunization Policies and Laws

The degree to which immunization policies constitute general recommendations to physicians or local health units, or specific regulations, vary and is not easy to determine in many cases. On one extreme Indiana, Maine, Ohio, Virginia, and Wyoming simply endorse the American Academy of Pediatrics report (1) for general use. On the other extreme Arkansas, Kentucky, Louisiana, Mississippi, Montana, North Carolina, North Dakota, Oklahoma, South Dakota, Tennessee, Texas, and West Virginia, in which a large number of immunizations are handled by public health personnel, have more definite policies. Alaska has made a major effort to set definite immunization policies because itinerant public health nurses must, at times, carry on their work far from any medical supervision. Puerto Rico has made a similar effort.

Hawaii seems to have the most specific and extensive compulsory immunization laws of any State or Territory. Hawaii legally requires

Dr. Eliot is pediatric consultant to the Arkansas State Board of Health and assistant clinical professor of pediatrics at the University of Arkansas Medical School, Little Rock.

universal inoculation against diphtheria, typhoid fever, and smallpox.

Six other States and one Territory were noted to have certain immunizations which are or could be required, or which have to be made available, by law. Arkansas requires smallpox vaccination by law before school entry. In Maine, each city, town, or plantation must provide free smallpox vaccination to all, and free diphtheria and pertussis immunizations to all children under age 12 annually. In New Jersey local boards of education are empowered to require diphtheria and smallpox immunizations before school entry if they deem these necessary. New Mexico requires smallpox vaccination for school children. North Carolina law requires that diphtheria and pertussis immunizations be given to all infants before they are a year old, although there is no indication of how this is to be carried out. West Virginia law requires all children to be immunized against smallpox and diphtheria, before or at the time of school entry, by private physician, county health department, or physicians specially appointed by county courts or municipal councils. Puerto Rico makes smallpox vaccination compulsory for all citizens.

Preschool DTP Immunization

The minimum age at which combined diphtheria-tetanus-pertussis antigens (DTP) may be started is 1 month in 4 States and 6 weeks in Mississippi (table 1 and fig. 2). The minimum age is 2 months in 19 States and Alaska. Five of the latter States simply endorse the 1952 American Academy of Pediatrics report, which says, "There is no objection to beginning immunization in the second month of life." Several States recommend that a total of four DTP injections be given if they are started at age 2 months. The minimum age for starting DTP injections is 3 months in 14 States and 2 Territories, and 4 months in 2 States and 1 Territory. Rhode Island recommends starting the vaccinations at 6 months. Four States do not specify a minimum age. North Carolina and Oklahoma do not supply the combined vaccine, but recommend starting pertussis vaccine at age 2 months and diphtheria toxoid at 6 months.

The maximum permissible interval between

injections in the primary DTP series varies a good deal (fig. 3). In 22 States and 1 Territory the interval is stated as 1 month, with no flexibility either way. Mississippi permits 5 weeks to elapse and 5 States allow 6 weeks. Two States and two Territories permit up to 3 months between injections, and three States permit a 4-month period. Up to 6 months is allowed between injections without asking that the series be started over in 8 States and 1 Territory, including those States which simply endorse the American Academy of Pediatrics report. A few States make no recommendation regarding this interval. Two States have continued with separate antigens. Oklahoma recommends a 1-month interval for each antigen, and North Carolina makes no recommendation as to interval.

The recommended age for giving the first DTP booster dose is fairly uniform in 35 States, Alaska, and the Virgin Islands. The age is stated as about 15 to 24 months or simply about 1 year after completion of the primary series (table 1). A few States recommend a shorter interval, varying between 4 and 10 months, before the first booster dose. Other States recommend that the first booster dose be given between ages 2 to 6. Rhode Island gives no routine DTP booster, but gives the series over if the child is Schick positive in the first grade. Most States advocate a DTP booster injection shortly before or at the time of entering school, although five preferred to omit the pertussis antigen after ages 2 to 4. Twenty-one States and four Territories feel it desirable to intersperse another booster dose between the first booster dose and the one at the start of school. Alabama feels that annual booster doses are necessary up to age 5 to maintain immunity to diphtheria.

DTP Immunization of School Children

There seems to be a fairly definite division between those States which do not continue pertussis immunization into the school years and those which do. Twenty-five States and one Territory make no recommendation of pertussis immunization in the school years. Twenty States and three Territories continue pertussis immunization in the school years. Of

the latter, 15 States and 3 Territories discontinue pertussis immunization after age 10, and 3 continue pertussis immunization in the form of DTP to ages 12 to 14. Two States recommend pertussis immunization to age 8. Colorado and Pennsylvania recommend it on exposure at any age.

Fifteen States and one Territory which do not recommend DTP vaccination in the school years advocate at least one dose of combined diphtheria-tetanus toxoids in this period. Six States permit diphtheria-tetanus toxoids as an alternate to DTP in the school period. Twenty-seven States and three Territories do not mention the use of diphtheria-tetanus toxoids in the school period. Seven States advocate separate diphtheria toxoid during the grammar school years.

Many States warn against the routine use of diphtheria toxoid for children over age 10 because of the increased possibility of bad reactions. However, 14 States have been recommending use of either usual or reduced doses of diphtheria toxoid, separately or as diphtheria-tetanus, through ages 12 to 15 (table 1). Michigan and South Dakota recommend the diphtheria toxoid at this age only for those who are Schick negative. Iowa recommends it only for those who are shown not to be sensitive to the toxoid. Those States which simply follow the American Academy of Pediatrics report presumably support its recommendation of a Schick test done at ages 12 to 14, and another 4 years later, to test immunity and to act as a small stimulating dose to arouse immunity. Vermont advocates repeated Schick tests at monthly intervals until the test becomes negative, if there is a special desire for immunizing a child over age 10 against diphtheria (usually 4 to 6 Schick tests). Rhode Island gives Schick tests to all school children in the first and fifth grades and gives Schick-positive children in the first grade a DTP immunization series or a diphtheria series in fifth grade.

Adult Diphtheria Immunization

It is evident that a number of States feel that diphtheria immunization can and should be extended to high school students. Twenty-seven States and three Territories also extend

immunization to adults under various special circumstances with preliminary Schick and, sometimes, toxoid sensitivity tests (table 2 and fig. 4).

So long as there were substantial numbers of diphtheria cases and carriers among children, most adults received occasional casual exposure to the disease which served to boost their immunity to it. This concept was expressed in the immunization literature of the Territory of Hawaii. However, numerous studies (2-4) have shown that with the decrease of diphtheria in children, adult populations are increasingly susceptible to the disease, and when the disease has assumed epidemic proportions, a marked shift of incidence into the adult population has been shown.

Seven States have expressed concern over this trend. Massachusetts has engaged in studies, paralleling and coordinated with those of the U. S. Armed Forces, to determine a dosage and type of diphtheria toxoid which can be given safely and effectively to adults without the administrative difficulties associated with the use of Schick and toxoid sensitivity tests.

As a result of these studies, the Massachusetts Department of Public Health, division of biologic laboratories, is now producing a combined fluid diphtheria-tetanus toxoid which contains about one-tenth the amount of diphtheria toxoid contained in the standard diphtheria-tetanus mixtures. This product is being used both for primary immunization and for booster immunization against diphtheria and tetanus in adults. It is similar to, but has even less diphtheria toxoid than, the diphtheria-tetanus toxoids used successfully by the Canadian armed forces for the past several years. The U. S. Armed Forces have developed a precipitated product with similar properties (5). None of these products requires prior Schick or toxoid sensitivity testing. Arkansas plans to utilize the type of material developed by the U. S. Armed Forces for diphtheria immunization in adults.

Tetanus Immunization Intervals

The importance placed on continued tetanus immunization in older children and adults varies a good deal. Nineteen States and two

Table 1. Summary of DTP immunization policies, United States and Territories

State or Territory	Date of last policy revision	Preschool children			School children		Diphtheria for adults when needed

¹ After Schick test. ² From State plan. No printed policies. ³ Use or planning to use the American Academy of Pediatrics report, 1952. (Date in parentheses indicates the States that adopted the report in lieu of separate policies.) ⁴ No Schick or toxoid sensitivity test. ⁵ Present policies not available. ⁶ After Schick and toxoid sensitivity tests. ⁷ After toxoid sensitivity test. ⁸ Diphtheria only, not DTP or diphtheria-tetanus. ⁹ Reference 6. ¹⁰ No written policies, but description of work is quite up to date. ¹¹ Primary series repeated at 6 years if Schick positive. ¹² Repeated Schick tests used.

Territories make no mention of routine tetanus toxoid booster doses beyond school age (table 2). Two States recommend that persons get a tetanus booster dose every 2 to 3 years. Eleven States and one Territory recommend this dose every 3 years. One State recommends an interval of 3 to 4, and 6 States recommend 3 to 5 years. Two States recommend a booster dose every 4 years, and 3 States recommend boosters every 5 years. Hawaii recommends a tetanus toxoid booster every 8 years, and Massachusetts recommends a 5-year interval through school years, and an interval of 10 years after school. Arkansas will follow the same schedule as Massachusetts.

Smallpox Vaccination Policies

The emphasis placed upon repeated smallpox vaccinations likewise varies from State to State, although nearly all States mention revaccination in the presence of a smallpox epidemic. Eighteen States and two Territories recommend revaccination at 5-year intervals throughout life, while others recommend it every 5 to 6 years, 5 to 7, 5 to 9, or 5 to 10 years (table 2). A few States recommend intervals of 3 years, 3 to 4, or 3 to 5, or 4 to 5 years. Connecticut recommends revaccination "periodically." Nine States and two Territories make no mention in their immunization policies of smallpox vaccinations continued on through school and adulthood, while Oklahoma continues smallpox vaccinations only through school. Ipsen, of the Massachusetts Department of Public Health, recently advocated an interval of 10 years between smallpox vaccinations in adults as providing a level of immunity in the population sufficient to prevent rapid epidemic spread of the disease (6). Arkansas will follow this policy.

Only a few States indicate how soon a smallpox vaccination should be repeated if it fails to take. Pennsylvania permits it to be repeated in 5 days, Missouri permits it in 7 to 9 days, and Arkansas, Michigan, and Oklahoma permit it in 2 weeks. Idaho, Iowa, and Mississippi require a 3-week wait, and New Mexico and West Virginia require 4 weeks between vaccination attempts.

Typhoid Immunization Policies

The giving of immunizations against typhoid fever is subject to wide variation. On one extreme are 10 States and the Virgin Islands which do not carry out this immunization or do not mention it in their policies. On the other extreme, Hawaii requires universal typhoid immunization by law. Most States take a middle ground, recommending typhoid immunization only for individuals exposed to a case of the disease or to a carrier, for individuals forced to use an unsafe water supply (as in disaster areas), for individuals dwelling in or traveling into areas where the disease is endemic, and sometimes for individuals about to go to a summer camp or about to travel generally. Most southern and southwestern States and Puerto Rico place greater emphasis on the immunization, or have done so in the past. These States generally recognize the need for this immunization on a routine basis in portions of their rural areas at the present time.

The interval permitted between typhoid vaccine injections in the primary series is about 1 week in 11 States and 1 Territory, 1 to 2 weeks in 3 States, 1 to 3 weeks in 1 State, and 1 to 4 weeks in 13 States and 2 Territories, and 1 month in 1 State.

A minimum age for starting typhoid immunizations is usually not stated, but in 14 States typhoid vaccine is given at any age when indicated. In 5 States and 1 Territory it is given at age 1 or under when needed, and in 2 States only over age 1.

Of the 37 States and 3 Territories which mention typhoid immunizations, 22, including Arkansas, authorize and encourage the use of intradermal typhoid booster doses, either in their own publications or through endorsement of the American Academy of Pediatrics report. The other States simply do not mention intradermal typhoid booster doses; no State specifically forbids them.

The interval between typhoid booster doses is set at 1 year in 10 States, at 1 to 2 years in 13 States and 1 Territory, at 1 to 3 years in 1 State, at 2 to 3 years in 1 State, and at 3 years in 3 States, including Arkansas. It is not mentioned in the Puerto Rico manual.

¹ Typhoid immunizations not mentioned in policies of Delaware, Kansas, Massachusetts, Montana, New Jersey, New York, North Dakota, Pennsylvania, Rhode Island, Wisconsin, and the Virgin Islands. ² Present policies not available. ³ Before or after DTP. ⁴ As recommended in reference 6. ⁵ Only mentioned as a procedure to be done by private physician. ⁶ With DTP or 1 month later.

Public Education

Some States furnished samples of immunization information available to parents, and presumably most States have such material. Some of these pamphlets are very thoughtful and attractive, for example, those from Connecticut, Delaware, Idaho, Massachusetts, Minnesota, Nebraska, Wisconsin, and Hawaii.

Special emphasis is put on public information and education concerning immunizations in various ways by different States. Arkansas stresses information for the public and for school authorities in its new question and answer manual concerning immunizations. Delaware sends a letter concerning immunizations to every family as the new infant nears 4 months of age. The Iowa immunization manual places thoughtful emphasis on the approach to immunization, carefully preparing parents and children for the experience, and educating them on the nature and value of the immunizations.

In Kansas distribution of immunization information is made through the schools. Kentucky's manual contains a helpful question and answer section intended to prepare the person giving immunizations for some questions commonly asked by parents. Maryland's immunization schedule places emphasis on health education of the family concerning the nature, need, schedule, and value of immunizations at the time they are given.

Nebraska has a manual for community leaders concerning immunization programs, and, for teachers, quite extensive classroom discussion guides on immunizations. New Jersey has a thorough manual on communicable diseases for its schools. Both North and South Dakota stress preplanned public education by many routes.

Puerto Rico has prepared immunization policies in Spanish. Vermont uses a Canadian leaflet printed in French for its French-speaking population. There are doubtless many other special considerations and measures taken to assure public education in various States, which did not come to this reviewer's attention.

Tuberculin Testing

Tuberculin testing is considered along with the immunization program in certain States.

Idaho recommends tuberculin testing of children at age 1 and again at age 3. Iowa mentions routine tuberculin testing of children. Michigan advocates tuberculin testing of children at ages 2 to 3. Texas uses tuberculin testing in its well child clinics, but cautions against mass school tuberculin testing without adequate followup.

Discussion and Conclusions

The general impression gained in this comparative review of selected aspects of the immunization policies of the States and Territories is that some of the variation from one area to another is desirable and sensible, but much of the variation is needless and confusing. There should always be room for individualization of immunization programs, but there is no reason why there could not be more common agreement on standards of reference. The increasing use of the American Academy of Pediatrics report represents a trend in this direction.

One characteristic of immunization policies stood out. In virtually no other medical field have action policies been laid out with so little regard for citation of references or sources. In a sense, those States which have referred to the American Academy of Pediatrics report have cited authority, but the report itself (1952 edition) cites not a single reference to original studies. Apparently it has relied solely upon the organization's name to persuade the reader of the validity of the recommendations. Iowa, Kentucky, Oregon, Utah, and West Virginia present exceptions to this general observation, as they cite some references in their immunization policies. The manuals of Michigan and Pennsylvania are so thoughtful and thorough that they could not have been written without extensive knowledge of original studies, even though no references were made to such studies.

Massachusetts, with its own extensive program of original investigations of antigens and immunization schedules, occupies a unique position. Arkansas, with no facilities for original investigation, has felt a compulsion to cite the studies of others in justifying the current revisions made in its immunization policies and has embodied this bibliography in a question and answer manual on its immunization policies.

technical publications

Research Grants and Fellowships Awarded by the Public Health Service in 1954

Public Health Service Publication No. 423. 1955. 70 pages. 25 cents.

This booklet lists alphabetically by State and institution all research grants and research fellowships awarded by the National Institutes of Health, Public Health Service, for the period July 1, 1953, through June 30, 1954. There were 2,855 research grants in the amount of \$29,951,150 and 490 research fellowships in the amount of \$2,132,004.

These grants and fellowships went to individuals in 372 institutions, located in 43 States, 2 Territories, the District of Columbia, and in 13 foreign countries.

Premarital Health Examination Legislation

Public Health Service Publication No. 383. 1954. 114 pages. 40 cents.

A compilation of the laws now in effect in 40 States and in Hawaii and Alaska, requiring a blood test and a physical examination for venereal disease as prerequisites for obtaining a marriage license, is contained in this publication. A history of the efforts to obtain enactment and an

analysis of the effectiveness of such laws are included.

A copy of the law in effect in each State or Territory is reproduced with citations to the legal sources.

Studies on Household Sewage Disposal Systems—Part III

Public Health Service Publication No. 397. 1954. 134 pages. \$1.00.

Part III of these studies includes data and findings on single and multicompartment septic tanks, sludge and scum accumulation, soil-absorption capacity, clogging characteristics of septic-tank effluent, effect of zeolite softener salts, effect of ground garbage and synthetic detergents on household disposal systems, evapotranspiration and plant growth, and investigation of various distribution devices, sludge and scum measuring devices, design improvements, and septic-tank "cleaning" products.

Parts I and II of this report dealt with studies on individual sewage-disposal systems conducted at the Robert A. Taft Sanitary Engineering Center (then the Environmental Health Center), in Cincinnati, Ohio, from November 1946 to July 1949. Part III continues from that point to the end of the studies in June 1953.

The broad program of studies was financed jointly by the Housing and Home Finance Agency and the Public Health Service.

Poultry Ordinance, 1955

Public Health Service Publication No. 444. 1955. 37 pages.

This model ordinance prepared for use by State and local governments to supplement Federal regulations came about through close cooperation among the Federal agencies concerned, State and local health and agricultural authorities, and the representatives of the poultry industry.

The ordinance embodies the best available information on poultry sanitation at the present time. It will be revised as new experience or research indicate. The current issue was prepared with the assistance of a public health-industry committee.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Although data available do not permit an accurate appraisal of Navajo health conditions, mortality and morbidity rates appear to be unnecessarily high.

Health Conditions Among Navajo Indians

By J. NIXON HADLEY

THE NAVAJO Reservation, located at the only point in the United States where four States meet, occupies portions of Arizona, New Mexico, and Utah. It is a territory of about 25,000 square miles, approximately the same size as the State of West Virginia. It is an isolated territory, difficult of access. A major United States highway, No. 66, barely touches the southern border, and two subsidiary highways flank the reservation to the east and west. In between these, there are less than 100 miles of all-weather roads, according to a recent estimate (1).

The people whom we call Navajo call themselves *Dineh*, which means "The People." The name implies a feeling of self-sufficiency, a feeling which past history confirms. The Navajos occupy today approximately the same lands that they occupied before the arrival of Columbus. This occupancy has been continuous, except for 4 years' captivity at Fort Sumner in

eastern New Mexico after their subjugation by the Army about 90 years ago. The return was at their own request, because of their desire to live their own style of life in their home country. After the return few contacts with the surrounding white people were available or desired. As a result, the majority of the Navajos, even today, do not speak English, cannot read or write in any language, and follow a culture pattern which is still basically Navajo rather than white-American.

The isolation of the Navajos began to break shortly before World War II. The tribe had increased steadily, from about 9,000 in 1868 at the return from Fort Sumner to nearly 50,000 in 1940. The reservation, although large in acreage, is an arid land that can support no more than 35,000 persons at a minimum subsistence level (1). Overgrazing by the sheep and goats needed to maintain 50,000 persons at even a starvation level was deteriorating the land still further. Reduction of livestock to carrying capacity of the range was essential to avoid its complete destruction. This program involved the Navajo families in new contacts with non-Navajos representing the Soil Conservation Service and the Bureau of Indian Affairs, and, since emergency relief programs were substituted for lost income from livestock, with the Civilian Conservation Corps, the Public Works Administration, and other agencies. World War II increased outside contacts. Nearly

Mr. Hadley, a statistician, is a staff member of the Indian Health Survey in the recently created Division of Indian Health, Bureau of Medical Services, Public Health Service. He was chief statistician of the Branch of Health, Bureau of Indian Affairs, Department of the Interior, from 1951 until the branch was transferred to the Public Health Service on July 1, 1955.

4,000 Navajos were in the armed forces, and wartime labor shortages brought about such active recruiting even among non-English speaking Navajos that 15,000 worked off the reservation (1).

At present the Navajos are well aware of the surrounding world. They look to it for trade and employment as a supplement to their inadequate land resource. With increased contacts, attitudes are changing in regard to their need for education, medical care, and other similar benefits. Nevertheless, at present the Navajo is described as "ill-fed, ill-housed, sick, and uneducated" (2), even though prospects for future improvement are encouraging.

Population Estimates

The members of the Navajo Tribe today probably number more than 70,000, but this figure is only a rough estimate. The last complete count was made in connection with the issuance of ration books during World War II. On the basis of this count, reports of vital events, and the United States census of 1950, the Navajo Agency estimates that in 1950 there were 69,000 Navajos who were residents of the Navajo Reservation or the adjacent allotted and public domain lands in New Mexico (3). The 1950 census could serve as only a partial check on the World War II count, primarily for two reasons.

First, the census recorded tribal affiliation of Indians only within the boundaries of major Indian reservations. Hence, it is known that there were 55,000 Navajos within the boundaries of the Navajo Reservation at the time of the census. Outside the reservation boundaries in New Mexico, there is a sufficiently large number of Navajos allotted on public domain lands to require that a hospital be operated at Crown Point for their benefit. Since tribal data are not available for Indians outside the reservations, the Navajos in this area cannot be tallied specifically, but the census reported about 9,000 Indians in this area who would be preponderantly Navajo.

Second, no allocation to place of residence was made in the census for migratory laborers, who were assumed to be residents of the place where they were found. As was indicated

above, the Navajo has a strong sense of attachment to his home country, and, consequently, even though forced by economic need to off-reservation employment he will normally return to the reservation at frequent intervals. It is a matter of record that in 1950 there were about 8,000 Navajos working intermittently for the railroads but who were also maintaining residential ties on the reservation. It is estimated that about 2,000 additional Navajos were working in mines, timber lands, reclamation projects, and the like in areas away from the reservation. An unknown, but probably minor, proportion of these were permanent nonresidents of the reservation.

It is not possible to determine exactly how many of the 9,000 Indians reported from the public domain area are Navajos, nor is it possible to determine exactly how many of the 10,000 Navajos working on nonreservation jobs should have been, but were not, reallocated in tabulations by residence to the reservation. It would seem, however, that the estimate of 69,000 resident Navajos in 1950, including public domain allottees and persons engaged in temporary off-reservation employment, might be low rather than high.

Reporting of Vital Events

If the estimated figure for resident population is inaccurate, the main reason is to be found in the under-reporting of vital events. The test of birth registration completeness made in connection with the 1950 census throws some light on the problem of under-reporting. The test was conducted through the cooperation of the Bureau of the Census, the National Office of Vital Statistics, and the various State, Territorial, and independent city registration officials. It involved an attempt to match birth certificates with cards prepared by the census enumerators for all infants found by them who had been born during the 3-month period preceding the date of the census (4). For the six counties which include the Navajo Reservation, the birth registration test revealed that the names of less than one-half of the Indian infants born during the test period could be matched to filed birth certificates, according to unpublished tabulations prepared by the National Office of

Vital Statistics. This is an improvement over 1940, when less than one-fourth could be matched (5).

In considering the results of the birth registration tests as a measure of registration completeness among the Navajos, however, it should be remembered that they represent the degree of success in matching names between two records for an illiterate and non-record-conscious people whose culture allows for easy change of name. The same individual may be known on different records as Silversmith's Son, recorded in either English or Navajo; Tall Man, recorded in either English or Navajo; and John Jones. If the recordkeeper knows a little Navajo, the identity of the Navajo and English forms of the same name may be recognized, but only field investigation will develop the identity of the three independent variants. Consequently, although we know that out of about 600 names on the Indian infant cards prepared by the census enumerators in the 6 Navajo counties there were approximately 300 that were not matched to birth certificates, we do not know how many unmatched birth certificates also remained.

A basic assumption of the birth registration test was that the infants listed on the infant cards were a representative sample of all infants and therefore that the addition of infants not listed would not affect the proportions of registered and unregistered births. Thus, there was an implied assumption that birth certificates not matched to cards represent infants for whom no card was made. As indicated above, this is not a safe assumption for the Navajos because of their custom of using alternate names. A possible alternative assumption is that the infants listed on the infant cards were a representative sample of the ratio of medically attended births to total births, an assumption which provides a slightly different estimate of birth registration completeness among the Navajos.

According to the census enumerators' reports, 47.5 percent of the 638 Indian infants born during the 3 months of 1950 in the Navajo area counties were delivered by a physician (table 1). Registered Indian births within these counties during all of 1950 have not been tabulated by person in attendance, but nonwhite births have. Since there were only 70 non-Indian

births among the 2,391 nonwhite births, the nonwhite births can be taken as representing Indians. According to the birth certificates filed for nonwhite residents during 1950 (6), 1,865 of the births were attended by a physician (table 2). If it is assumed, then, that these 1,865 births represented only 47.5 percent of the total number of births, the proportion reported by the census enumerators for the first 3 months, it can be estimated that there were actually about 3,900 total births during 1950, of which slightly more than 60 percent (2,391) were registered.

The 60-percent estimate of birth registration completeness corresponds moderately well with a 1944 estimate that about one-third of the births were not registered (7). However, the number of uncontrolled variants in all of these estimates is so large that about all that can be said with assurance is that a large but unknown proportion of Navajo births are not registered.

No data are available on the extent of under-registration of deaths among the Navajos. Since a considerable proportion of deaths occur in infancy and early childhood, it is assumed that an appreciable number are not recorded, but a percental measure of the degree of under-registration does not seem readily attainable.

Birth and Death Rates

The effect of under-reporting of vital events on Navajo birth and death rates is evident in

Table 1. Indian births during first 3 months of 1950 in Navajo area counties, as reported by census enumerators

State and county	Total number of births	Attended by a physician	
		Number	Percent
Total-----	638	303	47. 5

Navajo County.....	502	342	68. 1
New Mexico:			
McKinley County.....	577	450	78. 0
San Juan County.....	273	229	83. 9
Utah:			
San Juan County.....	39	15	48. 7

every study that has been made of Navajo health conditions. Two recent studies made by the Bureau of Indian Affairs will demonstrate the point (8, 9). These studies were based on Indian births and deaths by county as tabulated by the National Office of Vital Statistics. Rates were calculated on the resident Indian population as reported by the 1950 census. As indicated above, the census figures are probably an understatement to the extent of the number of persons absent as migratory laborers. If these persons were included in the base population, it would, of course, decrease the rates.

Without correction for underestimation of resident population or for under-reporting of births and deaths, the birth rate for the period 1949 through 1951 was calculated to be 32.7 per 1,000 resident population and the death rate to be 12.6 per 1,000 resident population. Both figures are lower than would be expected. The Apaches of San Carlos and Fort Apache Reservations of Arizona, one of the nearest neighbors to the Navajos, are reported to have a crude birth rate of 40.3 and a crude death rate of 19.6. The difference appears to be more likely under-reporting among the Navajos than any marked difference in actual conditions of the two groups.

Bearing in mind that rates for the Navajos are understated by an unknown but appreciable amount, a comparison of Navajo age-specific death rates with United States averages, as shown in table 3, is of interest. (The Navajo rates were calculated from National Office of

Vital Statistics data as described above.) Even on an understated basis the Navajo death rate for infants and preschool children is 5 times as high as the United States average. The infant mortality rate per 1,000 live births for the Navajos is 139.4, also about 5 times the United States average. The death rates for children of school age are about 3½ times as high, and for young adults, more than 4 times as high. Navajo death rates markedly exceed the United States averages at those ages when deaths are preponderantly from communicable diseases or accidents, that is from the most readily preventable causes. In the older age groups, Navajo death rates are as low as or lower than the United States rates.

Causes of Death and Illness

The National Office of Vital Statistics has not tabulated deaths by cause for Indians in the six Navajo counties. The only cause-specific data available are those provided by the hospitals and clinics under the supervision of the Bureau of Indian Affairs. These data are still less complete than those in the tabulation above (which included all known deaths to Indian residents of the six counties), apparently covering about three-fourths of the deaths.

Without adjusting the data for under-reporting, they show that the three leading causes of death for the calendar year 1950 were tuberculosis, gastroenteric diseases, and ill-defined and unknown causes. Rates for these causes

75 and over.....	57. 1	109. 6	. 52

for the Navajos and the total United States population are given in table 4. The next three causes of death among the Navajos in 1950, according to Bureau of Indian Affairs data, were diseases peculiar to infancy, influenza and pneumonia, and accidental deaths. None of the three leading causes for the general population—diseases of the heart, malignant neoplasms, and vascular lesions affecting the central nervous system—was among the six leading causes for the Navajos.

Morbidity data for the reportable diseases are available for the calendar year 1953 from the same sources as deaths by cause, and it may be assumed that they are under-reported to at least the same degree as are deaths by cause. Even then, the case rates for many diseases are extremely high, as can be seen in table 5 (10).

Trachoma, a disease of negligible importance for the United States as a whole, is still one of the leading diseases among the Navajos. The rate for new cases not previously reported is nearly 600 per 100,000 population. Rates of more than 1,000 new cases per 100,000 population are reported for pneumonia and for tuberculosis. Rates for most of the common infectious diseases of childhood are high, particularly measles and mumps, for which rates are $2\frac{1}{2}$ times the United States rates. However, scarlet fever and streptococcal sore throat are reported less than one-fifth as frequently as in the total United States population.

The major venereal diseases are reported about 3 to 6 times as frequently among the

Navajos. No cases of the minor venereal diseases were reported, but in a population of less than 100,000 the probability of uncovering a case of a comparatively rare disease is not high.

Dysentery is over 10 times as frequent among the Navajos as in the total United States population, with a rate of about 150 per 100,000. This includes both bacillary and amebic dysentery. If data were available on the incidence of all gastroenteritis and diarrhea, hospital experience indicates that it would be one of the leading causes of illness.

Summary

Measurement of health conditions among the Navajos is hampered by lack of complete data either on the base population involved or on deaths and illnesses. Even with this lack of specificity, however, it is obvious that mortality and morbidity rates for most of the major dis-

eases are far in excess of the rates for the total United States population.

Memorandums on Economic Poisons

In April 1955 the Technical Development Laboratories of the Communicable Disease Center, Public Health Service, made available its annual revision of the material on economic poisons. In mimeographed form, the memorandums are designed primarily for the guidance of physicians who are directly concerned with diagnosis and treatment of persons extensively or intensively exposed to insecticides.

Each clinical memorandum, after briefly giving information on the identity, formulations, and uses of a poison, discusses its toxicology with special reference to human cases, the dangerous dose in man, laboratory findings, and treatment. Each operational memorandum gives formulations and procedures for the control of the various susceptible insects or rodents that are of importance to public health. The chemical memorandums deal with the preparation of biological samples and their analysis for insecticides.

The revision contains separate clinical and operational memorandums on benzene hexachloride, chlordane, DDT, demeton, dieldrin, dilan, parathion, sodium monofluoroacetate (1080), TEPP, toxaphene, and warfarin. There are also clinical memorandums on dinitrophenols, kerosene, and xylene; and operational memorandums on aldrin, allethrin, ANTU, DDD, Diazinon, Dipterex, EPN, heptachlor, lindane, malathion, methoxychlor, Pival, and pyrethrum. There are chemical memorandums on DDT and lindane.

Persons who may have use for such memorandums may request copies from the Technical Development Laboratories of the Technology Branch of the Communicable Disease Center, U. S. Public Health Service, Box 769, Savannah, Ga.

PSYCHOLOGY OF AGING

Bethesda Conference

A conference to plan for research on the psychological aspects of aging was held April 25–27, 1955, at the National Institutes of Health, Public Health Service, Bethesda, Md., under the joint sponsorship of the American Psychological Association and the National Institute of Mental Health. Twenty-seven experts in the fields of psychology, biology, and sociology—many of them former leaders in child psychology—met to consider the most profitable methods for studying the aging process from infancy through old age. Public Health Reports presents in brief eight papers from the conference as representative of the five panels of the program.

Two Aspects of Adjustment

PHR Members of this panel on the personal and social adjustments made by the aging person have fixed their attention on the adult years, from 30 or 40 to 60 or 65. They agree that adjustment has two aspects: an outer aspect, that of social adjustment, and an inner aspect, that of personal adjustment.

According to Kuhlen, external observers evaluate the social adjustment of a person in terms of his objectively measured capacity to function appropriately and efficiently in his dealing with the external world. Efficiency and performance on the job or status and functioning within a group, as viewed by that group, represent examples of social adjustment.

With respect to inner adjustment, Kuhlen believes that a person is deemed to be personally adjusted to the extent that he achieves a relatively integrated satisfaction of his various psychological needs; experiences a pleasurable sense of well-being, contentment, and relative freedom from unpleasant tension and anxiety; and is able to maintain this state of affairs by dealing with frustrating and threatening situations constructively and with a minimum of handicapping emotional stress.

Three papers are concerned mainly with personal adjustment, and a fourth—my own—deals with social adjustment. The papers on personality agree in using concepts which mean that a person who is well-adjusted is able to cope with a complex world. These concepts are: affective complexity (complexity of emotional reactions to a complex world), tolerance of ambiguity, flexibility, expansion. Indicative of poor adjustment are the concepts of

rigidity, simplicity, constriction. None of the three papers attempts to set out explicit criteria for good adjustment, or successful aging, yet each one offers some implicit criteria of success.

Kuhlen writes of the "quality" of adjustment as dependent on the satisfaction of certain basic psychological needs, but his interest lies more in describing and measuring changes in personal adjustment during the adult years than in measuring quality of adjustment.

Peck describes some variables which clearly have a favorable meaning for adjustment, but he does not seem to be willing to postulate these as conveying the meaning of the term "successful aging."

Henry says that affective complexity and clarity of perception of available roles in the individual's social life space might be the major variables for describing personal adjustment. He concludes that these two factors are not seen as necessarily being definitive of the concepts of adjustment or successful aging but as providing an important empirical basis for subsequent study of persons independently judged successful or unsuccessful in respect to general life adjustment or to some specific life role.

Henry writes that all situations in adult life involve stress for the individual and that it is the manner of adaptation to this stress which constitutes the variable of greatest importance in successful living.

It might be useful for members of this panel to explore the extent of agreement and disagreement between Henry's strategy of studying the individual's ways of coping with the complexities and stress of the world and the proposals by Peck and Kuhlen that it is not so much the person's way of adapting to his life situation which is important but rather his retaining the offensive in his approach to life so as to maintain activity and expansion.

Another path for exploration is that of the techniques and the most useful combinations of techniques we can use in the study of adult personality.

Henry relies on projective techniques—the thematic apperception technique and the sentence completion test—which reveal the inner personality. Peck would use an intensive personal interview, supplemented by projective in-

By Robert J. Havighurst, Ph.D., professor of education, University of Chicago. As coordinator of the opening panel on research on personality and social adjustment, Dr. Havighurst in his paper summarized and commented on the papers of William E. Henry, Ray G. Kuhlen, and Robert F. Peck.

struments, self-ratings, and interviewer ratings. Kuhlen uses attitude scales and other forms of self-report.

Still another question for consideration is that of the nature of the group of people to be studied. Normal people should be studied, we all agree, but should they be selected on a sample basis at random from the population or from certain social classes or occupational groups? Should they be volunteers who are happy to cooperate in our research, or should they be a randomly selected group containing those who are neutral or even hostile to our research?

Assessment of Aging

PHR

In both physiology and psychology, work on animals has made such extensive contributions that from the standpoints of theory and practice it is impossible to trace many significant generalizations to either area, so interwoven are animal and human studies. In the field of aging, however, interest is only now returning to animals after a lag of some 30 years. Yet animals with their short life span and great possibilities for control of conditions are ideal for aging studies. Calhoun examines this area in some detail.

One can say that every scientific problem on human beings at some point dips into the genetic background of the person. Even longevity varies with and within species and leads to the assumption of upper limit to the life span for the individual and the species.

Have we really modified that limit by our

changing life expectancy, or has it remained substantially the same?

Kallman points out that there is a wide variety of other genetic problems within this general area. Studies of the genetic basis of aging are important both for understanding what happens to older persons and for the understanding of all life.

Underlying human behavior is the nervous system, which not only is our trigger, tracking and holding device, but also the integrator. Modern developments in the construction of computers and automation have given new insights into the range and variety of its functions.

Streicher shows that, although the changes in the aging nervous system are substantial and cumulative, their significance for behavior is not altogether clear.

Here is a link between Calhoun and Kallman. Genetic studies of aging in animal nervous systems along with experimentally introduced conditions and subsequent studies of nervous structures in animals offer much hope, not only as supplements to studies on human beings but also as ways of obtaining knowledge of fundamental relations.

If we consider the human being as a communication system which converts incoming stimulation into activity, the speed with which that system transmits messages becomes an important factor.

Birren's paper is devoted to this important problem. In a sense we are viewing the functioning of the nervous system from another angle. Perhaps the phenomena described by Streicher are reflected in the phenomena described by Birren.

Environmental Settings

Kleemeier's concern is with the effect of environmental settings upon the behavior and adjustment of older persons. This is a very large area with many psychological implications that have never been fully explored, yet millions of dollars are expended each year in the design of living arrangements for older people.

A multitude of problems of psychological moment have arisen in the design of institutions and homes for older people upon which a psy-

By John E. Anderson, Ph.D., professor, University of Minnesota, and former director of the Institute of Child Welfare. Dr. Anderson, as chairman of the panel on the assessment of aging—background in theory and experiment, summarized papers presented by James E. Birren, John C. Calhoun, Franz Kallman, Robert W. Kleemeier, and Eugene Streicher.

chologist should be able to give advice, but he finds little in the literature with which to answer the practical questions of the architect.

How many foot-candles of illumination should be provided for older people?

How thick should walls be to control noise?

What types of knobs and catches are easiest for old people to manipulate? Where should they be located?

What types of equipment and materials facilitate self-help? How do you teach an old person to learn to use the equipment?

We need to know both the optimal pattern, arrangement, or design, and how to bring the old person to adapt to it.

Another interesting problem of settings concerns the relation of design to findings in other scientific areas. To what extent should the design of living arrangements take into account activities and recreation?

Cataloging Changes With Age

It seems to me that many features of decline in older persons resemble aspects of growth in children. Decline like growth is neither uniform in all individuals nor for all processes and functions within the individual. Quite apart from pathological changes, variations in the rate and character of declines appear.

Much as in the earlier period of growth studies, we need to describe and plot these changes in a wide variety of structures and functions against time or age in order to catalog what occurs. Problems of the interrelations of these various declines then arise.

Is there an overall commonality in decline which can be used as a base from which to analyze the decline of particular parts or structures, or is it the summation of a host of specific declines?

There are also the problems of the point at which decline begins and the point at which it becomes crucial for the functioning of the part and of the organism as a whole. These problems resemble those of the initial and terminal points for growth.

In addition, we need detailed information on the effect of age upon the rate of recovery from insults and upon the rate of learning. Both of these involve specifically designed experimental

studies, with care exercised to explore the phenomena at several scattered age levels since we need to know the age ranges over which such basic mechanisms operate.

In modern psychology there has been a movement toward so-called hypothesis research in terms of theoretical models and constructs. But in the study of living organisms such developments represent an advanced stage in the history of science, which appears only after a great wealth of descriptive, observational, and crude experimental data is available. From this point of view the scientific study of aging is still in the exploratory and programing stage.

Studies, then, of a variety of structures and processes made on cross sections of persons sampled by age and by other criteria from the population in ways that can be described with precision are badly needed. We find many areas of meager information on what seem to be simple and obvious variables. Our cataloging has been haphazard rather than systematic.

Neglect of Sampling

In contrast to the many well-designed studies at earlier age levels, we find masses of anecdotes, case studies, and surveys often presented without specific age reference. We find many studies in which individuals from 60 to 85 are grouped together without any age breakup of the data, yet no good basis exists for this grouping since we know that the change that occurs from 60 to 85 is tremendous.

We find much neglect of sampling. Some of the studies in the late 1920's set up better sampling controls than do more recent studies. To a much greater extent than in any other area, investigators on aging take whatever subjects are at hand. Often, even when available subjects are used, no attempt is made to define the sample in terms of such standard categories as education, socioeconomic status, and occupation.

Areas of Research

As the human being moves forward in time, he carries with him many functions and capacities which together make up his personality. We may well ask questions about the effect of aging upon different classes of phenomena in

order to envisage various research possibilities.

1. There are undeveloped capacities. Generally we assume that of the resources available at birth only a few can reach full potentiality because of the limitations of time and the high selectivity imposed by the fact that the person can only do one thing at a time.

We may well ask how long such capacities can be retained and how and when they can most effectively be activated? To what extent do they depend on other characteristics that change with age?

If the resources of an older group of persons could be explored and deliberate attempts made to develop particular capacities, we would learn more about holding mechanisms as well as about educability.

2. There are the emergency reaction mechanisms which are called into play when stress arises. In addition to the repair and learning mechanisms, these involve the emotional and motivating devices which underlie adaptation, adjustment, and problem solving in a very broad sense. We need data about age relations, the preservation of the mechanisms, and their interrelations with other functions.

3. There are the skills and knowledges of the person, the thousands of organizations of behavior in all degrees of complexity built up during his life and carried forward in some degree to later periods. Many are kept functioning by incidental practice. All have some degree of dependence on subordinate processes. They are affected by growing deficiencies in sense organs, muscles, in communication pathways, and in subassemblies.

4. There are the attitudes and value systems of the person, which are products of life experience that seem to be carried forward with even more stability than many of the skills and knowledges. We need knowledge about the origin and maintenance of rigidity and flexibility in the system as a whole, as well as in the various parts and functions.

Preservation of Function

Finally, I come to what I consider the most important research problem—the relation between use and activity and the preservation of function. The hypothesis may be formulated

in general terms as “energetic activity accompanied by deep concern delays deterioration for a measurable time.”

This proposition has both physical and psychological implications. On the physical side, there might be an optimal activity level for maintaining the best tone and greatest functional effectiveness in the bodily mechanism. On the psychological side, there might also be an optimal level of functioning for preserving tone and effectiveness.

The principle is related to a biological principle of greater extension, namely, that use both increases and preserves functioning and that in a living organism a minimal rate of interchange with the environment results in deterioration.

In considering this proposition it becomes clear that deterioration will ultimately come because even apart from pathological changes, the force which we call life runs down. But potentials under optimal conditions are probably far greater than we ordinarily assume. If we could throw out the cases in which there is failure of a specific organ or function and direct our attention to a group of essentially sound, normal individuals moving along their course, the basic principle would become clearer.

The practical importance of this proposition, if established, grows out of the fact that the amount of use of an organ or structure or of the organism as a whole is, within limits, under our control. For the organism without pathology, it is almost the only factor which is under direct control. Yet when we search the scientific literature, we find little direct evidence supporting or denying the principle. Our practical literature now makes the basic assumption that participation, interest, and activity contribute to health. But we seem to be just at the end of a period when precisely the opposite assumption that inactivity promoted well-being, seemed to be generally held.

Moreover, in the popular mind the myth of retirement and the general conception of aging seem oriented about the principle that absence of activity is both beneficial and preservative.

I would like to know whether human beings wear out or rust out and when the process starts.

I would also like to know how to preserve and increase effective functioning.

And I would like to know the answers not only in terms of organisms as a whole, but also for particular processes and functions.

The Aging Nervous System

Anatomical, physiological, and biochemical alterations of the central nervous system are possibly more intimately related to the behavioral aspects of aging than with almost any other single phase of psychology. However, the degree to which biological transformations modify the attributes of personality and mental ability remains largely unevaluated. The purpose of this paper is to highlight the major results of research on organic age changes in the brain, and no attempt is made to present a comprehensive review of the voluminous literature.

A number of distinct neuroanatomical alterations are usually encountered with advancing age. Brain weight and size are diminished by several percent, and the volume of the cerebrospinal fluid is increased. The dura mater is thickened and may contain deposits of calcium. Cell counts indicate loss of neurons accompanied by gliosis. Microscopically, changes include neurofibrillary thickening and contortion, deposition of argentophile material (senile plaques) of unknown origin, and the accumulation of pigmented substances (lipofuscin) composed of lipid and protein which may be derived from mitochondria. Anderson observed other histological transformations, such as hypochromatic staining of the Nissl substance, nuclear basophilia, and vacuolization. Although these apparently pathological alterations in the structure of the nervous system do not seem to have definite behavioral correlates, it is often assumed that advanced pathology of

this nature is accompanied by functional deterioration. However, with very few exceptions, the mass of data recorded on this subject is qualitative, and as yet it is uncertain whether or not senile dementia is associated with the pathology of specific regions of the brain, such as the thalamus. Of course the modifications that are observed in the aged brain cell do not constitute presumptive evidence of altered neuronal function.

Electrophysiological Changes

Certain electrophysiological changes, such as slowing of the alpha rhythm and elevation of the threshold to electroshock, have been definitely associated with the aged nervous system. The aged usually manifest several neurological deficits as reflected in sensory loss and the absence of reflexes such as ankle jerks. Little is known of age changes in neural integration and synaptic transmission although Birren has clearly demonstrated in rats that auditory and electric shock reaction times increase after 24 months of age. Since the electrophysiological characteristics of peripheral nerve are normal, it appears fairly certain that the increased latency reflects alterations in central synaptic and neurointegrative mechanisms.

It is the contention of some investigators that mental aberrations associated with senility are primarily the result of subclinical vascular impairment which affects certain sensitive cortical regions. This would imply that the psychosis accompanying cerebral vascular pathology has a similar etiology to that of senile dementia, except for the extent and locus of the lesion. Others maintain that these two conditions represent distinct clinical and pathological entities, although some degree of arteriosclerosis is usually evident in most autopsy material independent of the presence or absence of behavioral symptomology. It should be emphasized that the occurrence of systemic arteriosclerosis is not necessarily indicative of cerebral involvement since the process of vascular aging in the systemic and cerebral vessels is dissimilar. In the rat, there is little evidence of neurovascular pathology accompanying the aging process, and it is therefore an ideal animal in which to study

*By Eugene Streicher, Ph.D., Section on Aging,
National Institute of Mental Health, Public Health
Service, Bethesda, Md.*

the aging nervous system without the complications imposed by vascular dysfunction.

As a rule the aged brain is more than normally susceptible to insult by vascular insufficiency. For example, therapeutic ligation of one common carotid artery in the older individual commonly produces a loss of consciousness. However, if the operation is carried out in a series of steps, syncope is often absent. Clinically, coronary insufficiency in an older person is sometimes diagnosed as apoplexy because of the predominance of neurological symptoms, and mental recovery is usually rather prolonged and may be incomplete. Cerebral blood flow is diminished with age, but only to about the same extent as the cerebral metabolic rate, that is, from 10 to 25 percent. It is still a matter of conjecture whether vascular pathology or neuronal loss is the primary cause of these effects.

Biochemical Changes

Changes in the chemical constitution of human and animal tissue with advanced age have been observed for a variety of substances. Increases have been reported in the levels of sodium, lipid, calcium, and iron, and decreases in the concentrations of ascorbic acid and potassium. The water content of rat brain diminishes with age although in human material both increases and decreases have been observed. Also, a decline in the solubility of tissue protein has been noted.

The oxygen consumption of rat brain tissue measured *in vitro* decreases after 2 years of age. (Approximately 50 percent of the animals survive to 2 years of age, and about 1 to 5 percent are alive after 3 years.) The data reviewed by Kety indicate that the cerebral oxygen con-

sumption of unanesthetized male patients is approximately 10 to 25 percent lower in older subjects than in young men. However, the cerebral metabolic rate of "normal" old people and of patients with cerebral arteriosclerosis, or senile dementia, are essentially similar.

The rate of synthesis of neuronal protoplasm as a function of advancing age has yet to be determined although it is precisely this factor that is thought to be fundamentally implicated in the aging process. Thus the time required for the regeneration of sectioned nerves is prolonged in the 2-year-old rat.

There appear to be several rather profitable directions for research in neurobiological gerontology. The relationship of histopathology both to neuronal function and to behavior remains to be demonstrated. Progress in this sphere awaits the quantification of morphological data in terms of cellular loss, gliosis, and possibly alterations in the ground substance of the brain. On the biochemical side, major issues center about the rate and nature of enzyme activity and protoplasm synthesis in advanced age. Electrophysiological studies are also sorely required to evaluate the consequences of sensory impairment, synaptic interrelationships, and the efficiency of facilitatory and inhibitory mechanism responsible for neural integration.

The analysis of fetal and neonatal material at various ages constitutes one of the classic methods utilized by biologists to study structure-function relationships and to investigate the underlying mechanisms of cellular activity. At these early developmental stages there is a fairly good correlation between nervous structure and behavior. Unfortunately few of these investigations have been extended temporally to include mature and older material although

"... what can I, upon the verge of my seventy-fourth birthday, with a shaking hand, a darkening eye, a drowsy brain, and with all my faculties dropping from me one by one, as the teeth are dropping from my head—what can I do for the cause of God and man, for the progress of human emancipation . . . Yet my conscience presses me on; let me but die upon the breach."

—John Quincy Adams (1767–1848)

the fundamental process of aging in cells has been studied by physiologists for almost a century. At the present time attention is focusing on these issues, not only because of the growing medical problems in this area, but also because of the unique basic biological information which can be elicited by such investigations.

Changes in Speed and Timing

PHR The slowed reactions which are associated with the aging adult may be without apparent significance for the individual's social roles, esthetic values, or happiness. Yet, as a vantage point for exploring the nature of the changes in behavior and the aging nervous system, the study of age changes in speed and timing holds promise.

Speed and timing are important in survival. Even turtles or porcupines, which use a specialized form of passive defense, usually require a rapid timing of the defense reactions. The speed factor appears to be intrinsic to many types of activities. Individual differences in speed in the young adult may be largely a dependent variable in relation to motivation and other aspects of personality, but in the aging person speed or response latency (meaning the interval between stimulus and response) appears to be an independent variable for attributes of personality.

Status of Time Measurements

Time measurements may be a very sensitive indicator of minimal changes in skills and may be used to differentiate levels of ability wherein no errors are made. When we are learning a mental or manual skill, speed continues to im-

prove beyond the stage of making errors, but when a skill declines, the speed or timing may be affected before errors are noted. Time measurements are likewise useful in describing behavior and also have conceptual potential in linking psychological and physiological phenomena of aging.

Despite convincing evidence of age changes in speed of response, the measurement and analysis of time differences have not been regarded favorably by many psychologists, presumably because they reflect adversely on the performance of older individuals.

In mental testing of the elderly, time measurement is often avoided because time limitations are regarded as arbitrary penalties against the older person. Such views are without experimental validity. Recent physiological studies suggest that measurement of speed of simple responses can be useful in assaying the mental status of aging individuals. A speed writing test, for example, differentiated more clearly between patients with senile psychoses and control subjects than did various combinations of standard mental tests.

Psychophysics and Aging

Research on aging has a deep concern with psychophysics by virtue of the kinds of changes which may occur with age in the relations of responses to properties of the stimuli. Psychophysics is concerned with relations between a physical continuum (stimulus) and a psychological continuum.

In general, the higher the intensity of a stimulus the greater must be the increase in intensity to be perceptible. The bearing of this relation to aging is seen in the results of Szafran. His findings that older persons benefit relatively more than the young from increased illumination prompt the question whether the age changes in sensory function are limited to the minimum energy required to stimulate or whether the whole range of discrimination has been changed.

In vision, it has been shown that the minimum light threshold is higher with advancing age. Coppinger's study in which he measured the flicker fusion threshold at three different brightness levels in young and elderly subjects

By James E. Birren, Ph.D., chief, Section on Aging, National Institute of Mental Health, Public Health Service, Bethesda, Md. Dr. Birren took part in the panel on the assessment of aging.

showed a smaller absolute increase for the elderly in threshold as brightness was increased.

This information can be used to equate stimulus intensities for young and aged subjects. If a stimulus is weak for an elderly subject, then presumably greater improvement will be seen in his judgments as the stimulus magnitude is increased than would be obtained in judgments in a young subject.

Speed and Difficulty

A question of concern to many psychologists is how the performance of the elderly differs from that of the young when tasks are varied in difficulty. The term difficulty is generally applied to the stimulus and is defined by the response. Thus, a difficult problem is one which takes a long time to solve and which has a low probability of being solved correctly.

Kay reports experiments in which he found that the speed of response for the elderly was more affected than that of the young when the distance between the response keys and stimulus lights was increased. He makes a strong plea for controlling task difficulty.

My associates and I have studied both the probability of a correct response and speed in simple addition of columns of digits of varying length. As the series of digits was increased, the probability of a correct response declined more rapidly for the elderly than for the young, and the time required changed relatively more for the young than for the elderly although the absolute increases in time were greater for the elderly.

In a similar study of verbal fluency and aging, we measured difficulty by the number of words in the category to be associated. As fewer words became available, the elderly showed a greater absolute increase in time but a lower relative increase than the young subjects.

In verbal fluency there is no external stimulus which ~~must~~ be perceived. The subject generates his own associations according to a criterion or set. Thus, since not all of the changes in response latency can be attributed to alterations in sensory perception, there is the suggestion that internal associations in nor-

mal thought processes may be slower in advanced age.

We can infer that even for easy or familiar material there exists a type of latency in the linkage of perception and overt response which becomes slower in the elderly. We might also ask whether there is any relation between the speed of doing a task of near zero difficulty and the rate of change in performance as difficulty increases. In aged persons there is reason to suspect that the initial constants of performance bear an important relation to performance at higher levels of difficulty.

Serial Movements

As a skill deteriorates it may again assume the quality of separate movements. There is evidence in Kay's experiments that older individuals have difficulty with timing of sequential tasks, but the role of the longer response latency in the sequence has yet to be thoroughly explored. In our own work we have seen that the handwriting of senile individuals tends toward a series of discrete movements instead of a smooth overlapping.

Timing appears to have a perceptual character—one "sees" or "feels" the right moment. If the serial elements of information follow one another too closely, the subject frequently does not respond. It is not known to what extent the discrete character of many activities is a result of altered perception.

Perhaps the study of age changes in humor in the adult years has been neglected from the viewpoints of timing as well as the kind of material which elicit laughter. This is an excellent field for a projective and neurophysiological study in which the content or meaning of events can be coupled with observations about how the content is handled by the nervous system.

Speed and Inhibition

Perhaps more common in daily life than the demand response of the reaction-time measurement is the situation where the stimulus is anticipated and received in advance of the appropriate moment for the response. Good timing is thus as much a matter of inhibiting a

response until the proper moment as it is a matter of facilitation. Before regarding the slow behavior of the older animal as adaptive, it should be recalled that the aged animal cannot react quickly under any circumstance. Similarly, the slowness of an aged person crossing the street is maladaptive.

A distinction is often made between the brain of man and lower animals on the basis of size and possible combinations owing to man's greater number of neurons. A functional progression might also be emphasized—as one ascends the phylogenetic tree, animals become more able to delay appropriate behavior without the behavior being forgotten.

There is considerable evidence for a longer latent period with increased age, but further work is required to verify the existence of a reduced upper limit of time beyond which the response pattern disintegrates. Responses from senile subjects suggest that if a relevant response is not evoked in some maximum interval the stimulus or task has to be reinstated in order.

The hypothesis is that an age change occurs in the latent period and also that the maximum time a response may be delayed is reduced. Within these time limits the older person is apparently less able to inhibit a response. The evidence for this change in inhibitory control ranges from studies of language and learning to negative functions.

A recent study confirms the finding that the senile are both slow in their responses and show less inhibitory control over their associations. This evidence prompts the question whether the variable is not one of a dominant priority of association based upon experience rather than inability to control or inhibit an overlearned association in deference to an appropriate one. Results of learning experiments, however, suggest that with advanced age it is relatively more difficult to modify an older response than to acquire a new one.

Altered inhibitory control appears to be a more important variable in the behavior of the aged than is the priority of past experience or reduced ability to learn. To avoid a paradox in explaining the data it seems necessary to adopt the view that the responses of the elderly are faster relative to their latent period.

Applying Our Knowledge

Perhaps we can make attempts to link results of mental tests, psychophysics, and neurophysiology by means of time and timing measurements. Knowledge of this kind may be applied for human benefit in three ways:

If defects associated with aging become clearly defined and localized, then particular environmental stresses may be reduced by engineering around the limitations.

In critical job performance, selection of personnel may be used to reduce particular stresses.

With adequate insight into the changes of aging it is likely that we can begin to develop social and biological prophylaxis to minimize the development of defects which are highly resistant to reversal once they appear.

The aged nervous system appears to be more determinate—the response tends to be a direction of the stimulus. There is, of course, the tendency to cultivate certain types of redundancy, that is, the social graces, and it is of interest that the social facade may be the last bit of behavior to disintegrate in a senile psychosis. The cultural pattern determines which areas of our behavior may be novel and which are expected to be predictable.

Cultural influences determine the sources and extent of motivations in the elderly. It may be a mistake, however, to assume that merely by raising the level of motivation, ability to learn always remains unimpaired. Thus, it is not easy to see why, if motivation is a dominant variable, elimination of errors for the elderly appears to be a more difficult process than acquisition of new responses.

Kay raises a most important issue when he questions the assumption of lower motivation as an explanation of the performance of the older individual. The assumption is tenuous that ability to learn remains unimpaired, whereas the motivation to learn declines, if only because of the difficulty in separating ability and motivation on an operational basis. Behavior is not infinitely plastic as evidenced by the persistence of patterns of neurotic adjustment. Further research should reveal information about life patterns which sustain plasticity of behavior with increased age.

The Intellectual Functions

PHR Members of the panel on perceptual and intellectual abilities have discussed the strategy of attack upon problems of aging from several points of view.

Kaplan emphasizes the importance of comparative studies in normal and pathological groups, pointing to the need for more appropriate psychometrics, for better procedures in differential diagnosis, and for assiduous effort to coordinate psychological data with social, medical, and biological findings.

We do not know the extent to which psychotic deterioration has elements in common with normal decline. Kaplan makes the sound point that, until we have learned more about the nature of the senile psychoses, it is obviously unsafe to predict the ultimate role of psychology (or, he might add, of other disciplines) in the control of these disorders.

Mensch calls attention to gaps in our knowledge concerning the aging of sensory processes and touches on the problems in social perception and self-perception and their relation to personality. Perception is a topic of considerable current interest in the psychological laboratory but quite largely on the basis of theoretical formulations which ignore individual differences and age differences. Age changes in the sensory and perceptive processes should be examined in relation to physical and mental health and to experimental treatments such as in the hormone studies at Washington University.

Owens points to the need for environmental studies with older persons, as has been done for children. He would have studies of the influence of educational factors, the intellectual

demands of an occupation, and the effects of the social environment in terms of social status or of rural versus urban living.

Need for Longitudinal Studies

All three agree as to the special need and unique value of longitudinal records. This rarely practiced approach is strongly advocated by Bayley, who emphasizes the need for obtaining information about individual differences in growth patterns.

Growth in both mental and physical traits may occur in many different channels and with idiosyncratic changes in rate. These changes are partly psychometric, owing to changes in test composition, and partly environmental. To some extent, however, they reflect an intrinsic patterning which cannot be predicted from a study of the external environment.

Individualities in growth may constitute long-term trends, as in the slower rate of mental growth of the feeble-minded, or short-term variations which have been conceived as related, to some extent, to the less adequate homeostatic mechanisms of early childhood. But the later years may also be marked by idiosyncratic changes, which can only be traced and related to antecedents if observed as phases of a life history.

Current Studies

Bayley and Oden, in their study of a university group with extremely high ability levels, have shown that the gain in mental test score within an age range in which a decline is usually registered may be attributed partly to the high degree of selection in the sample and partly to the nature of the tests, which were essentially vocabulary tests (analogies and synonyms-antonyms). The hypothesis may be offered that at the extremely high ability levels of this group, the analogies test presents a mental task chiefly discriminating with regard to the knowledge of words.

In reviewing the work Conrad and I have done with a rural group, I have shown that while the information and opposites tests resist age decline, the task of analogical thinking becomes increasingly difficult in this sample, apart

By Harold E. Jones, Ph.D., director, Institute of Child Welfare, University of California, chairman of the panel on perceptive and intellectual abilities. Other members of the panel were Nancy Bayley, Oscar Kaplan, Ivan N. Mensch, William A. Owens, and L. L. Thurstone.

from changes which can be attributed to speed of reading.

Owens has found significant gains in several mental functions between the ages of 19 and 50. Since many studies have shown continued improvement in mental test scores during the years in college, possibly these gains were due chiefly to the fact that testing started before the end of adolescent mental growth. The growth from 19 to 23 in some functions perhaps was sufficient to mask an actual decline in the later decades. Special interest attaches, however, to the fact that for those retested at 50 the average alpha score was at about the 70 percentile of the scores at age 19, whereas for the same age interval in the same test Conrad and I found a decline of almost the same amount. To me this implies that the differences between our results and those of Owens are chiefly an expression of the age increase in variability, which is found in so many aspects of physiological and psychological functioning.

Owens offers two possible explanations of increasing individual differences: the cumulative effects of differential decline at different ability levels and the influence of organic impairments at all ability levels. It is not clear that the latter would significantly increase variability in intellectual functions unless the weight of impairment were greater at the lower levels.

Among children, the correlation between intelligence and measures of health or of freedom from physical handicap is nearly always found to be positive but too low to suggest an important degree of interaction. Over the decades, however, the cumulative effect of this relationship may deserve greater consideration, particularly when the decline in homeostatic functions makes it more difficult to resist the persistent and increasing drag of other impairments.

Renewed emphasis should be given to the necessity of studying the positive aspects of age changes, as well as the characteristic age losses. It is not realistic to expect that mental functions will be immune to the age changes which occur in other processes. But the role of intellectual abilities in social and occupational adjustment may not be the same at different ages. With diminishing mental speed and power, greater support may be enlisted by

some individuals from the reserves of skills and knowledge created through experience and from superior work habits. We need more information as to the conditions under which these reserves are best brought into play. At the highest levels of creative endeavor, it is probably rare for compensating factors to operate effectively beyond the middle years of life. But in more routine tasks, of possibly great social importance, the decrements in ability may for a long time be more than matched by increments in other work factors.

The study of these positive features of performance in later life deserves more attention than it has received in the past.

Education of the Aging

PHR Many of the studies since Thorndike established the fact that older people can and do learn have been concerned with showing how they learn and particularly in what way their learning differs from that of younger persons.

These studies have shown that the learning of older individuals, as compared with that of younger adults, is characterized by a decreasing gradient of efficiency, as expressed in both errors and time scores, a greater use of habitual pattern of response, a more concrete approach to test tasks, a tendency toward feeling of inferiority in learning situations, a beneficial effect from recent practice in learning and recall, and a difference in ability to remember verbal rather than abstract materials.

Application of these findings would allow for some definite modification of educational techniques to take account of the special characteristics of the learning process in older adults.

By Wilma Donahue, Ph.D., chairman of the division of gerontology, Institute for Human Adjustment, University of Michigan, and a participant in the panel on learning, motivation, and education.

Some further investigations are indicated, however, before present-day knowledge is crystallized into an educational psychology for later maturity. Among the questions needing further study are some related to selection of test populations and to learning ability and education of older adults.

Selection of Test Samples

The older adult group is not homogeneous. It consists of at least two subgroups: those who are to be classified as the aging and those who may be considered to have become definitely aged. It is particularly undesirable to lump these groups together in a single group, 50 and over, or 60 to 80, when considering the psychological effects of aging.

In the first group, the normal processes of senescence are not so profound as to have seriously changed the functionality of the individual. He is still coping effectively with his environment, still able to concentrate long enough and well enough to carry out instructions in test situations.

For the second group, degeneration may be assumed to be quite widespread; the individuals are apt to show symptoms of confusion, disorientation, and inability to continue independent living; or if they manage to maintain themselves, it is at great personal effort. In test situations, they tend to lose the set and to forget instructions before the task is completed.

In selecting samples of older adults for study, careful consideration needs to be given both to the use of criteria which will discriminate the aged from the aging and to other factors such as education and intelligence.

Other variables which should be considered are those of occupation, health, motivation, recency and extent of practice in skills required by the test, and environmental conditions in which the test is performed. Only when such variables are controlled can comparisons be made between different age groups with assurance that the individuals compared are equated on points effective in determining test scores or performance. The investigators who have been careful to equate some of these variables are the exception, and many studies need to be repeated under better and more controlled conditions.

Learning Studies

The classic studies of Miles, Jones and Conrad, and Foulds and Raven have produced age curves with the same characteristics as the one described by Thorndike: a rapid rise to a peak efficiency in the twenties, then a slight down gradient for the thirties and forties, followed by an acceleration of the negative gradient. The shape of the curve remains essentially the same regardless of the nature of the material learned, but the magnitude of the change depends on the type of material learned.

Perhaps past studies have been definitive enough to establish the fact that age brings disablement in learning ability, but there are a number of further investigations which appear to be needed before such a conclusion is adopted unequivocally.

It is possible that the shape of the learning curve, based as it is on studies of groups of subjects of different ages, does not necessarily represent changes in the ability to learn with advancing age but may reflect the early onset of degenerative processes in a significant number of subjects.

Lack of criteria for measuring the early senescent changes may make it impossible to avoid an adverse effect on the average test performance of the age group. However, with the new Wechsler intelligence scale, it should be possible to select a group of the most effective oldsters in comparison to the norm for their peer group.

Investigators who have compared a younger with an older group of superior and presumably undeteriorated men usually show the older group to be definitely handicapped by what is assumed to be a slowing down of the mental processes. This conclusion, however, should be looked at carefully from the point of view of the attitudes and qualitative differences in the approaches of older learners as compared with those of younger ones.

For reasons known only by speculation, the older person approaches a learning task with a considerable feeling of inferiority, especially if he knows that his performance is to be compared with that of younger learners. Camp concluded that an older man does not differ from a younger one in his memory for recorded events or in his ability to learn but that inferi-

ority feelings constitute an emotional handicap to his learning.

Another study which illustrates the insecurity which older people feel when required to learn is that reported by Welford. He found that subjects in their twenties seemed to approach the learning task without any clear idea of what they were going to do and allowed the task to dictate their method while subjects in the thirties, forties, and some in the fifties and sixties asked questions about the methods of learning they should adopt before beginning their first trials. Apparently they felt the need to evolve a technique before beginning to work and hoped thereby to perform more intelligently.

Other interpretations, however, can be placed on the behavior of these older subjects. It may represent an attempt to apply some habitual type of solution to the new problem, thus avoiding the exertion of new learning. It may indicate less fluidity in thought processes than those of younger people, thus causing the older learner to take a more concrete approach to the problems. But it may be equally plausible to assume that the longer experience of older people has taught them the disadvantages of error and the advantages of succeeding in competitive situations, thus invoking some negative feelings toward any learning situation.

When the older student frankly adopts the eagerness for learning found among younger people, he frequently excels his younger classmates. But when he is defensive and fails to accept an exploratory learning approach, the experience is likely to be one of great frustration and emotion, and one which no amount of application can overcome. Studies are needed which will make clear the extent to which the difficulties of older people in learning are those resulting from changes in ability and to what extent they are the effects of experience and unfavorable attitudes.

Effects of Practice in Learning

Lack of practice in learning may account for some learning disability among older adults.

Thorndike, like the doctor who prescribed digestion as the best cure for indigestion, sug-

gested that adult learning is probably a partial cure for adult inability to learn.

Sorenson, undertaking to test the theory that disuse—as expressed by the absence from methods used in acquiring information for university study—is the explanation for apparent disability in college courses with advancing age, reported that the slight disability of those who have not been engaged in vigorous learning for a period of several years can be overcome by resumption of study.

Further studies are needed to determine to what extent the renewed ability to learn and remember accruing from classroom experience can be transferred to the more casual living situations:

Must practice be provided in all types of learning, or does the training in learning one type of material serve as an antidote to difficulties in learning other kinds of material?

Is the improved ability to learn reflected in increased mental alertness in other situations?

How much learning must take place in order to restore the ability to peak level of efficiency, and how much must continue to take place to keep it there?

Do the various levels of intellectual ability respond to practice in adult learning in the same way, or is practice necessary only for the less able?

Education of Older People

Few studies have been made as yet to determine the teaching methods and course content most useful in training older people. At present we must rely on known effective methods for children and youth. These may not differ greatly from methods which will be found to be most effective for older learners, but some adaptations undoubtedly are required.

Anderson says that young people and older adults improve performance with continued practice under motivation. Both start learning a task ineffectively and gradually attain expert skill. Both respond in the same way to skill of teachers, use of audiovisual aids, dramatic presentations. Both are strongly influenced toward learning by what their contemporaries do.

He also described differences between the two

age groups. The older individuals bring an accumulation of experience to the learning situation which may help or hinder the new learning. They are more concerned about the effects of their errors. They are more difficult to motivate and less willing to learn for the sake of learning.

Studies of motivation of older people to participate in any task or program are among the most pressing of today's needs. Literally, at present, much more is available to older people in the way of education, recreation, health programs, and so forth, than is being used by them. The task is how to motivate the aging person to want to take the initial step required to become a member of such groups and programs. The problem is complex and needs to be broken down into its several components.

Some of the difficulty lies in our lack of knowledge about how to communicate with older people. We know very little about how information reaches them, what channels of communication are open to them, and what relative values they place on different sources of information. Although radio listening and television viewing are common among the group, the effectiveness of the participation of the older person in this type of communication is practically unknown. Further, the extent to which information gained in this passive fashion can be expected to result in action is also still to be determined.

There is considerable resistance to participation in educational activities because older people do not feel that it is permissible for them to go to school. It is not until deeper understanding of the need for continued creative expression comes about that many older adults will take part willingly in learning activities. How to change attitudes of this type constitutes an important field of research.

Studies on the motivating values of different factors such as methods for presenting stimuli, knowledge of results, active versus passive participation, timing repetitions, reinforcing experiences, reward and punishment are needed as a basis for making adaptations in teaching methods and for inspiring adults to set and attain new levels of aspiration.

Education for aging is to be looked upon as the new challenge. Psychologists have a re-

sponsibility for determining the ability of adults to learn some of the things needed for the enjoyment of leisure and for determining methods for teaching and involving the adult in learning situations in order that new techniques for creative experience may be gained. The educator is faced with the challenge of applying his knowledge to the requirements and proper teaching of adults so that they may have the opportunity to pursue the stimulating aspects of life into old age.

Skill and Employment

PHR My assignment is to try to indicate what we need to know about the organism as an efficient unit in relationship to aging. Of particular concern is the organism's essential goodness in terms of productivity.

Herein lies the implicit assumption that we ought to be able to assign some characteristic number to an individual which would serve as an index of his aging status much the same as the IQ is taken as a measure of intellectual capacity. While this represents an ideal, it is based on the assumption that there is some common factor involved in aging.

From a theoretical point of view, this is an important research problem. I see no reason why we should not attack it on a broad front much as we have approached the isolation of factors involved in other performances. We could apply a wide variety of performance tests to individuals over a wide age span and then see what common factors could be isolated from test results.

As I see it, until we have access to cooperative subjects in large numbers—with the active col-

By Nathan W. Shock, Ph.D., chief, Section on Gerontology, National Heart Institute, Public Health Service, Bethesda, Md., and visiting physiologist, the Baltimore City Hospitals. His brief is from the panel with the same title.

laboration of many research people and industry—we are going to be handicapped in describing age changes in performance. Since it appears that age changes are often related to reserve capacities, it is essential that any test batteries include measurements made not only under resting conditions but under conditions of measurable stress and displacement.

In addition, there is also the practicable problem of what older people can do. This is within the province of institutes of industrial relations and the research activities of private industries. A detailed job analysis, in order to determine the skills and conditions required for performance of these jobs, is an essential first step. Then would come an evaluation of the specific types of performance within aging workers, with the hope that ultimately requirements of the job and the capacities of the worker could be adequately matched.

Our laboratory (operated in collaboration with the Baltimore City Hospitals) has been interested in the problem of human performance for a number of years but has placed major emphasis on the physiological aspects of the problem, with an attempt to evaluate specific performance of organ systems as well as that of the total person. All I can hope to do is to present a few broad generalizations with respect to age changes in performance and to indicate questions which need further research.

Factors Affecting Performance

Let us examine briefly some of the physiological limitations of performance that change with increasing age. When we are dealing with the human animal, the question immediately arises as to whether changes in physiological functions are due to disease or whether they can be regarded as the effects of age alone.

As I see it, we are interested in the performance of aging people, and if disease is an inherent part of the older organism, it will have to be accepted as such.

If we were able to study large numbers of individuals selected at random from the total population, we would not necessarily need to exclude subjects on the basis of medical examinations. However, when we choose subjects from an institution, we need to exclude subjects

with identifiable disease because the incidence of disease may be greater than in similar subjects living in the community. Thus, the research method and design depend on the population under study. Therefore, the first essential for effective studies of aging is the identification and description of the population under observation. Unfortunately, this has not always been done.

It is obvious that sensory changes may have an important bearing on performance. Rather extensive studies have shown that hearing for particularly high frequencies diminishes with increasing age. Studies on vision also show that the range of accommodation, visual acuity, rate and level of dark adaptation, pupil size, and the rate of flicker fusion frequency show a gradual impairment with increasing age. Vibratory sensitivity gives some indication of similar decrements with age. The problem of age changes in sensitivity to pain still awaits systematic investigation, owing largely to a lack of an acceptable objective measurement of pain.

Sensory changes associated with aging could serve as valuable indexes of the overall rate of aging in the individual even though they may be adequately corrected so that performance need not necessarily suffer. This also is a problem which has not been solved.

Of even greater importance to performance is the question of perception and the ability to extract information and utilize it in terms of behavior. This is a question which has received relatively little consideration from students of aging but for which extensive techniques have been recently developed by the Armed Forces.

The problem is one of determining the individual's ability to receive information presented simultaneously from a variety of sources and to abstract the information which is pertinent to specific performance. It would seem that this type of activity is one in which elderly people might show significant changes.

There is little doubt that the speed of performance diminishes with increasing age. This decrement in speed shows itself in studies of simple or complex reaction time, in speed of muscular movement, in psychological performance, and in even more complex performances included in many tests of intelligence.

Although Miles has demonstrated that reduction with age in performance includes both perceptual and effector processes, there is no information on the effects of age on the rate of performance of isolated muscle groups. Nor is there any information on the interrelationship in the same individual between speed of performance on different types of activity although a broad generalization would imply a relationship.

Welford, experimenting with the conceptions presented by Bartlett, has provided some evidence to indicate that simple measurements of the total time required for a given response should be supplemented with observations on the detailed segments of the total performance. Within this framework he has demonstrated significant age changes which otherwise would have escaped detection.

When we examine the performance of specific organ systems within individuals, we find a variety of age changes. Some systems show little evidence of functional alterations with increasing age. This is particularly true of measurements made under resting conditions where a number of physiological processes are involved in maintaining a stable equilibrium. However, under circumstances of physiological stress, age differences may be observed. For example, the rate at which the blood sugar is restored to resting levels, after the intravenous administration of excess glucose, diminishes significantly with increasing age. Similarly, the administration of an acid or an alkali requires more time in the older individual to readjust the acidity of the blood than in the young.

In other organ systems there is evidence of the reduction in function even in the resting state. For example, the amount of blood pumped by the heart, as well as the amount flowing through the kidneys, shows a gradual reduction as age increases.

Thus, our physiological studies have indicated that with increasing age there is a gradual reduction in reserve capacities and in the effectiveness of interorgan system correlation. A finding common to all these measurements is that the rate or speed of readjustment is diminished in the older individual.

We may well question the assumption that

the rate of metabolism of individual cells diminishes with age. While it is true that the basal oxygen consumption, taken as an index of overall rate of metabolism, diminishes gradually with increasing age, we cannot assume that this is a reflection of the rate of metabolism in individual cells. This is because with increasing age there is a gradual dropping out of functioning cells from various organs and tissues and an accumulation of body fat which does not contribute to metabolic activity. The apparent diminution in metabolism might well be a reflection of this change in functioning protoplasm and an accumulation of inert substances.

Our laboratory has attempted to relate basal oxygen consumption to a measure which might be more representative of the total amount of functioning protoplasm in the body. For this purpose, the total water content of the body, as measured by antipyrine, has been utilized. When the oxygen consumption per unit of body water is calculated for each individual, it is found that there is no decrement with increasing age.

When we turn to studies made on cells and tissues for an answer to this question, we face disappointment since relatively few studies on really old animals have been carried out and since no estimates of the number of cells remaining in the tissue slice, for example, have been made.

The effect of age on the ability to perform physical work has not been investigated extensively. Robinson's studies indicated that older people were unable to increase their pulse rates as effectively as young in response to exercise but did not find significant differences in oxygen uptake.

Similarly, Norris in our laboratory has found no difference in the efficiency of old versus young subjects performing standardized amounts of arm exercise. We do know, though, that older people are less able to perform heavy work and that their rate of recovery, with respect to pulse rate, respiration, or oxygen uptake, is diminished.

We also know that there is a gradual reduction in muscle strength and endurance in the higher age categories. Whether this diminution in muscle power is a result of loss of muscle cells, or whether it is more functional in nature

and comparable to an atrophy of disuse, is still an open question.

We do know that older individuals require a greater turnover of respiratory air in order to obtain a given level of oxygen uptake under conditions of exercise, but whether this is a respiratory impairment or can be ascribed to alterations in the capacity of the heart to pump blood is still another open question.

Although the mechanical efficiency of old and young is indistinguishable at moderate rates of work, at both low rates of work as well as at maximal rates of work, the mechanical efficiency of the older individual is impaired, Norris has observed. This opens an interesting point for investigation since the low efficiencies at slow rates of work in older people were completely unexpected.

It is possible that this impairment of efficiency is a reflection of poorer muscle coordination and impairment of neuromuscular control. Since the physical requirements of most jobs are minimal, the question of maximum workloads that older people can perform is of relatively little importance in problems of employment. Of greater importance is the question of endurance and the effects of repetitious tasks. This is a question which has not been systematically investigated on an age-wise basis.

and health are significant independent variables in relation to the social psychology of aging.

In the chronologically advanced years of life, especially for men, aging as perceived by oneself and by others is largely a function of withdrawal from making a living and of decline in state of health. Research shows that people of 60 and over who are occupationally active and in good health are younger in their own eyes and in the eyes of others than are those who have withdrawn from the labor force and are in poor health.

Somewhat less success has been derived from efforts either to establish or to interpret the relationship between occupational roles and health in old age. Most, but not all, research findings in this area show a positive correlation between the two variables.

Even if our findings were consistent, we would still be confronted by the problem of the meaning of the correlations. Which of the two variables is independent, and which one is dependent? Some claim that occupational roles are independent and that health is the dependent variable. Others argue that health is a predisposing factor rather than a consequence of occupational roles.

A tentative resolution to this controversy lies in the following compromise stated by Mathiasen:

Persons who die soon after retirement in all likelihood are succumbing to physiological conditions which would have caused death whether they had retired or not, but this does not rule out the possibility that retirement shock may precipitate an occasional fatal cardiovascular accident. It is difficult to estimate the effect of the sudden cessation of work on health in the absence of any techniques for measuring quantitatively the effects of emotional disturbance on health or for separating precisely the psychosomatic disorders from organic disease.

We may be inviting continuing frustration if we persist in taking an either-or theoretical position even in this modified compromise. For there is an inherent limitation in assuming that occupational roles and health are related to each other exclusively as independent and dependent variables in a yet unknown pattern. It may be more rewarding in the long run to consider them as interactive partners in a re-

Occupational Roles

The dynamics and interrelationships of occupational roles, health, and aging comprise one of the crucial problems of gerontological research. Gerontologists in general would accept as reasonable the hypothesis that occupational roles

By Milton L. Barron, Ph.D., associate professor of sociology, City College, New York. Participating in the panel on skills and employment, in addition to Dr. Barron, were Ross McFarland, Josef Brozek, Charles Odell, and Nathan Shock.

ciprocal relationship. Each probably acts and is acted upon by the other although not with equal influence.

Misplaced Research Emphasis

Gerontologists working on the problem of occupational roles in old age seem to assume that the transition from employment to retirement is the crux of difficulties associated with occupational roles. Yet research findings indicate that the unemployed aged who do not consider themselves to be retired have more acute economic, psychological, and social problems than do the unemployed aged who do consider themselves to be retired.

The reluctantly unemployed in our older population deserve far more attention from researchers than they have been given. Unwilling to tolerate the economic idleness to which they have been relegated, this group has the most emphatic minority-group reactions of all occupational groups among the chronologically aged.

Some of our findings definitely suggest that we have been concentrating on problems of physical health when we should be studying more intensively the problems of mental health. Physical ailments in the older population are not as severe and widespread as they are generally reputed to be.

The relatively little gerontological research on mental disorders in later life indicates that they are more extensive than problems of physical health. The Cornell University survey revealed that the majority of the urban older people are troubled some of the time by psychosomatic symptoms, nervousness, and forgetfulness. Much more needs to be known about the social and cultural bases of the major mental disorders of later life.

Social Science Concepts

The time is overdue for more utilization of relevant social science concepts and theory in gerontological research on problems in mental health as well as other problems of aging. Studies have already intimated that the kind of social relations in which older persons participate is a crucial factor in the etiology of

their mental disorders. These social relations are fruitfully characterized by orthodox social science concepts such as Durkheim's "anomie," Jung's "loss of significance," and Faris and Dunham's "isolation."

The theoretical framework basic to much contemporary social psychology seems to be adaptable to gerontological research on problems of mental health. This framework implies that the social self not only embodies the group's normal attitudes but also the frustrations and confusions of the group. Society's tensions and cultural contradictions contribute to the conditioning of the self. When the self is mentally and emotionally disordered as well as physically ill, the family, the neighborhood, and society itself constitute a considerable part of the etiology.

The attention of gerontological researchers should be drawn to other potentially relevant concepts and theoretical schemes of social science as well:

Does the self-fulfilling prophecy have any bearing on the dynamics of occupational roles and health in old age?

Can we hypothesize that expectations of morbidity and mortality in old age are intensified by retirement so that they become self-fulfilling prophecies expressed in hypochondria and functional symptoms of illness?

To what extent does psychological unemployment account for the difficulties of the unemployed aged who do not consider themselves retired in returning to gainful employment?

Is unplanned, involuntary, and abrupt retirement the kind of experience meant by the concept catastrophic reaction?

The need-for-illness concept is another social psychosomatic tool with gerontological possibilities. It describes a condition which is an outgrowth of repeated frustrations in the individual in attempting to handle complicated problems. The person does not consciously seek illness as an escape but rather the care that one receives in illness, the kind of care that corresponds to the maternal love given a child who has met difficulties.

Middle-Class Norms

A pitfall to be avoided is the indiscriminate gerontological usurpation of concepts and the-

oretical frameworks from a heretofore youth-bound social science. More than an imminent danger, possibly an actuality, is the heavy reliance of research on middle-class norms. Are the concepts adjustment, social satisfactions, and avocational interests truly free of restrictive class connotations?

There is some basis to the suspicion that educators, scientists, physicians, clergymen, and industrial and business personnel—typical middle-class sources—have played a more influential part in defining the problems of aging and introducing these norms to an age status in urban industrial society than have the representatives of other social classes.

This suspicion is reenforced by our observations of the negligence of older people in preparing for retirement. Many of the norms for such preparation are implicit in hobbies, travel, avocations, and club sociability, for these activities offer more appeal and meaning to older people of the middle classes than they do to those of lower economic, social, and educational strata.

Relevant here is Noetzel's observation that in some counseling programs, foreign-born and semiskilled manual workers react negatively to

any discussion of hobbies. To them the word connotes "make work," childishness, or futile play. This becomes especially significant in the face of evidence that older people in our society are geared socially toward the working classes more than to any other social strata. The Cornell survey found that the majority of its respondents considered themselves to be members of the working classes. Furthermore, the formal education of the sample was geared toward the lower level of cumulative years of schooling.

Gerontological research on the dynamics and interrelationships of occupational roles, health, and aging obviously cannot rely completely on concepts and theory already available in the social sciences. There is need for new, imaginative theoretical formulations; for example, the typology recently put forward by Riesman for analyzing materials gathered in the Kansas City study of middle age and aging.

Riesman points out that reaction to aging in the United States is largely governed by norms that vary according to social group. Not only do we need to recognize the substrata among older people, we must also adapt norms to the various substrata.

Medical Problems of Atomic Warfare

Medical problems facing the military services and the Nation in an atomic war will be presented at the 3-day program of the Association of Military Surgeons of the United States, meeting in Washington, D. C., November 7-9, 1955, for its 62d annual convention.

Topics will include the medical effects of nuclear warfare; care of mass casualties, such as protective measures, initial aid and rescue, and treatment of large numbers of blast, thermal, radiation, and neuropsychiatric casualties; and organizing the various medical and technical specialists and facilities for managing thousands of casualties at one time.

Scheduled for addresses are the Chairman of the Atomic Energy Commission; the Assistant Secretary of Defense (Health and Medical); the Surgeons General of the Army, Navy, Air Force, and the Public Health Service; medical chiefs of the Veterans Administration and the Federal Civil Defense Administration; and representatives of the medical industries.

Major Causes of Illness and Death

Morbidity investigations usually study disease characteristics such as the distribution of cases by diagnosis, by age and sex, by season of the year, by acute and chronic manifestations, by severity in such terms as nondisabling, disabling, confinement to bed or to a hospital, and by the case fatality.

Many health workers are interested in the illness of different groups of persons rather than in given diseases. Age groups from infancy to old age differ a great deal in their illness patterns, and this paper is an attempt to show graphically the most frequent causes of illness of varying severity and of death in each of six age periods from preschool to old age. Needless to say that the causes of illness and death differ greatly as between early infancy and old age, although these two age periods have the highest death rates.

A separation of illness into acute and chronic diseases gives a picture of moderate but declining rates of acute illness in the preschool and early school ages, and of increasingly higher rates of chronic diseases as age increases. Carried to early infancy, this situation means extremely high death rates for the very young as well as extremely high illness and death rates for the aged, whose vital organs have degenerated over the long period of continuous functioning.

The major causes of illness and death at the different ages are not discussed in this summary, but the study includes charts which illustrate the illness, hospital care, and mortality picture for each of the six ages.

Public Health

MONOGRAPH

No. 30

The accompanying summary covers the principal findings presented in Public Health Monograph No. 30, published concurrently with this issue of Public Health Reports. The authors are with the Division of Public Health Methods, Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

Public Health Monograph No. 30 (Public Health Service Publication No. 440). 22 pages. Illustrated. U. S. Government Printing Office, Washington, D. C., 1955. Price 25 cents.

This report covering the continental United States is made jointly by the Tuberculosis Program, Division of Special Health Services, Public Health Service, and the National Tuberculosis Association.

Change in Tuberculosis Beds Occupied

—Spring 1954–Fall 1954—

By STANLEY GLASER, JOSEPHINE JOHNSTON,
and DONALD A. TRAUGER

INFORMATION concerning the changes taking place in tuberculosis bed occupancy has been incomplete and has given rise to conflicting speculation. Because of this, the survey reported in this paper was undertaken to provide current trends in this important area of tuberculosis control. The results of this survey indicate that there has been an average decline of slightly more than 6.5 percent in the number of tuberculosis beds occupied in the continental United States in the 8-month period between April 1, 1954, and November 30, 1954.

For the last 50 years, emphasis has been largely placed upon providing more and more tuberculosis beds to accommodate the large number of patients who needed tuberculosis hospitalization. In the past, most States lacked enough beds for the care of the known tubercu-

losis patients. In many instances, the beds that were provided left much to be desired in terms of proximity to patients, adequacy of the physical plant in which they were located, and scope and quantity of services provided. In terms of numbers, however, the supply had begun to catch up to the demand in some places. Within the last year or so, a few States have been indicating that they have more than enough beds to take care of all of their tuberculosis patients and that beds were being closed, or were going unused in relatively large numbers. In an effort to determine the average degree of the downward trend and the variation from State to State, the Public Health Service and the National Tuberculosis Association have undertaken the study reported in this paper.

Study Pattern

The Tuberculosis Program of the Public Health Service annually collects information about the number of tuberculosis patients hospitalized in the United States. This information is obtained directly from the hospitals which take tuberculosis patients for treatment or for temporary care. The information collected in connection with this inquiry for April

Mr. Glaser and Miss Johnston are statisticians with the Tuberculosis Program, Division of Special Health Services, Public Health Service. Their work in tuberculosis hospital statistics began in 1947 and 1951, respectively. Mr. Trauger is associate director, division of social research, National Tuberculosis Association.

1, 1954, was used as the study baseline (1).

In the fall of 1954, the National Tuberculosis Association inquired (2) as to the number of tuberculosis beds occupied in each hospital with tuberculosis beds. These data do not give information about any single day, but refer only to the day on which the replies were prepared. However, most of the data show the situation in November 1954. For convenience in notation, the data for April 1, 1954, are designated as "spring 1954," and the data collected subsequently by the National Tuberculosis Association and by the Public Health Service (as specified below) are designated as data for "fall 1954." In general, the data cover an 8-month span and are treated in this paper as though they were based on observations 8 months apart.

The number of non-Federal hospitals reporting in each week interval is shown here (2, 4-6) :

<i>Week</i>	<i>Number of hospitals</i>
1954:	
Prior to November 14-----	7
November 14-----	223
November 21-----	108
November 28-----	25
December 5-----	8
December 12-----	5
December 19-----	38
December 26-----	29
1955:	
January 3-----	10
January 10-----	7
January 17-----	2
January 24-----	1
Total -----	463

The National Tuberculosis Association data include information on the number of tuberculosis beds occupied in 450 non-Federal institutions. To this number the Public Health Service staff has added occupancy data for 145 hospitals (mostly Federal hospitals) bringing the total number of institutions in this study to 595. (Data for the 145 additional institutions were obtained from State health department reports, sanatorium reports, and Federal agency reports.) This paper presents the information resulting from the analysis and comparison of the data collected in the fall of 1954 with the data collected in the spring of 1954. For convenience, the term "TB bed occupancy" as used in this paper means the "number of TB beds

occupied," and does not denote "the percentage of TB bed capacity which is occupied."

Estimate of Average Decrease

In the 595 Federal and non-Federal hospitals for which we had information, the decrease in occupancy in the 8-month period is 6.7 percent (table 1). We have no doubt that the seasonal fluctuation in tuberculosis bed occupancy is responsible for some part of this decrease. However, because we have little information about the magnitude of the seasonal fluctuation, we cannot estimate with confidence the percent decrease on an annual basis.

Non-Federal Hospitals

Information obtained from the inquiry conducted by the Tuberculosis Program in the spring of 1954 indicated that on April 1, 1954, there were 75,951 patients occupying tuberculosis beds in 568 non-Federal institutions (1, 3). In the fall of 1954 data were available for 463 hospitals including 31 which had ceased to take tuberculosis patients sometime after April 1, 1954, and two new hospitals which were not in operation in the spring of 1954, but which had tuberculosis patients occupying beds in the fall of 1954. The number of tuberculosis beds occupied in the 463 hospitals declined by more than 7 percent in the 8-month period (table 1). These 463 hospitals represent about 82 percent of the non-Federal institutions which had 5 or more tuberculosis beds on April 1, 1954; 89 percent of the non-Federal tuberculosis beds which were occupied on that date were in these 463 hospitals (1-3).

Three hundred forty-seven of the 463 non-Federal hospitals are tuberculosis hospitals. In this group the decrease in beds occupied is 7 percent. The remaining 116 hospitals in the non-Federal group are chiefly general hospitals which have a specified number (5 or more) of tuberculosis beds. The number of tuberculosis beds occupied in these hospitals has declined by 9.5 percent (table 1).

A comparison of the number of tuberculosis beds occupied in non-Federal hospitals between the spring and fall of 1954 is shown in table 2. The analysis of

States in terms of the individual States as units has many disadvantages because of the lack of homogeneity within States and because of the lack of comparability between States. However, in spite of the fact that the State must be considered an arbitrary and—in some statistical senses—an unsatisfactory unit of comparison, it is a unit that is generally accepted and understood. It will serve here to illustrate the great differences geographically in the change in tuberculosis bed occupancy over the 8-month period under consideration. Observe, for instance, that while one State experienced a decrease of 24.6 percent in the number of non-Federal tuberculosis beds occupied, another State experienced an increase of 18.0 percent.

For these two States, every hospital that reported in the fall also reported in the spring. If reporting had been as complete for all other States, the greatest percent increase might have been more than 18 percent and the greatest percent decrease more than 24.6 percent, but neither of the extremes could have been smaller. Nineteen States showed decreases of less than 5 percent; 9 showed decreases of between 5 and 10 percent, and 13 had decreases of 10 percent or more. Seven showed increases ranging from about 2 percent to 18 percent.

Pattern of Change

There is no apparent geographic pattern to the changes in absolute numbers or percentages.

Table 1. Change in number of tuberculosis beds occupied, by type and control of hospital, continental United States, spring 1954–fall 1954

Type and control	Number of hospitals ¹	Number of TB beds occupied		Increase or decrease in beds occupied spring 1954–fall 1954

Tuberculosis hospitals.....	21	7, 787	7, 514	–273	–3. 5
Other hospitals.....	87	7, 952	7, 820	–132	–1. 7
Other Federal hospitals.....	24	3, 386	2, 972	–414	–12. 2

¹ Thirty-one of these hospitals had tuberculosis patients in the spring of 1954 but were closed to tuberculosis patients by the fall of 1954 and two new hospitals were not in operation in the spring of 1954 but had tuberculosis patients occupying beds in the fall of 1954. No hospitals are included which had less than 5 beds for the care of tuberculosis patients.

² Since this study relates to continental United States only, 150 Alaska native patients hospitalized under contract are not included. Fourteen of these are in local government hospitals; 136 in other private hospitals.

³ In the spring of 1954 there were 95 hospitals with 5 or more tuberculosis beds; in the fall of 1954, there were 108. For comparative purposes the number of beds occupied has been enumerated on the basis of the reporting method in effect in the fall of 1954—by type of bed patient.

² Number of hospitals for which reports were available in the fall of 1954.

³ Chiefly general hospitals with facilities for tuberculosis patients.

SOURCE: References 1–6.

Furthermore, there is no relationship between the changes in tuberculosis beds occupied and the rate of newly reported tuberculosis cases or deaths, or in the changes in these rates. On the other hand, the States which show the largest decline in tuberculosis bed occupancy are the ones which, in general, have the greatest number of tuberculosis beds per newly reported active tuberculosis case. This relationship is apparent when the data for all States are considered. It is even more obvious when the observation is based only on those States from which information about 95 percent or more of their tuberculosis beds was available.

An analysis of official rated bed capacity indicates that the greatest average percentage decline in number of TB beds occupied has oc-

curred in the smallest hospitals. Hospitals with less than 50 beds showed the largest decrease. The average decrease in beds occupied for this group is almost 22 percent. For hospitals with between 50 and 99 tuberculosis beds, the average decrease was close to 14 percent, and for hospitals with between 100 and 149 beds the average decrease was 9 percent. Table 3 shows that this relationship extends to the groups of still larger hospitals—the larger the hospital, the smaller the average percentage decline in number of beds occupied. This is apparent when all types of hospitals are grouped by size, as well as when the tuberculosis hospitals are considered separately by size.

Tables 1 and 4 show changes in bed occupancy by ownership of hospitals. The non-Federal

groups called "other" in these tables are, for convenience, called private in the text. They are all nongovernment hospitals. This classification, however, refers to the ownership of the hospitals and not to the source of funds for the care of the tuberculosis patients. The care of some patients in nongovernment hospitals is provided at public expense. Some of the changes in TB bed occupancy in private hospitals may be due to changes in the availability of public money for the care of patients in private hospitals.

When the ownership of the hospital is considered, it is evident, as shown in table 1, that

the smallest average decline in the occupancy of tuberculosis beds occurred among the State-owned hospitals. The largest average decline in occupancy was among the private hospitals, with the local government hospitals falling in between. There is a pronounced relationship between the ownership of tuberculosis hospitals and their size. On the average, State tuberculosis hospitals are the largest, local government hospitals are intermediate in size, and private hospitals are the smallest (table 1).

There arises, therefore, the question of whether the relative changes in tuberculosis bed occupancy are associated with the hospitals be-

Table 4. Change in number of tuberculosis beds occupied in non-Federal hospitals by size (TB rated capacity) and type of hospital, continental United States, spring 1954-fall 1954

cause of their size or because of their ownership. Table 4, while it does not present an unequivocal picture, shows that size is probably a more important determinant of the change in tuberculosis bed occupancy than is ownership. For instance, among institutions with less than 50 beds there are relatively large numbers of institutions in the categories of local government hospitals and of private hospitals. For each of these categories, the percent decrease is substantially the same. In the group of hospitals with between 100 and 149 tuberculosis beds, the State hospitals have the largest percentage decrease and the private hospitals have the smallest percentage decrease. This group is composed of a fairly large number of hospitals and a fairly large number of beds in each category. Among the large hospitals that have from 250 to 499 tuberculosis beds, the local government hospitals have the largest percent decrease in tuberculosis bed occupancy while the State and private hospitals show very small changes. In the largest group of hospitals—those that have more than 500 tuberculosis beds—the State and local government hospitals have decreases of about the same magnitude. It is interesting to notice, by way of contrast, that while the local government and private hospitals show smaller decreases in tuberculosis bed occupancy as we go up the size scale, the State-owned hospitals do not show this trend.

Distribution of Closed Facilities

Thirty-one of the 463 non-Federal hospitals which took tuberculosis patients in the spring of 1954 were closed by the fall of 1954 or had closed their tuberculosis units. These 31 hospitals had a total of 2,362 tuberculosis beds (official rated capacity). In the same period it is known that 2 new tuberculosis hospitals opened with a capacity of 470 tuberculosis beds. This resulted in a net decrease of 1,892 in the number of tuberculosis beds in the continental United States as a result only of the closing of old hospitals and the opening of new hospitals. The corresponding net decrease in tuberculosis bed occupancy is 1,341.

The 31 closed institutions were all located in 10 States; 9 of the institutions were in 1 State which has a progressive program of new

construction to replace small outmoded institutions (1, 2, 4-6).

Twenty-five of the closed institutions were tuberculosis hospitals, the majority of which were old and had a fairly small capacity for tuberculosis patients. Five of the 25 were from 51 to 86 years old; 8 were from 36 to 50 years; 10 were from 14 to 29 years; and only 2 were fairly new, 4 to 5 years old. Eleven of these tuberculosis facilities had less than 50 beds; 6 had from 50 to 74 beds; and the remaining 8 hospitals had 75 beds or more. Table 5 shows the distribution of closed hospitals by rated capacity for tuberculosis. (The size classification shown in tables 3, 4, and 5 is in terms of rated capacity for tuberculosis, as distinguished from the size classification given in table 6, which is in terms of the numerical change in the number of beds occupied.) Six of the 25 tuberculosis facilities were privately owned, 2 were State owned, and all others were owned by the local government—city, county, or district.

The remaining 6 hospitals in the non-Federal group were general hospitals which closed their tuberculosis wards. These facilities were mostly in old hospitals ranging from 35 to 61 years old, the only exception being a 14-year-old hospital. Three of the 6 hospitals had less than 25 tuberculosis beds; only 1 had more than 50 beds (table 5). All except one were owned by the local government; it was privately owned.

Twenty-four of the 31 closed institutions had less than 50 tuberculosis patients each on April 1, 1954. The other 7 institutions had 50 or more patients hospitalized on that date (table 6).

Federal Hospitals

In the 132 Federal hospitals for which data were available in the fall of 1954, there is a decrease in tuberculosis bed occupancy of 4.3 percent (table 1). One hundred and eight of the Federal hospitals (about 82 percent) are Veterans Administration hospitals in which there were 15,334 beds occupied by tuberculosis patients in the fall of 1954. This number represents 83.8 percent of the total number of tuberculosis beds occupied in the 132 Federal hospitals.

Data furnished by the Department of Medi-

cine and Surgery of the Veterans Administration show that the number of tuberculosis beds occupied in the Veterans Administration hospitals has decreased by 2.6 percent in the 8-month period. This decrease appears to be small by comparison with the average decrease and by comparison with the decreases in some other classes of hospitals. This figure, however, reflects only the change in the number of persons hospitalized for tuberculosis in VA hospitals; it does not take account of those persons hospitalized under contract in other hospitals. The number of tuberculosis patients receiving care under VA auspices in contract hospitals has been decreasing since February 1947, and in the 8-month period between March 31 and November 30, 1954, decreased from 916 to 528. This policy of decreasing contract hospitalization and making maximum use of VA hospitals in the presence of a decreased demand for tuberculosis beds is responsible for part of the decrease in bed occupancy in other Federal hospitals and in non-Federal hospitals. Because of the effect of this policy, the average decrease of 6.7 percent for the whole United States has more meaning as a summary figure than the average decrease of 7.4 percent for non-Federal hospitals only. The total number

of patients hospitalized by VA in both its own and in contract hospitals decreased by about 5 percent.

Also of importance in connection with the demand for tuberculosis beds is reliable data about waiting lists. Although such data cannot be assembled for the whole United States, it is available for VA beneficiaries. On March 31, 1954, there were 947 such veterans awaiting admission as compared with 456 veterans on November 30, 1954. Thus, the total number of tuberculous veterans hospitalized and awaiting admission to VA hospitals was 17,614 on March 31, 1954. By comparison there were 16,358 on November 30, 1954, or a decline of slightly more than 7 percent. Here, however, one must recognize that a substantial number of patients may have obtained hospitalization elsewhere before they were reached on waiting lists.

If the VA hospitals are eliminated from the Federal data, the decline in the occupancy of tuberculosis beds in the remaining 24 Federal hospitals is 12.2 percent (table 1).

The Meaning of the Data

The decrease in tuberculosis bed occupancy discussed in this paper is a phenomenon of rela-

tively recent times. Previously, the trend has been steadily upward. Construction of hospital facilities solely for tuberculosis patients started just before the turn of the century. By 1904 there were fewer than 10,000 tuberculosis beds in the United States. This number increased until on April 1, 1953, in the continental United States, there were almost 110,000 tuberculosis beds in which there were more than 96,000 patients. While the number of tuberculosis beds continued to increase, the number of tuberculosis patients hospitalized, however, has shown a decline since April 1, 1953.

During the first half of the century there was urgent need for more tuberculosis beds. As tuberculosis hospital facilities were increased, the number of tuberculosis patients hospitalized increased proportionately. During this period a continuous backlog of patients exerted pressure for the construction of more tuberculosis hospital facilities. However, even with this

SOURCE: References 1-6.

pressure, it was considered normal for 10 to 15 percent of the tuberculosis beds to remain unoccupied.

The decreases which are apparent may be assigned to three causes: reduced demand for tuberculosis hospital facilities, seasonal fluctuation in the data, and representativeness of the reporting hospitals.

While the data available for this paper are much more comprehensive than the occasional reports about bed occupancy which were available around mid-1954, even the data used here leave much to be desired. Although the response rate was remarkably high on the whole, many States are represented by only a small proportion of the total number of beds in the State (table 2). Confidence in the results of this study must be based upon the magnitude of the response rather than upon knowledge of its representativeness. Although the response rate is quite high, we do not know whether the respondents are representative of the whole United States. Nor do we know whether the respondents in a given State adequately represent that State unless every hospital with tuberculosis beds reported in the fall of 1954. The smaller the proportion of beds reported, the less our confidence in the representativeness of the available data.

Moreover, it is not safe to assume that there is a uniform surplus of beds in a State even when all hospitals report, and when the State shows a decrease in tuberculosis bed occupancy. Even this situation may mask serious bed shortages in some parts of the State, or for some classes of patients. For instance, Missouri shows a decrease of 7.2 percent in the number of non-Federal beds occupied over the 8-month period under consideration. However, there are no beds available in Kansas City for children under 12 years of age. Children who need treatment are given limited hospitalization at the Kansas City General Hospital isolation ward. If continued care is indicated, children under 12 must be sent out of the State to a private hospital. Moreover, in Missouri, in spite of the decrease in tuberculosis bed occupancy shown by this study, there were, in October, 41 patients awaiting admission to the State sanatorium at Mount Vernon. In Kansas, which showed a decrease in tuberculosis bed occupancy

of 8.1 percent, there is usually a 3- to 4-week waiting period for admission to State hospitals. In Kentucky, which showed a small decrease of 3 percent in tuberculosis bed occupancy, there is a waiting period of several weeks.

The decrease in tuberculosis bed occupancy for the State of Alabama is so small in the 8-month period that it may be entirely discounted on the grounds of its being due to non-representativeness or to seasonal fluctuation. However, because there does appear to be a slight decrease (table 2), it is useful to notice that at the time the 1954 annual report for the Jefferson Tuberculosis Sanatorium in Alabama was written, there were more than 80 Negro patients awaiting admission to the institution (7). Mississippi also shows a very small decrease but according to the report of a Public Health Service staff member on April 18, 1955, there are 245 Negroes on the waiting list, and it is believed that this number is an underestimate of the actual number of patients waiting for beds since many applications have not been filed because of the already long waiting list.

The preceding paragraphs illustrate that a decrease in bed occupancy can occur in a given State even in the presence of a need for additional beds. It is apparent from the foregoing that these figures, at best, reflect only changes in demand. Since there is a considerable difference between demand and need, these data should not be used as a direct measure of the change in need for tuberculosis hospital beds. Moreover, more beds than are now occupied or needed would be required if tuberculosis case finding and followup were more aggressively implemented. In "Tuberculosis Case Finding in Iowa," (8) for instance, it is pointed out that three-fourths of all of the cases of tuberculosis diagnosed in Iowa during 1952 came to diagnosis "because of symptoms associated with tuberculosis." Many of these cases could have been found earlier by aggressive case finding.

A careful study in Polk County, Iowa, including the city of Des Moines, showed that about 60 percent of the 83 new tuberculosis cases discovered during 1952 and 1953 came to diagnosis because of symptoms. Moreover, for two-thirds of the cases, earlier occasions were identified when a diagnosis of tuberculosis might have been made. Forty percent of

the missed opportunities were attributed to a break in the followup procedure. It is especially interesting to note that the "missed opportunities" were identified only among the moderately and far advanced cases; none could be found for the minimal cases (9).

Additional evidence that X-ray case finding has not yet reached the limit of its usefulness is found in the facts that:

'A million and a half more case-finding films were taken in 1953 than in 1952 without a decrease in the yield of new cases resulting from the case-finding efforts (10). Moreover, 78 percent of the newly reported active and probably active cases for which the extent of disease was specified in 1953 were in the moderately or far advanced stage of disease at the time they were reported. There was essentially no change between 1952 and 1953 in the proportion of cases reported as minimal, moderately advanced, and far advanced (11).

About 5 percent of all newly reported tuberculosis cases were first made known to the health department only at the time of death (11).

Summary

1. The overall average decrease in the number of tuberculosis patients occupying beds in all types of hospitals, Federal and non-Federal, in the continental United States, was 6.7 percent in the 8-month period between April 1954 and November 1954.

2. States which show the largest decline in non-Federal tuberculosis bed occupancy are the ones which, in general, have the largest ratios of tuberculosis beds per annual newly reported active tuberculosis case.

3. The greatest percentage decrease in number of non-Federal tuberculosis beds occupied has occurred in the smaller hospitals; the larger the hospital the smaller the average percentage decrease in number of beds occupied.

4. There is wide variation in the changes in bed occupancy in non-Federal hospitals from State to State. More States show decreases than increases; however, not all of the States which show decreases have a surplus of beds.

5. The average decrease in number of tuberculosis patients occupying beds in all Federal hospitals is 4.3 percent. The Veterans Admin-

istration hospitals, accounting for about 82 percent of the beds in the Federal group, show an average decrease in tuberculosis bed occupancy of 2.6 percent. This average becomes about 5 percent when contract hospitals are combined with Veterans Administration hospitals. The average decrease in tuberculosis bed occupancy in the remaining Federal hospitals (Army, Navy, Air Force, Public Health Service, and the former Bureau of Indian Affairs) is 12.2 percent.

Institutes in Care of Prematures

Three physician-nurse institutes in the care of premature infants have been scheduled during 1955-56 at the New York Hospital-Cornell Medical Center.

The institutes, now in their seventh year, are sponsored by the New York State Department of Health and the Children's Bureau of the Department of Health, Education, and Welfare. They are designed for physicians and nurses in charge of hospital premature nurseries and special premature centers and for medical and nursing directors and consultants of State and local premature programs.

The institutes, of 2 weeks' duration for physicians and 4 weeks for nurses, start September 26, 1955; November 21, 1955; and January 30, 1956. If the number of applicants is sufficient, additional institutes will be scheduled in 1956 beginning April 2 and May 21. Each institute is limited to six physician-nurse teams.

Participants pay no tuition fee, and stipends are provided to help cover expenses during attendance.

Early application is essential in planning the institutes. Additional information may be obtained by writing: Box 143, Institute in the Care of Premature Infants, New York Hospital, 525 East 68th Street, New York 21, N. Y.

The 1954 National Conference on Shellfish Sanitation

By E. T. JENSEN, B.S.C.E.

SANITARY control of growing, harvesting, and processing of shellfish in the United States is achieved by a unique cooperative program operated jointly by the Public Health Service, the States, and the shellfish industry.

This cooperative shellfish sanitation program had its start in the wake of a serious oyster-borne typhoid epidemic. Late in the winter of 1924, simultaneous outbreaks of typhoid fever were noted in Chicago, New York, Washington, and several other cities. In all, 1,500 cases of typhoid fever and 150 deaths in excess of the normal incidence for the disease were reported. A comprehensive epidemiological investigation implicated fresh oysters as the vehicle responsible for the outbreak (1).

The resulting adverse publicity caused sales of oysters and clams to drop virtually to zero in some areas, and the shellfish industry was soon in a state of economic collapse. To reestablish public confidence in raw, fresh shellfish as food, the industry and certain governmental agencies appealed to health authorities for assistance.

Accordingly, the Public Health Service called a public meeting in Washington, D. C., on

February 19, 1925, to formulate a plan for sanitary control of the shellfish industry. The meeting was attended by many State health officers, city health officers, and representatives of other interested State and Federal agencies and of the shellfish industry.

The result was the development of a system of shellfish sanitation which placed responsibility for shellfish sanitation with the States and which is coordinated by the Shellfish Sanitation Section of the Public Health Service.

The Public Health Service was to develop standards, conduct research, review State programs, and advise receiving States of the effectiveness of shellfish sanitation programs in the producing States. This last responsibility has been fulfilled in recent years by distribution of a periodic compilation of State-certified shellfish shippers. The program is considered supplementary to the Food, Drug, and Cosmetic Act (2), and is universally supported as necessary because of the sanitation problems peculiar to shellfish growing and harvesting. In the program, shellfish is defined to mean only oysters, clams, and mussels. The shellfish certification system does not apply to crabs, lobsters, or shrimp.

The success of the shellfish sanitation control program is indicated by the absence of major outbreaks of shellfish-borne typhoid or enteric disease during the 30 years it has been in operation. Despite this long period of successful operation there has been need for a critical re-

Mr. Jensen is the acting chief of the Shellfish Sanitation Section, Division of Sanitary Engineering Services, Bureau of State Services, Public Health Service, Washington, D. C.

view of the shellfish certification system by participating organizations. This need resulted from technological advances in food-handling methods and from the realignment of State health department environmental sanitation activities.

To Review Certification Program

The Association of State and Territorial Health Officers, at its 1953 meeting, adopted a resolution calling on the Public Health Service to sponsor a conference for review of the shellfish certification program.

Acting on this request, the Surgeon General of the Public Health Service invited State and Federal agencies, the shellfish industry, and the Canadian Government, because of our interrelationship with Canada's shellfish certification program, to send representatives to the National Conference on Shellfish Sanitation, in Washington, D. C., September 9 and 10, 1954. The chief and deputy chief of the Bureau of State Services, Public Health Service, presided at the conference.

The conference was attended by 8 State health officers, 28 representatives from State agencies having interests in shellfish sanitation, and 20 from the shellfish industry. Four members of the Canadian Government were present. Our Government was represented by officials from the Department of State, the Department of Interior (the Fish and Wildlife Service), and the Department of Health, Education, and Welfare (the Food and Drug Administration and the Public Health Service). Only 3 interior States were represented; there were no representatives from the east coast clam industry.

To achieve an orderly discussion of all major topics, a 14-member representative committee had prepared an agenda, which included:

- Problems in sanitary control of shellfish production.
- Problems in sanitary control of shellfish marketing.
- Public Health Service participation in shellfish sanitation activities.
- Different sanitary regulations for intra-state and interstate shellfish shippers.
- Importation of shellfish.
- Classification of growing areas.

- Need for specific sanitary requirements for various species of shellfish.

- Future operations of shellfish control programs.

Discussion of these topics led to several general conclusions, most important of which was the indication of satisfaction with the cooperative control program which was expressed by all present at the conference. It was apparent that everyone concerned with shellfish sanitation was convinced that the certification system had been most effective in controlling the spread of shellfish-borne disease and that the system should be continued.

The problem of maintaining interior State interest in shellfish certification was discussed at length, but no conclusion was reached regarding a method of obtaining such interest. The question of breaded-shellfish certification was similarly discussed, but no positive conclusion was reached. However, it was apparent that there was a division of opinion on need for certification of prepared shellfish products. Several State representatives stated there was insufficient public health justification for extending certification to the breaded product.

While it was decided that problems related to shellfish importation (3) should be further discussed among the interested Federal agencies, the State representatives were unanimous in their opinion that shellfish imported into this country should meet the same sanitary standards as required for domestically produced shellfish.

The Future of the Program

The following resolution, unanimously adopted, expresses the sense of the conference:

Whereas, to safeguard public health, there is a continuing need for a program for sanitary control of shellfish processing and distribution in receiving areas, and

Whereas, the establishment of adequate control measures in both producing areas and receiving areas will assist the shellfish industry and provide protection for the ultimate consumer, therefore, be it resolved:

1. That the present policy of Federal-State and industry cooperative relationship be continued, including the listing of certified shell-

fish dealers by the United States Public Health Service, based on its endorsement of the various States' programs.

2. That the Public Health Service develop specific minimum requirements for endorsing States' shellfish programs, which shall take into account varying geographic and other conditions and the various species of shellfish grown therein.

3. That the certification of shellfish packers and repackers, with endorsement of satisfactory State programs by the United States Public Health Service, be developed in all receiving States.

4. That all States be encouraged to require that only shellfish from certified dealers be permitted to be sold.

5. That the program for sanitary control of the shellfish industry be maintained throughout the year in both producing and receiving States.

6. That the Public Health Service maintain a staff to carry out its responsibility in this program, including the necessary research and consultation service.

Action to implement the several sections of the resolution will be initiated by the Public Health Service. However, the ultimate measure of value of the shellfish certification program will be determined by the States' action in refusing to accept shellfish having a questionable certification status.

Syphilis Serology Courses

Nine laboratory refresher courses will be offered at the Venereal Disease Research Laboratory of the Public Health Service in Chamblee, Ga., September 1955-May 1956.

Six of the courses cover the serology of syphilis in general. They include lecture, demonstration, and participation classes in the most widely used American methods for the serodiagnosis of syphilis, including the latest developments. They are to be held on the following dates:

September 26-October 7, 1955	February 6-17, 1956
October 24-November 4, 1955	March 12-23, 1956
January 9-20, 1956	April 2-13, 1956

Tests for syphilis using *Treponema pallidum* as an antigen source are the subjects of two

courses offered October 31-November 10, 1955, and April 16-27, 1956. There will be some class participation in the complement fixation, agglutination, and other such tests.

A course in the management and control of syphilis serology by the regional laboratory, designed for assistant laboratory directors and senior laboratory staff members, is scheduled for April 30-May 11, 1956.

Applications for any of these must be signed by a State health officer or laboratory director, or by a medical officer in charge in the Public Health Service. Application forms may be obtained by writing to: Director, Venereal Disease Research Laboratory, Division of Special Health Services, Public Health Service, Department of Health, Education, and Welfare, P. O. Box 185, Chamblee, Ga.

view of the shellfish certification system by participating organizations. This need resulted from technological advances in food-handling methods and from the realignment of State health department environmental sanitation activities.

To Review Certification Program

The Association of State and Territorial Health Officers, at its 1953 meeting, adopted a resolution calling on the Public Health Service to sponsor a conference for review of the shellfish certification program.

Acting on this request, the Surgeon General of the Public Health Service invited State and Federal agencies, the shellfish industry, and the Canadian Government, because of our interrelationship with Canada's shellfish certification program, to send representatives to the National Conference on Shellfish Sanitation, in Washington, D. C., September 9 and 10, 1954. The chief and deputy chief of the Bureau of State Services, Public Health Service, presided at the conference.

The conference was attended by 8 State health officers, 28 representatives from State agencies having interests in shellfish sanitation, and 20 from the shellfish industry. Four members of the Canadian Government were present. Our Government was represented by officials from the Department of State, the Department of Interior (the Fish and Wildlife Service), and the Department of Health, Education, and Welfare (the Food and Drug Administration and the Public Health Service). Only 3 interior States were represented; there were no representatives from the east coast clam industry.

To achieve an orderly discussion of all major topics, a 14-member representative committee had prepared an agenda, which included:

- Problems in sanitary control of shellfish production.
- Problems in sanitary control of shellfish marketing.
- Public Health Service participation in shellfish sanitation activities.
- Different sanitary regulations for intra-state and interstate shellfish shippers.
- Importation of shellfish.
- Classification of growing areas.

- Need for specific sanitary requirements for various species of shellfish.

- Future operations of shellfish control programs.

Discussion of these topics led to several general conclusions, most important of which was the indication of satisfaction with the cooperative control program which was expressed by all present at the conference. It was apparent that everyone concerned with shellfish sanitation was convinced that the certification system had been most effective in controlling the spread of shellfish-borne disease and that the system should be continued.

The problem of maintaining interior State interest in shellfish certification was discussed at length, but no conclusion was reached regarding a method of obtaining such interest. The question of breaded-shellfish certification was similarly discussed, but no positive conclusion was reached. However, it was apparent that there was a division of opinion on need for certification of prepared shellfish products. Several State representatives stated there was insufficient public health justification for extending certification to the breaded product.

While it was decided that problems related to shellfish importation (3) should be further discussed among the interested Federal agencies, the State representatives were unanimous in their opinion that shellfish imported into this country should meet the same sanitary standards as required for domestically produced shellfish.

The Future of the Program

The following resolution, unanimously adopted, expresses the sense of the conference:

Whereas, to safeguard public health, there is a continuing need for a program for sanitary control of shellfish processing and distribution in receiving areas, and

Whereas, the establishment of adequate control measures in both producing areas and receiving areas will assist the shellfish industry and provide protection for the ultimate consumer, therefore, be it resolved:

1. That the present policy of Federal-State and industry cooperative relationship be continued, including the listing of certified shell-

fish dealers by the United States Public Health Service, based on its endorsement of the various States' programs.

2. That the Public Health Service develop specific minimum requirements for endorsing States' shellfish programs, which shall take into account varying geographic and other conditions and the various species of shellfish grown therein.

3. That the certification of shellfish packers and repackers, with endorsement of satisfactory State programs by the United States Public Health Service, be developed in all receiving States.

4. That all States be encouraged to require that only shellfish from certified dealers be permitted to be sold.

5. That the program for sanitary control of the shellfish industry be maintained throughout the year in both producing and receiving States.

6. That the Public Health Service maintain a staff to carry out its responsibility in this program, including the necessary research and consultation service.

Action to implement the several sections of the resolution will be initiated by the Public Health Service. However, the ultimate measure of value of the shellfish certification program will be determined by the States' action in refusing to accept shellfish having a questionable certification status.

Syphilis Serology Courses

Nine laboratory refresher courses will be offered at the Venereal Disease Research Laboratory of the Public Health Service in Chamblee, Ga., September 1955-May 1956.

Six of the courses cover the serology of syphilis in general. They include lecture, demonstration, and participation classes in the most widely used American methods for the serodiagnosis of syphilis, including the latest developments. They are to be held on the following dates:

September 26-October 7, 1955	February 6-17, 1956
October 24-November 4, 1955	March 12-23, 1956
January 9-20, 1956	April 2-13, 1956

Tests for syphilis using *Treponema pallidum* as an antigen source are the subjects of two

courses offered October 31-November 10, 1955, and April 16-27, 1956. There will be some class participation in the complement fixation, agglutination, and other such tests.

A course in the management and control of syphilis serology by the regional laboratory, designed for assistant laboratory directors and senior laboratory staff members, is scheduled for April 30-May 11, 1956.

Applications for any of these must be signed by a State health officer or laboratory director, or by a medical officer in charge in the Public Health Service. Application forms may be obtained by writing to: Director, Venereal Disease Research Laboratory, Division of Special Health Services, Public Health Service, Department of Health, Education, and Welfare, P. O. Box 185, Chamblee, Ga.

Air pollution, chronic illnesses, radiological health, dental health, and accident prevention call for fresh activity in a State occupational health program.

Potential of an Occupational Health Program in a State Department of Health

By DANIEL BERGSMA, M.D., M.P.H.

FIFTEEN YEARS AGO, when a program of industrial hygiene was started in the New Jersey State Department of Health as a Public Health Service demonstration, we learned the credo of preplacement physical examination, engineering control, and industrial hygiene toxicology. These items form the foundation stone of occupational health activities today, but they are only the foundation stone. Upon them can be built a superstructure that reaches into many areas of public health and community life.

Informing Community Groups

One of the great untapped potentials in occupational health is the informing of community groups who have an interest and responsibility in the health and welfare of the working population. Henry Doyle, chief of the Public Health Service's Occupational Health Program, has stated the unfortunate truth and

the remedy: "It is generally recognized that the public . . . knows relatively little about what the government is doing to protect the health of the worker. In creating a climate of favorable opinion and action, publicity can serve as an invaluable tool."

Office memorandums, reports of field trips, letters to plant owners or plant managers are all an integral part of an official occupational health program, but these writings should not be the ultimate repository of all the staff's knowledge; neither should the technical paper nor the technical conference. It is the duty of every person engaged in an official health activity to translate his information, his special skills, and his achievements into terms that the community can understand. Then, administrative channels of communication must be established and so managed that the information reaches the public and the public is motivated to make use of it. Time consuming though it may be, the personnel of an occupational health unit must be ready and willing to teach at colleges or universities, to participate in industrial work shops, and to speak at association meetings and community forums.

As an example of such an activity, staff members of the New Jersey State Department of Health will soon present a lecture-demonstration at the annual meeting of the New Jersey State Bar Association. The presentation,

Dr. Bergsma, who joined the New Jersey State Department of Health in 1938, has been commissioner of health of New Jersey since the creation of that title in June 1948. This paper was presented before the 1955 Industrial Health Conference at Buffalo, N. Y., on April 26.

which is entitled "Methods of Prophylaxis and Diagnosis of Occupational Diseases," has been meticulously worked out to demonstrate the physician-engineer-chemist teamwork approach. Thus, while admitting that much still remains to be done in public health medicine, we are preparing to invade one fringe of the law relating to public health.

Coordination With Other Programs

Recognizing that the worker has a place of residence as well as a place of work and that he is usually part of a family group, New Jersey's program of industrial hygiene was expanded to the program of adult and industrial health more than 7 years ago. The current name is adult and occupational health, which expresses the present-day philosophy of man as a total integrated human being.

With this view of man, it seems to me that plans for an occupational health program should be based upon coordinated public health practices. I believe that almost every activity in public health or preventive medicine could be improved by coordinating it and occupational health. In some instances, the occupational health program should take the initiative in organizing such joint effort.

Air pollution control, which is creating a pressing problem for most health departments, is one activity that might well be coordinated with occupational health. Rightly or wrongly, industrial installations are often accused of being the perpetrators of the crime of air pollution. In any event, an investigator who knows what is going on inside an industrial plant is in a particularly advantageous position to know what is coming out of it. Since this knowledge is in the hands of the occupational health unit, this unit is one logical place for a health department to organize an air pollution control program.

But, of course, industrial air effluent is not the only cause of air pollution. Pollens, for example, are often a significant part of the total picture. Therefore, if the occupational health unit is responsible for air pollution control, it will need to coordinate its work with that of the unit in charge of pollen sampling and eradication of ragweed.

A recent study in New Jersey of house paint discoloration allegedly caused by a nearby rubber industry revealed that the agent of the discoloration was mildew. We have no bureau of fungus control in the New Jersey health department, but I am happy to delegate this function to the adult and occupational health program.

With the exception of berylliosis, specific disease syndromes from air contaminants are difficult to establish. It has been said that an epidemiological study extending over 20 to 30 years is necessary for a determination of the long-term effects of air contaminants. Such a study must obviously be a coordinated project of the programs for occupational health, chronic illness control, and vital statistics. In the study, morbidity and mortality records, multiphasic screening to detect chronic diseases, and air sampling would be of equal importance.

Having once joined forces with the chronic illness control program, the vital statistics unit, and other health department activities, the occupational health program should be ready and willing to cooperate with them in the use of every available resource to restore and enhance the health of the community. The newer multiphasic screening techniques furnish an excellent means by which the occupational health program may assist in the development of a positive adult health program. Through education and demonstration efforts designed to initiate preplacement and periodic physical examinations in industry, it can be emphasized that industrial medical services are preventive not only for occupational diseases but for the far more numerous nonoccupational illnesses that afflict industrial workers.

Tuberculosis, diabetes, heart disease, cancer, and venereal disease are among the disorders that can be revealed by relatively simple methods. Every industrial plant should be encouraged to expand the spectrum of its preplacement and periodic physical examinations so that symptoms of these diseases may be detected. Proper facilities may be available at the plant, mobile units may be used for demonstrations, or employees may go to community health centers.

Mass serologic testing programs to uncover venereal disease can easily be performed in in-

dustrial plants either by community public health personnel or by plant medical personnel. Such programs can be stimulated by the staff of the adult and occupational health program, and proper followup and treatment of any cases detected, as well as the tracing of sources and contacts, can be assured through coordinated effort.

Following the development of cancer detection services, industrial plant management should be encouraged to have employees participate, especially those employees 45 years of age and over. In industrial areas where cancer mortality or cancer morbidity of a specific type increases suspiciously, personnel of the adult and occupational health program should be requested to visit the plant and to conduct studies to determine the presence of known or suspected carcinogenic agents. In the present state of our knowledge, the environmental and occupational carcinogens compose the only phase of cancer control in which true prevention can be a fact.

Radiological Health

Any current discussion of cancer control as a public health activity leads one to problems of radiological health. Radiation is an excellent example of a two-edged sword. It can be used to detect and treat new cancer growths, but, also, it has definitely been incriminated as a prime agent in the causation of cancer of the skin, the bones, the lungs, and the blood. The increasing use of radioisotopes and all other sources of ionizing radiation has created the need for organized public health programs in radiological health. Personnel willing to be trained, and capable of being trained, in the new science of nuclear physics are found in occupational health units.

Industrial X-ray machines, industrial radiography using radium or cobalt-60, static eliminators, beta gauges, and tracer uses of a variety of radioisotopes have been the initial stimulus for expanding industrial hygiene techniques into the field of radiation. However, the public health problem is larger and more complicated than industrial utilization of ionizing radiation. X-ray machines for diagnosis and therapy, radioisotopes for research and for treatment, detection, and localization of path-

ology, fluoroscopic shoe-fitting machines—all these increase the radiation exposure of the general public and make necessary education in the safe handling of these items and varying degrees of regulation and control.

It has become one of the functions of New Jersey's adult and occupational health program to administer all phases of radiological health. The most effective way to reach professional groups has proved to be through the health department's medical programs. Monitoring of mobile chest X-ray units and of tuberculosis clinics, heart disease clinics, and multiphasic screening installations has impressed physicians, nurses, technicians, and local health department staffs with the basic principles of good radiological methods. It is, of course, not adequate for the occupational health representative to perform the required instrumentation, make a report, and then depart. Unless he learns something about the incidence and prevalence of disease in the community and obtains a working knowledge of what the radiation procedure is expected to accomplish, he cannot draw valid conclusions concerning the justification for a single radiation exposure as extensive as that used in angiocardiology or for the repeated exposures used in suspected or arrested cases of tuberculosis, for example.

Approaching the Second Milestone

What I have discussed so far is about the extent of the progress made by our occupational health staff. We have not limited ourselves to strict routine; on the other hand, we have not utilized all the tools available to a State health department.

The New Jersey State Department of Health is well past the first of the two industrial hygiene milestones cited by Victoria Trasko (1)—the acceptance of industrial hygiene as a public health responsibility. The second milestone, the broadening of the concept of occupational health to embrace the total health of the worker, is just within sight on the horizon. To some degree, we are plagued by the usual shortages of personnel, equipment, and operating funds. Nonetheless, by maximizing cooperation with other health department programs, I am sure that the occupational health program could do

a better job without undue strain on present personnel.

One of the possibilities for further expansion is the coordination of occupational health and the dental health program. It is well known that a healthy oral cavity has a direct constructive influence on industrial production and, conversely, that an oral infection has an adverse influence. "An aching tooth in an individual can become a company's toothache affecting not only the well-being of the individual but jeopardizing the safety of fellow employees. Pain of dental origin causes loss of sleep, fatigue, and mental distraction. Accidents follow . . ." (2).

I can visualize a two-way process in which the public health dentist makes a contribution to occupational health and the occupational health staff expedites basic dental health activities. The services of the public health dentist may be enlisted to provide educational material for industrial employees as to the value of routine periodic dental examination. By virtue of his contact with State and county dental societies, he is also in a position to supply information concerning community dental resources. He may even contribute more directly by becoming the consultant on oral pathology due to specific occupational materials. In turn, the occupational health staff can assist in the encouragement of fluoridation by demonstrating that fluorides have been handled in industry for many years without the occurrence of toxic effects when adequate precautions are taken. This information properly and personally supplied by an occupational health physician or an industrial engineer or toxicologist would carry considerable weight in quieting the fears of those who suspect that fluoride in water constitutes a latent hazard.

Impaired hearing is another area in which the occupational health program may work constructively with other groups. Occupational hearing loss is one of the newer and more popular concerns of the industrial hygienist. Impaired hearing and speech defects in children receive attention in maternal and child health programs and in programs for handicapped children. Pooling the efforts of these programs should afford a considerable increase in the knowledge of hearing changes that occur with advancing age. It should also suggest to

the busy industrial hygienist that rehabilitation of persons suffering hearing loss is often possible for adults as well as for children.

Additional areas for investigation become apparent as occupational health is coordinated with the maternal and child health program. One of these concerns the common household substances which have proved dangerous, and even lethal, to children and the unwary housewife. The industrial toxicologist member of the occupational health team is preeminently qualified to discuss the hazardous components of cleaning fluids, bleaches, insecticides, and other substances and, with the industrial physician, to prepare a schedule of emergency treatments. The maternal and child health personnel, through their contacts with parent-teacher associations, women's clubs, and child care clinics, are in a position to spread the word.

A second joint project for occupational health and maternal and child health, one which I have not seen described elsewhere, concerns the probable special susceptibility of the pregnant woman to toxic materials, such as the chlorinated hydrocarbons, benzol, and radiation. The health department frequently receives requests from industrial plants and labor unions for information concerning the employment of pregnant women. The occupational health staff should have more to offer than the ordinary rules about rest periods and sedentary occupations.

Accidents and accident prevention have only recently begun to attract the attention of health departments. The accident-prone individual in industry has been described as careless, tired, nervous, worried, or in conflict with society. The problem of accidents in industry can be handled to some extent by health counseling, but actually it is part of the larger problem of community mental health.

Community agencies offer valuable resources for assistance with personal problems or health counseling. The occupational health staff might well investigate the community facilities that can assist the disgruntled, accident-prone individual or the individual who seeks escape by way of alcohol. Familiarity with the tenets of mental health will help in solving the problem of the tired, listless worker, whose emotional difficulties often arise from an unsatis-

factory environment. An employee's loss of satisfaction with his job added to his distrust of the society in which he lives and works may well result in fatigue, indifference, or illness. This concept of the emotionally disturbed worker underlies what has been called by some industrial hygienists human engineering. I think what is needed is the promotion of mental health, and I believe that mental health should be the responsibility of community organizations.

Strengthening Local Health Departments

Assistance in dealing with the problem of accidents is not the only way in which the community can contribute to occupational health. In fact, it is not expected that a State health department staff will be large enough to provide direct services on the community or local level. Perhaps the outstanding responsibility of a State health department is to strengthen local health departments and to provide them with consultation and ancillary services sufficient for them to administer direct services in their own jurisdiction.

The Committee on Scope of the American Public Health Association's Occupational Health Section has taken this stand on occupational health activities by local health departments (according to the committee's report at the 1954 meeting of the association): "The committee feels that there is an untapped reservoir of opportunities in occupational health at the local health department level. Not only in the development of pure industrial health activities by local health departments, but the use of occupational groups as a medium for the application of traditional health department functions needs to be exploited. For example, how many communities are there where industrial opportunities for the application of immunization programs, of adult health programs, of communicable disease control activities, etc., have been fully or even initially developed?"

When local health departments can be persuaded to attempt even minimal occupational health activities and to include industrial establishments and workers in their general health programs, a beginning will have been made

toward solving the problem of medical services for small industrial plants. Strong community organization may well supply the impetus for better health care for all members of the community. The State occupational health personnel must be ready to provide information, demonstrations, and technical assistance.

The Fullest Potential

The aforementioned activities are only a few of the projects that may be classified as potentials for an occupational health program in a State health department. New Jersey is a small State, densely populated and highly industrialized, with a great diversity of industries. It could well serve as a clinic for studying preventive medicine and the adaptation of the adult to the complexities of today's social order.

This fall, Seton Hall University will open the doors of its new school of medicine, the first medical school in the State. I am hopeful that before long the curriculum will include courses in industrial medicine and occupational health. No physician practicing in New Jersey can fail to have among his patients many whose lives have been influenced by industrial processes.

I was much impressed by Dr. Jean Spencer Felton's address, "Increasing the Awareness of Occupational Medicine in a Medical Center" (3). Every topic that Dr. Felton discusses—industrial health lectures, plant tours, multiphasic screening, rehabilitation, job placement of the handicapped, and, last but not least, community orientation—could well be adopted by a State health department. Not until an occupational health program, either alone or in conjunction with a medical school or university hospital program, has assimilated and coordinated all these functions will it have reached its fullest potential.

Approaches to the Quality of Hospital Care

By MINDEL C. SHEPS, M.D., M.P.H.

INCREASING ATTENTION is being paid to the problems of improving and of appraising the quality of health services in general (1-8) and of hospital care in particular. The general problems of measurement and evaluation in all these areas are similar (9-16). Basically, they involve finding valid and reliable measurements of quality and interpreting these measurements when made.

Purposes of Hospital Evaluations

Evaluations of hospital quality may have different purposes. The methods and standards selected must be related to the particular purposes for which they are being applied. The most familiar purpose is regulatory. Such an appraisal is designed to match an institution against specified standards that determine its acceptability for the purposes of the regulatory or accrediting agency. It is intended to correct abuses and raise the general level to an acceptable minimum. Various national bodies, now united in the Joint Commission for the Accred-

itation of Hospitals, have evolved minimum acceptable levels of facilities, equipment, administrative and professional organization, and professional qualifications. They have also made use of some numerical indexes of organization and performance. All of these have been set forth in the commission's Standards for Hospital Accreditation.

The requirements of licensing boards, health insurance funds, and other organizations serve a similar purpose. Regulatory appraisals set minimum or desirable levels by excluding institutions that fail to qualify. At the same time, this provides protection for patients and students who go to acceptable institutions (17-20). As yardsticks, these standards have one division that divides hospitals into two classes only—good enough or not good enough.

Improvement of Quality

The second purpose of appraisals is a closely related one—that of serving as a stimulus for the improvement of quality. Licensing and accrediting assessments serve this purpose as well as that of regulation. Hospitals also make self-appraisals for this purpose. The standards used may be minimum or optimum levels, similar to those used for regulatory purposes, or may provide for comparisons among physicians in the same institution. One of the chief instruments for such appraisals has been the medical audit (21-25).

The basis of the audit is a review of hospital records according to such criteria as qualitative judgments of the care given and examination of diagnostic errors (26-29), as well as such numerical indexes as mortality rates, rates for the

Dr. Sheps is research associate, department of biostatistics, Harvard School of Public Health, and lecturer on biostatistics, Boston University Medical School. She presented this paper at a joint session of the Medical Care Section of the American Public Health Association and the American Association of Hospital Consultants at the 82d annual meeting of the APHA in Buffalo, October 14, 1954. A news summary of Dr. Sheps' paper appeared in the February 1955 issue of Public Health Reports, p. 198.

incidence of specific complications, removal of normal tissues at operations (30-32), consultations, cesarean rates, and the rates for certain tests by diagnostic category. The term "professional service accounting" has been suggested for the compilation of these rates and "medical audit" for their evaluation.

Program Evaluation

The third, and more recently recognized, purpose for quality appraisal, is to study the effects of specific programs or procedures on the quality of care. Generally we may refer to this purpose as program evaluation. Certain procedures, such as clinical-pathological conferences, are believed to improve the quality of hospitals. Large-scale complex programs, such as regionalization, are under trial. It is essential that their effectiveness be examined. We need to know in detail the effect of such procedures on the care received by patients. Program evaluation is the attempt to study this effect, by seeing whether a difference or an improvement in quality is associated with a certain procedure or program.

In other situations the purpose of a program evaluation may be to see whether a certain institution is giving "good" care. Such an appraisal is basically an evaluation in which the judge compares what he finds with what in his mind seems desirable and possible.

For regulatory purposes, it is desirable to establish criteria which actually do differentiate between acceptable and unacceptable institutions. They must be discriminating at the level where the regulating agency feels the line must be drawn. To help in improving the quality of hospital care, the criteria used must discover the most important problems and reflect progress in meeting them. Criteria used for these purposes may be useful in program evaluation, but more refined measuring tools are also needed. A scale which only says "good enough" or "not good enough" is inadequate. What is needed is a scale that measures values along a continuum extending from one extreme to the other. The measurements used must be sensitive to those aspects of hospital quality that may be affected by the program.

Reference has been made to some of the standard methods in use. It has recently been stated

that the statistics used in judging hospitals are "usually meaningless, often illogical and frequently unscientific" (33). For example, post-operative mortality ratios are based on deaths within 10 days divided by the total number of operations performed. Thus, deaths after 10 days are omitted, and on the other hand procedures of varying risks, such as dental extractions and neurosurgery, are indiscriminately lumped together.

Moreover, there is a question regarding the validity of the standards by which some of the indexes are evaluated (33-36). A top limit of 3 to 4 percent is set for cesarean sections, but current clinical practice and results justify consideration of a higher level. Many of the standards were derived empirically, and their validity was not adequately established. Progress in clinical practice, in any case, calls for frequent revision and revalidation of the standards. The standards to be used, therefore, should be at levels which move according to changing medical knowledge.

The American College of Surgeons and the Professional Activity Study Group in Michigan are cooperating on a new approach to the audit as a measuring device and on the development of new indexes (36). A number of new indexes of hospital or medical care have recently been described (37-39). Studies currently in progress in the Rochester Regional Hospital Council, the North Carolina General Practice Study, and the Boston Evaluation Study may produce other indexes.

Other methodological developments of interest have been the application of the time study technique to hospital nursing (40) and a statistical analysis of the items included in hospital licensing regulations (41).

Problems of Measurement

Hospital care is multidimensional. It is a service provided by a coordinated group of professional, technical, and other workers under the direction of a physician. The quality of the care received by patients is affected by the adequacy of the hospital facilities and their maintenance, by the administrative and professional organization of the hospital, by the competence of the personnel, and by the inter-

personal relations among the staff as well as between the staff and the patients.

Any consideration of evaluation, therefore, must recognize the large number of factors involved in patient care. It has been frequently suggested that an appraisal form for hospital quality be developed. Some have extended this concept to include deriving a final score or number to represent the quality of a given hospital. Such a composite index would obscure important differences. Moreover, it would be impossible to choose the items to be included and the relative weights for them on a basis that was generally applicable. On the other hand, a number of measurements can be made and each of these allowed to stand by itself, thus producing a profile of the hospital (42). We do not try to represent the health status of an individual by a single figure such as 90 percent of the optimum, but rather, we say something like:

"This patient's health, in general, is excellent, except for mild obesity and a hemoglobin of 10 grams."

Similarly, would it not be meaningful and helpful for the final report of a study to state not that "the quality is good" but rather something of this sort:

"Differences found in the following indexes were highly significant . . . No differences were observed in . . . The quality of physicians' services was significantly higher . . . The differences in social service were not significant . . ."

An exhaustive discussion of all the aspects of hospital care that could be included in such a profile will not be attempted. Instead it is proposed to deal with some of the methodological problems involved.

The main techniques used in appraisals of hospital quality can be divided into:

- The examination of prerequisites or desiderata for adequate care.
- Indexes of elements of performance.
- Indexes of the effects of care.
- Qualitative clinical evaluations.

By Set Standards of Care

According to the first approach, it is assumed that it is possible to select prerequisites for adequate care and that improvement of these fac-

tors leads to improved care. These prerequisites are minimum or optimum levels of facilities, equipment, professional training, and organization. As examples we may mention:

- The provision and appropriate maintenance of adequate physical facilities.
- The existence of special facilities, such as blood bank, bone bank, special laboratory and diagnostic facilities, premature nursery, and artificial kidney.
- An effective organizational structure, both administrative and professional.
- Standards and functioning of service departments such as records, laboratories, and libraries.
- Numbers of personnel by size of hospital—interns, residents, nurses, social workers, physical therapists, nutritionists, technicians.
- The availability of specialized personnel for consultation and of facilities for consultation with others, as in certain regional programs.
- Arrangements for ward rounds, refresher courses, continuing education.
- Minimum qualifications of personnel.
- The existence and functioning of internal controls, such as tissue committee, obstetrical committee, and medical audit.

The use of this approach implies the hypothesis that, given certain facilities and standards, the desirable quality of care is achieved. This hypothesis should be recognized and tested explicitly so that valid criteria can be used in a more informed fashion and to better purpose.

Consideration of the norms used for these desiderata raises such questions as, should they be national averages, regional averages, minimum adequate levels or optimum levels, or, should the search for standards be abandoned and the findings on various hospitals simply compared with each other? The answer depends partly on the purpose of the appraisal. In program evaluation, for example, it may be preferable to use flexible indexes applicable to different types of hospitals and to different periods, rather than to adopt any fixed standard of desirability.

Similar considerations led Stouman and Falk (10), in their proposals for international health indexes, to abandon the search for standards. If one has valid measurements for a characteristic, then intelligent, directed appli-

cation of these measurements in some situations will provide useful information as to their variability and their significance without a norm.

The argument will perhaps be made clearer by an example. When we use an index such as weight of children, we need a knowledge of norms to assist in diagnosis of a particular child. However, if we want to test the effect of a certain vitamin on weight, we need to compare the gains made by children receiving the vitamin and those not receiving it. Knowledge of the norms is here irrelevant.

By Elements of Performance

The second approach to quality uses indexes intended to reflect one or more elements of performance. Indexes may be defined as "one or a set of measures . . . used to measure indirectly the incidence of a characteristic that is not directly measurable" (43). Patient care is such a characteristic. Its quality cannot be measured quantitatively, except by the arbitrary allotment of a certain number of points to a qualitative judgment. It is difficult to define; it is complex and intangible. It is therefore natural and logical that much of the effort to evaluate this quality has been focused on the development of indexes, for example:

- Utilization rates for specific procedures by category, such as admission chest X-rays as an index of preventive services, or rectal examination in specified groups of patients.
- Utilization rates of certain laboratory and other diagnostic procedures, by category.
- Indexes which would reflect the promptness and discrimination with which new procedures or drugs are used in the hospital.
- Referral rates and patterns.
- Autopsy rates.
- Cesarean rates.
- Pathological reports on surgical specimens.
- Correlations between preoperative and post-operative diagnoses and between ante-mortem and post-mortem diagnoses.
- Accuracy of diagnostic procedures.
- Average length of hospital stay by diagnosis.

It may be hypothesized that in a well-organized service where the staff members work with purpose and integration, hospital stay will be shorter, on the average, for certain types of cases.

- Listing specific diagnostic and therapeutic procedures expected for each type of case and matching records against them.

Good indexes are objective, reliable, and valid. By the reliability or precision of a measurement, we mean the degree of agreement among repeated measurements of the same things. Numerical indexes, such as rates or ratios, would appear to be relatively precise—anyone counting the number of autopsies done out of all hospital deaths should get the same rate provided that a hospital death is defined without ambiguity. Reliability is more difficult to achieve in indexes that require measurement rather than counting, as has been shown when different physicians measure the same enlarged livers (44), or the same reactions to tuberculin tests (45). Agreement on interpretation of X-ray films, even when repeated by the same physician, is far from perfect (46). Quality indexes that depend on such assessments or on diagnosis, however made, must be tested for precision. It is an error to assume that because they are numerical they are precise.

The use of these performance indexes depends on an assumption that they are valid for an assessment of hospital quality. Presumably this involves the hypotheses (a) that each index does measure an element of patient care, and (b) that one or a number of these indexes are highly correlated with the intangibles of care. These hypotheses can and should be examined in the light of clinical information and by statistical analysis.

Again, the desirability and validity of the yardstick for these indexes must be examined. We can all agree that the higher the proportion of correct diagnoses, the better the quality of medicine. But what proportion ought we to expect in 1955 in different hospitals?

Other standards are even less definite. There can be too many laboratory tests as well as too few; too few cesareans as well as too many. Discriminating standards would be based on studies of the relation between good patient care and the resultant number of procedures by category of case. The development of appropriate yardsticks thus involves studies to estimate desirable levels for the various indexes and the expected variation. These levels should be adaptable for different types of hospitals

and capable of reflecting progress in clinical medicine.

By the Effects of Care

A third approach to appraising hospital quality is the use of indexes intended to measure the effects of quality of care on patient health. The outcome of specific therapy is influenced by many factors in addition to that of treatment, factors such as age, sex, nutrition, stage of the disease, and the emotional state of the patient. The use of these indexes may therefore be highly misleading. It necessitates a careful evaluation of concomitant factors and an attempt to control them.

Some instances of such indexes are in fairly common use. They include:

- Specific mortality ratios such as postoperative, puerperal, and neonatal.
- Survival rates of premature infants in a specified weight range.
- The incidence of preventable complications such as postoperative infections.

These indexes would seem to be relatively precise if their basis is carefully defined. A postoperative mortality rate depends only on the careful definition of postoperative deaths and of the types of surgery counted. However, the validity of this rate as an index of the quality of surgery would still need to be established. The definitions used are highly relevant to this validity. But even then questions remain:

Does the death rate within 10 days after major chest surgery really reflect the quality of care?

What about the effect of such patient characteristics as diagnosis, complicating illnesses, age, sex, and nutritional status?

Objective indexes of the kinds discussed therefore require careful definition and evaluation. They hold considerable promise for the appraisal of hospital quality, but they are not yet the ideal measuring tools. At best, they are indirect and partial indicators of the basically intangible characteristic with which we are concerned. In a given organizational setting, with access to given standards of consultation and services, doing a certain number of laboratory examinations, one can have numerous shades in the range of quality of care, depending on the skill, the judgment, the experience and the

character of the persons involved and on their relationships with patients. This end product is what one really is trying to evaluate in any assessment of patient care. It is for this reason that some workers have tackled the problem of evaluating quality directly through the fourth approach, namely a clinical evaluation.

By Clinical Evaluations

Makover (47) included a clinical evaluation in his study of medical groups associated with the Health Insurance Plan of New York. The continuing HIP evaluation program has adapted some of his techniques as well as adding new ones. According to a preliminary unpublished report by M. A. Morehead, delivered at the 1954 New England regional meeting of the American Public Health Association, records from six clinical fields are selected and scores assigned on the completeness of records, diagnostic management, treatment, and reporting. Although performance is measured against prepared standards, the final score depends on the judgment of the consultant making the evaluation.

More recently, another type of combined appraisal was made by Goldmann and Graham (48). To an analysis of the availability of service and utilization of service, they added qualitative ratings of the efficiency of service organization and of a random sample of patient records.

Clinical evaluations are in the end subjective and thus less precise than some of the indexes previously discussed. However, they may be more valid since they are a direct approach to the characteristic we want to evaluate, the quality of patient care. Quality, though intangible, is not an abstraction. Nor is judgment of quality capricious or a purely personal whim. While agreement could not be expected to be complete, there are, in numerous situations, widely accepted concepts of what is meant by good care.

The reliability of qualitative judgments can be tested, and they can be subjected to statistical analysis (49-51). To make relatively precise estimates of quality, it is necessary to have the findings of several independent judges. This permits an assessment of the degree of agreement among judges (52, 53); it allows for an

objective test of the reliability of the evaluations and diminishes the effect of individual bias. Although more difficult than assessing the precision of interpretations of objective tests, it is the same in principle.

At times, agreement on judgmental evaluation is better than agreement on definitions and criteria. Reynolds (44) describes such a case. A group of clinicians attempting to outline criteria for ambulation of patients with infectious hepatitis could not reach agreement after a lengthy discussion of weighting procedures. But analysis of "paired comparisons" by which each man gave his preferences between the criteria in all possible combinations of two, resulted in good agreement on the ranks to be assigned them. Thus, it may be that several clinicians would agree more readily on the relative ranks of a number of hospitals than they would on the weights to be given various objective indexes in computing a quality score.

Judgmental assessments are resorted to in other fields. In some food industry situations the taste of a product must be evaluated. Objective tests give some information, but to answer the important question, "how does a particular process affect the taste," one must in the end resort to tasting the food. If it is necessary to study the effect of different ingredients and preparation procedures on the palatability of ice cream, the only way out is to ask a number of judges which product tastes better to them.

From such tests, valid results may be obtained notwithstanding the problems related to non-agreement among a group of judges and the lack of consistency on the part of an individual judge. The validity is also dependent on such controls as randomization of the tests and the judge's ignorance of which particular product he is testing.

Accordingly, it would appear that appropriate experimental and statistical procedures would enable more meaningful results to be obtained from qualitative evaluation of hospital care. In general, qualitative judgments are expressed through either ranking or scoring.

In ranking, a number of units are placed by each judge in order of his preference and the various ranks analyzed for consistency.

In scoring, a scale of quality is established,

and each judge assigns the score that he considers appropriate.

These techniques may be combined in various ways. Thus, individual scores can be given on quality in different clinical fields, and the findings combined into one overall score. The subjects may then be ranked according to the scores obtained.

As already emphasized, the use of these techniques depends on replication, that is, on securing at least two separate evaluations of the same set of units. This is not the same as asking a committee to make a combined appraisal. Only through separate evaluations is it possible to assess the consistency of the individual judgments and to arrive at a relatively unbiased estimate. The value assigned results from combining the different judgments, and is more reliable and objective than the opinion of a single individual. A committee of experts would emerge with one final appraisal, but this would not allow the internal checking suggested. It is even possible with such a panel that one or two members could influence the others so that the final assessment would not be truly a consensus.

If qualitative appraisals of hospital care are made, the particular aspect of care to be studied might be medical, surgical, obstetrical, nursing, social work, or a combination of these and others. Well-qualified, experienced practitioners in the field under study should make the evaluation. Although most clinicians, medical and other, would probably prefer to base their opinions on actual observations of patient care, a properly selected random sample of clinical records may provide adequate information. If various clinical fields were reviewed, replication would be desirable in each field. The evaluations in the major clinical fields could then be crosschecked to test the consistency among them.

It is obvious that such qualitative judgments would have meaning only as comparisons among different hospitals or subdivisions of hospitals. The rank or score would have no absolute value but merely a relative value within the groups appraised. Direct comparisons are unavoidable when we operate without a scale or yardstick. However, this only makes explicit the fact that comparison lies at the basis of all meas-

urement. Measurement has been defined as "the assignment of numerals to things so as to represent facts and conventions about them . . . under a consistent set of rules" (54).

The operations to which any measurements can be subjected depend on the rules that can be made and on the validity and reliability of the values obtained. However, with any measurements we make comparisons. If we measure height, we compare the height of the subject with the markings on an arbitrary scale. These markings have meaning only in terms of established norms, of earlier results on the same subject, or of readings obtained from another subject. When we don't have a ruler, we can stand two subjects next to each other and make the comparison directly. Similarly, any index of quality may be measured against a yardstick, or the values obtained on several hospitals may be directly compared.

The Basis of Comparison

Any of the four approaches to quality, therefore, involve comparisons, either indirectly through the use of standards or directly. In program evaluations the basis of comparison is vital. If a specific procedure has an effect on quality, it must be revealed in differences. To find such differences, the hospital under study must be compared with something, either with other hospitals or with itself before inception of the program. When differences exist, it is of paramount importance to isolate differences related to the program itself from differences owing to such other factors as changes in time, economic differences, cultural differences, and so on. The selection of a basis of comparison or control is crucial in this attempt.

The basis of comparison and the indexes to be used, in fact the plan for evaluation of a new procedure or program, should go hand in hand with planning the program itself. Ideally, before the new procedure is instituted, several similar hospitals would be chosen. By random selection, half would become experimental units for the new program, and half, controls (55). A careful study of patient care would be made in all the hospitals before instituting the new program and again at a suitable

time after the program was in effect. Medical and social progress occurring during this period might produce changes in both experimental and control units. But the changes might be different, and it is these changes that would be compared.

Such an experiment would be relatively simple if it tested only one procedure at a time. Thus one could, for example, estimate the effect of providing small hospitals with special courses for laboratory technicians by comparing changes in the accuracy of their results in certain procedures. More complex programs should also be amenable to this type of experiment.

However, there are cases where this does not apply. The effects of an existing program are to be evaluated, or a hospital plans to embark on a new program, and a study is to be made of quality before and after. The institutions then are self-selected and thereby are different from other hospitals. The before-and-after case does not make the problem simpler. A comparison within the one hospital at two different periods necessitates control of secular changes related to the passage of time or changes owing to extraneous factors that may have come into play.

This situation has parallels in population studies, in public health research, and in clinical research. Analytical studies of what exists, rather than of a planned experiment, call for a more critical evaluation of the findings, and the conclusions must be more tentative. This is even truer when the analyses are retrospective, being made after the fact (56-59). However, in some cases it may be possible to select suitable controls for comparison (60) and to test their suitability by an examination of variables that might affect the result. The careful selection and critical analysis of the controls (61) are basic to the validity of the findings.

An important step in program evaluation, therefore, is the search for suitable controls and for methods of eliminating some of the many variables that affect the quality of care. This is especially difficult because hospitals are highly complex institutions, and patient care is an intangible quality, influenced by many variables.

It is therefore possible that no comparable

units could be found for nonexperimental situations. In the event of failure to establish acceptable controls, or even as a complement to comparisons made with controls, there is another avenue of approach that might prove fruitful. One might formulate a hypothesis such as:

"Characteristic α is usually found only in teaching hospitals. A random sample of non-teaching hospitals in comparable communities will show low values for α , but an examination of hospitals in our group will reveal significantly higher values."

Characteristic α might be laboratory services of a certain type, or rehabilitation services, or one of the quantitative indexes considered. Such an approach, of course, adopts the rest of the country as controls. As in other situations, purely descriptive studies may be used as a basis for planning future experiments.

Many references have already been made to testing the validity of various indexes. This could be done in various ways. One would be through a statistically controlled clinical analysis of each index. Another would be through seeking correlations among various measurements (37, 62) including qualitative appraisals. Thus, correlations might be sought among two or more measurements which are believed to measure practically the same thing. It might be found that a relatively simple, inexpensive objective test showed a high correlation with the results of the qualitative judgments, or, more likely, that a combination of such tests did so. Once the validity and applicability of such indicators were established, there would be many instances where they could be used instead of more difficult, expensive, and cumbersome techniques.

Conclusions

Most of the work done to date in the appraisal of hospital quality has been related to the purposes of correcting abuses, setting minimum standards, and stimulating improvements in quality. The field of program evaluation is just beginning to be explored.

Techniques used in quality evaluations vary with the purposes of the particular study. The quality of care can be evaluated through a

multidimensional approach which results in a profile of the hospital. The main basis of the appraisal can be the use of one or a combination of: examinations for prerequisites for good care, indexes intended to measure elements of performance, indexes intended to measure the effect of care by results obtained, and qualitative clinical judgments.

Any indexes and standards used in such appraisals would be clearly defined, based on comparable data, and examined for their reliability and validity. Qualitative clinical appraisals should also be tested in a similar fashion and statistical controls and analysis applied to them as well.

Correlations among different indexes and judgments used should be attempted.

Appraisals which are intended to examine the effects of specific procedures or programs should be planned before the inception of the program.

The selection of an appropriate basis of comparison is crucial to program evaluation.

The development of practical and valid methods of measurement will involve the expenditure of considerable money and time. However, in view of efforts and money now being spent on programs to raise quality, it would seem essential to direct some of those resources toward the development of appropriate methods with which to judge their effects. Collaboration of clinicians, administrators, and statisticians is necessary for such a development.

A critical analysis of the particular methods used should be an explicit objective of a quality evaluation.

Sert's mural showing man's conquest of disease.

WHO, the Catalyst in International Health

By HENRY van ZILE HYDE, M.D.

WE ARE MEETING here for the next 2 or 3 weeks in a room which is one of the great rooms of the world—the Council Room of the Palais des Nations—a room in which history has been and will progressively be made.

All of us are inspired and uplifted, as we carry on the business before us, in studying

Dr. Hyde, chief of the Division of International Health, Public Health Service, served as chairman of the Executive Board of the World Health Organization from May 1954 until May 1955. He was first appointed by the President as United States expert on the board in 1948 and reappointed in 1953. Dr. Hyde delivered this address at the board's 15th session in the Palais des Nations, Geneva, Switzerland, January 18, 1955.

the murals by the great Spanish artist, Sert, which surround us. They are to me, as I study them, a record of man's emergence from the primitive. One of our opportunities and privileges is to carry that emergence further along.

We are all aware of the technological ascent represented in the small panel on the right. The rapidity of this ascent indeed underlies many of the problems of our times.

The panel in front of us typifies war and the horrors of war and the triumph of war and the complete distress of war. And here also is man's emergence from bondage. Directly above us is represented man's intellectual progress and the use of reason in cementing nations together in peace.

Over here, on the other side, we see man climbing up in the field of health—our field—man emerging to better things in health and so-

cial well-being. It is particularly important to us to recognize that this panel, which represents disease and man's conquest of disease, is included as part of the whole which symbolizes man's progress toward peace.

Man cannot make progress, cannot emerge to the fullness of his development, carrying a great burden of disease. We have the opportunity to do something about it—that is what we are here for. It is a very unusual opportunity. There are very few men in our profession who have the opportunity to serve on the Executive Board of the World Health Organization—just a handful through a generation of public health progress.

As we enter our deliberations, we should do so with proper solemnity and thoughtfulness. It is proper that we keep in mind, in the light of the Sert panel symbolizing man's freedom from disease, the central significance of health in our work. It is in the title of our organization. It is included in the WHO constitution as our central objective. I think we can recognize that health is a good thing in itself—that there does not need to be any other excuse for health than health itself and what it does in giving scope and range to the mind and the spirit of man.

The Setting for 1955

We are fortunate that in directing our efforts at health we are obtaining certain secondary effects, as byproducts, in economic and social advancement that are essential to total progress toward peaceful and decent living. We all know that we cannot have security in the world—we cannot have peace—without sufficient food for all people, adequate shelter, health, and I think particularly, an ever-widening horizon of opportunity. Man's emergence in technology, intellect, and spirit, which is so dramatically pictured in this room, must continue to provide the ever-widening horizon of opportunity.

Man's emergence is a relatively short story. It was only some 20,000 years ago that he stepped forth from his primeval state and began using tools. Progressively he freed himself from the all-encompassing hunt for food,

through the development of planting and the domestication of animals.

The period of his great technological development is a span of only some 4,000 years. It is the familiar story that begins in the Indus Valley, China, Mesopotamia, the Nile, and the Mediterranean. Through the period of technological emergence, there was constant groping for something deeper and more significant. In the millennium marked in midpoint by the beginning of the Christian era occurred the great flowering of the intellect and the spirit. This remarkable millenium included the classical period of Greece with its philosophers and the great moral and spiritual leaders of mankind—the Hebrew prophets, Zoroaster, Confucius, Lao-tse, Buddha, Christ, and Mohammed. It was the period of emergence of spirit and thought.

On the slate of history man seemed to go backwards for awhile, but a resurgence of cultural and intellectual development took place here in Europe in the 14th and 15th centuries. Later came the remarkable intellectual thirst of the 17th century which we see continuing today in the development of new concepts of the universe. That is indeed directly related to the work of this session of the Executive Board. The work of Newton and Galileo led to Einstein and to our present agenda, which includes an item dealing with atomic energy. This new source of power, instead of being a further step in man's emergence, can, if mishandled by you and me and by our generation, be the instrument of man's destruction—his final emergence to his own end.

This is the setting in which we find ourselves dealing in 1955 with the problem of health among men. It is appropriate that as we do so we pause to take a brief look at where our organization stands.

The history of the World Health Organization is an exceedingly brief one. We can find great cause for satisfaction in this history. In 9 years those of us who have had occasion to watch WHO have seen it grow from nothing to real greatness. It has attained stature as one of the great forces among men for good. It has become, on the world scene, a symbol for all that is best in international life: sympathetic under-

The Executive Board of the World Health Organization, January 1955.

standing among men; faith in the worthwhileness of the individual; helplessness, one to the other, without regard to false criteria; and man's full development of body, mind, and spirit.

Probably all of you who have studied the proposed annual WHO program and budget for 1956 (Official Records of the World Health Organization No. 58) have been impressed by the breadth of the work of this Organization, by how it has reached into the remotest corners of the world to places whose names even are new to you and me, despite the fact that we have traveled widely. As one reads the document, one obtains a sense of the reality of the fact that our colleagues, under the leadership of this body and our Director-General, are in myriads of places carrying on the very human work of the world.

Our regional directors, who are with us during this meeting, are closer to these problems than any of us, and they and their personnel are reaching the masses of the people. As a result the World Health Organization is better known to the millions of people in the less privileged areas of the world than any other international agency except perhaps FAO (Food and Agriculture Organization) and our fellow agency UNICEF (United Nations Children's Fund). I am sure that WHO is known and treasured in the hearts of persons to whom the political bodies of the United Nations are remote and incomprehensible unrealities, if indeed they are known at all.

It is encouraging that at the other end of the scale, in the cold and highly critical areas of science, the reputation of the Organization also stands secure. The world's greatest experts in

the medical sciences serve the World Health Organization with pride and readiness on its expert panels and expert committees. There was a recent example of the effect of the reputation of WHO in scientific circles, when, within a matter of a few days, the Director-General was able to bring to Geneva from great distances leading experts and authorities on the medical and biological aspects of atomic energy. There was no question about what WHO was, or where it stood, or what its reputation was. These men responded to the call of WHO immediately. I have seen some of our WHO monographs referred to by critics in responsible journals as classics in their field. In 9 years, to have produced classics in fields of health which are thousands of years old is a great accomplishment and is further testimony to the quality of the scientific work of the Organization.

I might say that in the field of administration also, WHO need bow to no other organization on the international scene. It provides a splendid demonstration of competent public administration in the highly complex environment characteristic of international life. I have had the privilege of working with your Standing Committee on Administration and Finance, and once again I have been tremendously impressed by the quality of the work done in budget planning and preparation and in the fiscal, financial, and administrative management of our organization. I am sure that when you review the reports coming forward from the standing committee, you will share my admiration.

Where the World Health Organization stands now, in these various respects, is indeed a vindication of the concept of the specialized agency within the United Nations framework. WHO is a triumphant example of the wisdom of the men in San Francisco who provided for this type of technical organization within the broad framework of the great political structure they created.

International Leadership

Now, I would like to say something for a moment about WHO and what its proper place is, as I see it, in the public health scene of the world. It is the leader, the stimulator, the catalyst in public health. The object of a local

health department is to mobilize and guide the total resources of the community toward the improvement of health. The local health department stimulates the department of education, the department of public works, the many voluntary agencies in the community, the associations, the clubs—all resources in the community—focusing them on the solution of the health problems of that community.

The World Health Organization, the directing and coordinating authority in international health work, as defined in its constitution, serves in this same stimulating leadership role on the world scene. It gives direction and leadership to the development of world health, and in so doing mobilizes all the available resources whether they are within the organization or are within the other specialized agencies, within the United Nations itself, within the voluntary agencies, or within the regional or national agencies devoted to social and economic development.

The annual report of the Director-General every year lists an amazing number of significant conferences in which WHO participates. Through such activity WHO influences many organizations to carry on health work and devote their resources to the solution of health problems which are pertinent to our organization and so stimulates great activity which otherwise would not take place. Further, you are all familiar with the technical conferences organized by WHO, the interregional and regional conferences that it has held on problems such as malaria and yaws, bringing all resources within large areas of the world to bear upon specific health problems.

It is heartening to see also the role that the World Health Organization is playing in regard to some of the bilateral programs of cooperation. It is my privilege to be familiar with the bilateral program of the United States of America, which, as many of you know, is a technical assistance program carried out in cooperation with a number of governments, and which has the same health objectives as the World Health Organization. The relationship between WHO and this program has avoided the pitfalls of possible conflict or duplication to become a truly intimate association with close integration of programs. This has

The Council Room of the Palais des Nations, Geneva, Switzerland.

greatly enhanced the value of both programs but particularly has contributed effectively and continuously to the total development of health in the countries where these programs are assisting in the development of national health activities.

I might cite just an example of how the World Health Organization is exerting its leadership. Many of you will remember that 2 years ago, here in Geneva, the leaders of WHO and of the bilateral program of the United States of America—the Technical Cooperation Administration as it then was—met together in a joint session and discussed objectives. That meeting had a tremendous influence on the course that has been taken by that program. Last year, a similar meeting was held in Panama, covering the Latin America area. At the moment, plans are going forward for a joint meeting of the WHO leadership and the chiefs of the United States bilateral health staffs in some 18 countries in

Africa and Asia. The meeting will be held in New Delhi and will consider common problems and common goals of the two programs.

In such ways as this, WHO is giving of its great knowledge and exerting leadership in all health programs that are being carried on at the international level. In no other place is there the concentration of knowledge concerning world health problems that there is in WHO.

A Balanced Health Program

We have already said something about the relationship of disease and health to the economy. Dr. C.-E. A. Winslow in his WHO monograph, *The Cost of Sickness and the Price of Health* (WHO Monograph Series, No. 7), presented this relationship with great clarity in a document which is among the classics produced by this Organization.

We must move forward in this field and give

our strength and our assistance to the programs of the United Nations in technical assistance for economic development. It is appropriate that when the United Nations has a program directed at economic development and recognizes the need for doing something about health as absolutely basic to that development, we should play an active role and give of our strength and our friendship to that program—not as a supplemental program in health but as an economic program of which health is an integral part.

We all know of the interest that people and their governments have in children: that they have opened their hearts and purses at this time in history to give special help. We, of course, have a keen interest in children, and we have the opportunity of doing special work for children in connection with UNICEF.

Interagency relationships are always complex: They are never entirely smooth. Certainly at the national level we have problems, all of us around the table, with other agencies within our own governments. And, I am sure, they have their problems with us. It is not strange that at the world level, which is even more complex, there should be occasional ripples on the surface. All we need do is to keep our high and total objective always before us—to remind ourselves of our ultimate goal, which is the progress of health.

I believe that we can handle these relationships with no real difficulty if we keep our sights sufficiently high. We must, of course, keep a balanced public health program. We are the agency responsible for total public health progress, and the Seventh World Health Assembly (1954) in its resolution on UNICEF

particularly pointed out the need for us to keep that balance. We must be sure that we do not deflect our central resources too far away from our central objective in giving assistance to other organizations. That is a matter of judgment and wisdom which this board is expected to exercise.

During this session we shall be dealing with these matters, and it will be a great opportunity for us, as individuals. We shall be getting better acquainted. I wish to welcome the new members who are among us. I am sure that in a few days we shall all be good personal friends and, at the end of our deliberations, very warm, firm, and permanent friends. That has been the experience of the board, and that is the spirit in which we do our business. Also, we shall have a chance to become acquainted with our great Director-General, with members of his staff, and, when we are particularly fortunate, with their families.

At this point I wish to pay a special tribute, if I may, to the WHO officials and their families. They have in my view the greatness of spirit that allows separations and personal sacrifices and even encounters with danger in the work that means so much to all men in the world.

So I might close by pointing out that the World Health Organization is a team of dedicated people and by expressing the hope that our visit here—yours and mine—may help to strengthen the Organization in its great work. We can be sure, as we settle down to the work in hand, that few undertakings can provide fuller opportunities than does WHO for the peaceful advancement of mankind.

A practicing pediatrician speaks on how physicians can help educate their patients in accident prevention.

Accidents and Poisonings in Children

By JULIAN P. PRICE, M.D.

ACCIDENTS and accidental poisonings are the leading cause of death in this country in children over 1 year of age. This is a condition that we physicians find difficult to accept, accustomed as we are to think of death in terms of disease. But accept it we must for the public expects leadership from the medical profession and from the family physician in matters of health, and any condition which causes 1 death out of every 3 in our children is certainly in the field of health.

Statistics are usually boring and quickly forgotten, so I will present only a few to show the problem which confronts us. It has been estimated that every year in the United States some 2,000,000 children are involved in accidents requiring medical attention. Of this number, 12,000 die—and 40,000 to 50,000 are permanently disabled or crippled. There is no way of determining the number of children who are accidentally poisoned, but we know that 1,250 under the age of 21 and 400 under the age of 5 die from this cause each year.

What can the medical profession do, and what can the individual physician do to reduce

the toll of accidents and poisonings? In attempting to answer this question I do not pose as an expert, but speak as a practicing pediatrician who has become keenly interested in the subject and who has evolved certain ideas from the writings of others and from his own personal experience.

Fields for Action

There are three special fields in which we should exert our efforts. First, we need studies and investigations to give us more basic information. Research on accidents in adults has been conducted for some time, but only recently has study been made of accidents in children. What has been done has been encouraging and enlightening—such as the work of Press, Wheatley, Dietrich, Arena, Shaffer, Dennis and Kaiser, and others—but we need more.

One phase of the problem which needs particular attention is that of the accident-prone individual. Langford and his associates have made a preliminary report on the study of nine such children. No definite conclusions can be drawn from this small number, but some of the observations and ideas offered are most suggestive. It is to be hoped that the work will be continued and enlarged. It is extremely important that we be able to recognize and help the accident-prone child before rather than after he runs into trouble.

The physician needs help to handle acci-

Dr. Price is a practicing pediatrician in Florence, S. C., and pediatrician at the McLeod Infirmary in Florence. This address was given at the annual meeting of the American Academy of General Practice in Los Angeles, February 1955.

dents and poisonings more effectively. This is a second field of activity which needs developing. If a child cuts his leg, the accepted procedure is to clean the wound, suture it, and give tetanus toxoid or antitoxin. But when a child is extensively burned, the problem of what to do is not so simple. Should the burn be cleaned? If so, how? Should the child be given a general anesthetic? What type of dressing should be applied? Does the child need sedation, plasma, electrolyte or glucose solution, or blood? Upon the answer to these questions may depend the life of the child.

When a little boy drinks kerosene—one of the more popular drinks among children these days—a recognized method of treatment is to empty the stomach, give an antibiotic, and watch for signs of chemical irritation of the lung. But what of the little girl who eats rat poison? What is the toxic ingredient in this particular preparation? Is there an antidote? What are the complications to be watched for? An immediate answer to these questions will help materially.

Burns, fractures, penetrating wounds, lacerations, shock, intracranial hemorrhage, and ruptured viscera are some of the conditions which may be encountered in the accident patient. Roach powder, pesticides, medicines, floor polish, moth balls, cosmetics are but a few of the poisons which may be eaten by the little child.

To help the physician to be more effective in his care of victims of accidents and poisonings, I would suggest that more time be given to these conditions in the training of interns, in general meetings such as this, and in post-graduate courses for the general practitioner and for the pediatrician. Further, I would urge that every doctor's office and every emergency room in a hospital have available for quick reference not only a textbook on traumatic surgery but also 1 or 2 reference books which discuss the common household items which might be implicated in poisonings. Two such volumes which I have found valuable are *Symptoms and Treatment of Acute Poisoning* by G. H. W. Lucas, and *Handbook of Pediatric Medical Emergencies* by Desanctis and Varga.

A recent development which should prove of considerable value in the realm of accidental

poisonings is the establishment of poisoning control centers in our larger communities. The first such center is now in operation in Chicago, and others are being established in Boston, New York, and Cincinnati. These centers will treat poisonings, conduct special studies as to their cause, and promote their prevention. They will also serve as information centers to which the practicing physician can turn for help at any time.

The third field of activity to which we must bend our effort is that of education. The only way in which we can hope to reduce the number of accidents and poisonings in children is through prevention, and prevention hinges on educating the public about the need and methods of forestalling accidents.

Many national organizations have engaged in educational efforts—the National Safety Council, the American Automobile Association, the American Red Cross, the National Board of Fire Underwriters, and the National Committee for Traffic Safety. Public health associations have carried on special campaigns. The American Academy of Pediatrics, through its Committee of Accident Prevention, has promoted State and local conferences. It has stimulated the formation of accident prevention committees, and, with the assistance of the Metropolitan Life Insurance Company, has prepared a number of educational pamphlets. The American Medical Association has long been concerned with accidental trauma and more recently has entered the field of poisonings through its Committees of Toxicology and Pesticides.

These organizations and others have done yeoman service, and they need our thanks for what they have accomplished and our support as they continue their work. But their efforts alone are not sufficient. They must be joined by that individual who, in my opinion, is the greatest single source of strength in our educational effort, the practicing physician. It is he who can most easily influence the two key individuals in our war against accidents and poisonings—the parent and the child.

It is my sincere hope that medical organizations will spearhead an educational effort in which the parents of America, along with their children, will be taught the fundamentals of

preventing accidents and poisonings. This education should be carried on where it will be most valuable—in the office of the physician and in the home of the child. And it should be carried on by the one whose word would be most heeded—the family physician.

What Physicians Can Do

There are a number of ways in which the practicing physician can participate in such an educational effort. I would like to make six specific suggestions—suggestions culled from the experience of others and from my practice.

The physician must become safety-minded in the prescribing of drugs. Specific instructions should be given to the family and to the druggist. The mother should be told what the drug is for and how it is to be given. General instructions on the label should be avoided. "A spoonful as needed," may be understood the day it is prescribed, but a month later the parents may have forgotten the indications for its use as well as the size of the spoon, with regretful results.

The amount of a drug prescribed should be limited to a quantity sufficient for 2 or 3 days only. Recently I saw a prescription written for 6 ounces of a sulfa preparation for a child with a mild upper respiratory infection. I pictured what might happen. The child would probably be well by the time he had taken 2 or 3 ounces. The half filled bottle would then be put in the medicine chest or on the windowsill in the bathroom. There it would sit until it could be used for some subsequent illness in the family, or else it would be found by some adventure-some youngster and gleefully drunk.

I may or may not have been right in this particular instance, but I know that the medicine closets of many families in this country are cluttered with bottles half filled with medicine or boxes partially filled with tablets which are potential poisoners of children. To prescribe only what is needed for a specific illness and that only for a specific period of time is good medicine—it is also one of the first steps in preventing drug poisonings.

The physician should take time to discuss accidents and poisonings with parents when they bring their children to his office. This is of

particular importance when the child is between the ages of 1 and 4—the danger age. Mention should be made of the type of activity in which the child is likely to participate such as crawling, climbing, investigating with the fingers, and putting objects in the mouth. The parent should be shown how these activities can lead to trouble if ordinary precautions are not taken.

Attention should be called to the special care which should be taken near such items as stoves, floor furnaces, hot water, stepladders, and electrical outlets. The need for keeping such articles as liniments, medicines, fingernail polish, floor wax, and insecticides in a place where the child cannot get to them should be emphasized. The parents should be urged to make a survey of the yard and playground to see that hazards such as broken glass, wooden stakes, and sharp tools are not present.

The children themselves should be talked to about accidents and poisonings. Many a youngster will listen with more attention to his doctor than he will to his parents. They should be told of the need for staying out of the street, of the care which they must exercise when riding tricycles and bicycles, of the dangers of playing with matches and firecrackers. They should be warned against taking medicines of their own accord. Older children, particularly boys, should be told of the need for caution with regard to swimming and diving—never to go swimming alone and never to dive into unknown water.

Literature should be available in the physician's office for parents to read and to take home for study. Quantities of home and child safety materials are available from many of the major insurance companies. Pamphlets on specific phases of safety education can be obtained from the National Safety Council. An excellent checklist for parents has been prepared by the American Academy of Pediatrics. Published information of this type, or perhaps material especially prepared by the American Academy of General Practice, needs to be placed in every general practitioner's office. There is no telling how much of this would be read, but I have yet to see a parent who did not appreciate an article or pamphlet on safety when I presented it with the request that it be taken home and studied.

The physician should investigate the home and yard environment when making calls. Are the stairs safe for the youngsters? Are there proper safeguards around the stove and fireplace? Are cigarette lighters or matches lying within easy reach of the children? Are the window screens securely fastened? Is there a special place for medicines?

These are but a few of the questions which the physician with a keen eye and inquiring mind will ask himself as he goes in to see the sick child. From what he sees, the physician can give pertinent advice to the parents.

The physician must become a crusader in the cause of accident and poison prevention. He must convince himself that accidents and poisonings are the number one problem in child health today—and then convince others. In the office, in the home, at meetings of the PTA, in public gatherings, whenever and wherever the opportunity presents itself, he must discuss the problem and enlist the support of others.

Typhoid fever was not eradicated with the discovery of typhoid vaccine; it only disappeared as the public was made to understand the value of the vaccine and was willing to have it injected into them. In the same way, accidents and poisonings will not be diminished materially through programs and studies. They will only be reduced as those who are pri-

marily concerned—physicians, parents, and children—appreciate and understand the problem and put into practice those measures which are needed to bring about a change.

There is nothing unusual or dramatic in the suggestions presented—it is the accident and not its prevention which is sensational. I am convinced, however, that if every member of this great organization would put these suggestions into effect there would be a marked reduction in the number of accidents and poisonings in children.

In conclusion, I would like to stress the need for joint effort in our fight against the number one killer of our children. The task is too large for any single organization or for any group of individuals. It challenges the combined effort of all. Local, State, and national organizations now in the field must be encouraged to continue and to increase their efforts. Medical associations such as the American Academy of General Practice, the American Academy of Pediatrics, and the American Medical Association must be urged to further activity. Above all, the practicing physician who deals with parents and with children must be made aware of the problem and be stimulated to join his colleagues in an all-out campaign of education in this fight for the safety and welfare of our boys and girls.

Cardiovascular Training Center for Nurses

A pilot cardiovascular training center for nurses, the first of its kind, will commence operation January 1, 1956, at the University of Minnesota School of Public Health, according to present plans.

Cooperating in the project with the Public Health Service and the University of Minnesota are the Minnesota Department of Health and other agencies in Minneapolis and St. Paul which will offer trainees field experience in special services for cardiovascular patients.

The center expects to give nursing leaders a better understanding of new developments in the cardiovascular field and methods of applying them to the nursing care of patients, both in the home and hospital.

Applications for the training center are being received at the University of Minnesota School of Public Health, Minneapolis.

Limitations of Water Treatment Methods for Removing Radioactive Contaminants

By CONRAD P. STRAUB, Ph.D.

RADIOACTIVITY has been known since 1896, when Becquerel first observed the phenomenon by its effect on photographic plate. However, until the first controlled nuclear chain reaction was demonstrated, the supply of radioactive materials was limited, and the opportunities for large groups of the population to be exposed to significant amounts of radiation were small. Since 1942, many kinds and considerable quantities of radioisotopes, many of high specific activity, have been produced in nuclear reactors.

Increased use of radioisotopes in recent years has resulted in the discharge of these materials to the environment. A 1954 report, based on a questionnaire sent out in December 1952 to 1,027 users of radioisotopes, showed that about 41 percent of them disposed of radioactive wastes by dilution and discharge to the sewers (1). In all probability, the amounts of radioactive materials used will increase many fold over the amounts employed now, as additional applications are developed. An increase in the amounts used will, in turn, result in the release

of a greater variety of radioisotopes, as well as greater quantities of radioactive materials. At present, considerable effort is being expended in developing nuclear energy as a source of power. These developments will aggravate the waste disposal problem and will add emphasis to the statement made in 1951 by Mark D. Hollis, chief engineer officer of the Public Health Service, that public health officials will be responsible for protecting the public against the harmful effects of ionizing radiations (2).

Maximum Permissible Concentrations

Ionizing radiations, which result from the disintegration of unstable nuclei, are damaging to living tissues. The extent of damage from internal exposure to radiation depends on many factors, some of which are the quantity of radioactive material deposited in the body; the point of localization; the type of radiation (alpha, beta, or gamma); chemical state of the isotopes deposited in the body; energy of the radiation; and the physical and biological half-lives of the isotopes. These factors and others are considered in establishing the maximum permissible amounts of radioisotopes in the human body and the maximum permissible concentrations in air and water. Maximum permissible amounts in the body and maximum permissible concentrations in the environment are summarized and reported in a handbook published by the National Bureau of Standards (3).

The maximum permissible concentration

Dr. Straub, a sanitary engineer with the Robert A. Taft Sanitary Engineering Center, Public Health Service, is in charge of the Center's Oak Ridge Field Activity, Oak Ridge National Laboratory, Oak Ridge, Tenn. This paper was presented on December 1, 1954, at a meeting of the Association of Military Surgeons in Washington, D. C.

(MPC) values serve as a guide to the public health official in determining the levels of radioactive materials that may be discharged from various installations and the amounts of these materials that may be permitted in the air we breathe and the water we drink. They represent the best available information on permissible concentrations of radioactive materials in the environment. It should be noted that these values have been derived on the assumption that the contaminated supply is the sole source of supply during the lifetime of an individual (taken as 70 years). Further, it is assumed that these values are superimposed on the natural background radiation of the particular area under study.

Comparison With Other Contaminants

The Drinking Water Standards promulgated by the Public Health Service define limits for specific materials in waters used for drinking on interstate carriers. In table 1 are shown some of these limits and the maximum permissible concentrations in water of similar radioisotopes. It can be seen that the concentrations permitted on the basis of radioactivity are many orders of magnitude lower than safe or ac-

ceptable concentrations of the stable isotopes of the same element. These extremely low concentrations present a problem of identification, since ordinary qualitative and quantitative procedures are of little value in detecting and identifying the presence of such minute concentrations of specific radioisotopes. However, because these materials are radioactive, it is possible to use this characteristic to detect, measure, and identify them. The radiochemical procedures used to identify specific radioisotopes, however, become less accurate as the number of different radioactive constituents present increases.

A characteristic of radioactivity that should be mentioned, in order fully to understand the difficulties in handling these materials and removing them from waters to make them safe for normal use, is that the rate of disintegration cannot be altered by any physical, chemical, or biological process. Other polluting substances can be removed or modified so that they are no longer noxious: For example, chromium or other heavy metals may be eliminated by precipitation; cyanides may be treated with chlorine to form the relatively nontoxic cyanate, which may decompose further to ammonium carbonate; or pathogenic bacteria may be de-

Table 1. Quantitative comparison of limits set by Public Health Service Drinking Water Standards and maximum permissible concentrations of radioisotopes in water

stroyed by disinfection, pasteurization, or sterilization. All that can be done with radioactive wastes is to transfer the radioactive component from one phase to another: The soluble materials, for example, may be removed by precipitation, adsorption, and the like. The radioactive fraction remains for disposal. Thus far, the only real solution, and it is a tentative one, is storage, and this is the method now used to dispose of high-level wastes. The less hazardous and low-level wastes may be discharged into surface waters or into the ground. When discharged into the ground, the wastes may come in contact with the ground water and move slowly with it, and some of the radioactive materials may be removed by adsorption on the soils through which the waste stream and ground water flow.

Basic Principles

The efficiency of conventional water treatment processes for the removal of radioactive contaminants must be geared to the MPC values. Since these values define the accepted permissible levels of contamination, they may be used to calculate the degree of removal that must be provided to meet these levels when the nature and the amount of activity initially present are known. For example, if a water supply contains $10\mu\text{c./ml.}$ of promethium-147 and the MPC value for this substance is $1\mu\text{c./ml.}$, treatment which will result in removal of 90 percent of the promethium must be provided. Or, if the efficiency of a particular process and the MPC value are given, the maximum concentration of that component in the waters used for public water supplies can be stipulated. For strontium-89, for example, with an MPC value of $7 \times 10^{-5} \mu\text{c./ml.}$ and a process that results in 90 percent removal of this substance, the highest concentration that may be present in the waters to be treated is $7 \times 10^{-4} \mu\text{c./ml.}$ The difference in the initial concentrations of promethium-147 and strontium-89 varies by a factor of approximately 14,000 and is due entirely to the difference in their MPC values.

Conventional water treatment processes include coagulation, settling, filtration, and disinfection. In addition, auxiliary treatment, such as aeration, softening, and iron and man-

ganese removal, may be used. Any discussion of treatment methods must take into account the fact that radioactive and stable isotopes of an element behave identically during chemical treatment. Thus, if the conventional process is not designed to remove a specific element, there is no reason to believe that the process will remove the specific radioisotope. Radioactive calcium, barium, or strontium, for example, will be significantly removed by softening, since the purpose of softening is to remove calcium. Barium and strontium will be removed with calcium, because of their similar chemical properties.

To show the limitations of conventional water treatment methods for the removal of radio-

active materials, the results of experimental work at Oak Ridge National Laboratory, which has been carried out in cooperation with the Public Health Service and the Engineer Research and Development Laboratories at Fort Belvoir, Va., and of studies reported in the literature are cited.

Coagulation

In coagulation, certain soluble constituents are precipitated as insoluble hydroxides or are carried along with the heavy metal hydroxides that are formed when alum or iron salts are used. With the exception of most cations of valence 3, 4, or 5, including the rare-earths group, coagulation has not been very effective for the removal of radioactive materials from water (4). Phosphorus-32 has been removed from waters contaminated with this radioisotope (4, 5), but considerable care had to be given to the coagulation step (5). Removals in excess of 98 percent have been reported. Iodine-131, which is in the form of an anion, cannot be removed by coagulation with alum or iron. However, the addition of small amounts of activated carbon (4), copper sulfate (4), or silver nitrate (4, 6) has been found to increase the removal of this anion to about 96 percent. Other data are reported in table 2.

Coagulation is also helpful in the removal

of radioactive material attached to or adsorbed on the natural turbidity found in many surface waters. Since coagulation will remove much of the turbidity, the activity attached to it will also be removed.

Sand Filtration

Except for removal by simple straining or sorption by the biological life contained in the *Schmutzdecke* sand filters, as shown in table 3, have not been effective for the removal of radioactive materials (7-9). Their major function is to remove the radioactivity previously incorporated in floc particles.

Softening

Softening with lime and soda ash has been studied (9-12) and, under proper conditions, effective removals of radioactive strontium, barium, cadmium, yttrium, scandium, and zirconium-niobium have been obtained (9). As shown in table 4, removals of 95 to 99 percent or better have been accomplished. For the most satisfactory removal of strontium, excesses of both lime and soda ash are required (10). Some recent studies have indicated that the strontium is removed by coprecipitation (10, 11) with the calcium carbonate by the mechanism of mixed crystal formation (11). Data on the removal of stable strontium from municipal water supplies (13) are given in table 5.

Ion Exchange

Another method of softening that has been practiced for some time in municipal and industrial water treatment is ion exchange. Removal of radioactive materials by this process is technically possible (12, 14, 15). For most effective removal, mixed bed or cation and anion exchange beds in series are recommended. Results obtained with various types of synthetic exchange materials and with greensand (9), a material which has found considerable use in municipal softening installations, are shown in table 6. For adequate removals and economic operation, the waters to be treated should be low in dissolved solids. Experience in the laboratory has shown that certain radioactive mate-

rials will continue to be removed (about 50-percent removal) even though the column has been saturated with calcium and the hardness is no longer reduced.

Modified Processes

Several modifications of existing water treatment processes have been studied in an effort to obtain better removals of specific radioactive materials. The most promising of these has been phosphate coagulation (16, 17), as indicated by the data in table 7. For many of the radioisotopes of interest, including strontium-89, relatively high percentage removals have been obtained, but for strontium-89 the

results were obtained under carefully controlled conditions of pH and the calcium-hydroxide/trisodium-phosphate ratio. Other methods that have been suggested for the removal of radioactive materials from water include the use of metal powders (18) and added clay (4, 19). Results obtained with these materials are given in tables 8 and 9.

Evaporation

Although not a municipal treatment method, evaporation is included in this discussion be-

cause it is the most effective process available at present for producing waters low in radioactivity. High decontamination factors are possible, but the cost is great. However, under emergency conditions, evaporation should prove to be very satisfactory.

Removal of Mixed Fission Products

The discussion thus far has centered on the removal of specific radioisotopes from waste solutions. For a fission products mixture or any mixture of radioisotopes, the efficiency of removal is a function of the individual radioisotopes comprising the mixture. To date, removals of mixtures in the order of about 70 to 80 percent have been obtained with alum or iron coagulation (4). A series of studies on actual process waste waters at Oak Ridge National Laboratory disclosed that up to 90 percent of the contaminants could be removed with excess lime-soda ash softening or with phosphate coagulation when coupled with the addition of clay, which is specific for the removal of the cesium in the waste. Experimental results in removing fission products mixtures are summarized in table 10.

Summary and Conclusion

Laboratory studies have shown that conventional water treatment processes may remove varying percentages of radioactive contaminants from water. However, the percentage

removal values have little meaning unless they are related to the initial concentration of the radioactive materials present and to the maximum permissible concentration value prescribed for the individual radioisotope. Generally speaking, unless the initial concentration is very low, certainly several orders of magnitude below the microcurie-per-milliliter range, water treatment processes will be ineffective for reducing radioactive contaminants to acceptable safe limits.

Radioactive materials should be retained as close to their source of production as possible. At present, the practice is to store the materials in tanks. The transfer of radioactivity from the liquid to the solid phase does not eliminate the problem, since suitable storage facilities still must be provided for the radioactive sludges, but it does reduce considerably the area of potential contamination.

To protect large centers of population that depend on sources of water which may become contaminated with radioactive materials, plans should be made now for supplying water from noncontaminated sources. For this purpose, existing ground water supplies may be used; other interconnected water supplies may be piped in; or special provisions should be made to bring in water from outside the area. These precautionary measures are applicable, however, only when radioactive contamination is not great enough to constitute an external hazard to man.

PHS exhibit

A new exhibit, Social Workers Help Heart Patients, prepared by the Public Health Service in cooperation with the American Heart Association, is now available.

The exhibit is designed to stimulate and extend social services to heart patients. It is suitable for use at social work, heart association, medical, nursing, hospital, welfare, and other professional conferences and health fairs.

Shown for the first time at the National Conference of Social Work in June at San Francisco, the exhibit is approved for use by the American Association of Medical Social Workers. It was produced by the Heart Disease Control Program of the Division of Special Health Services, Bureau of State Services.

Specifications: 3-panel exhibit on legs, 7 feet high, 9 feet wide. Total shipping weight 75 pounds. Borrowers must pay insurance and shipping costs both ways. Available with educational materials through local heart associations, the American Heart Association, 44 East 23d Street, New York 10, N. Y., or the Heart Disease Control Program, Public Health Service, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.

Progress in Reporting Mental Hospital Statistics

*Fifth Annual Conference of
Mental Hospital Statisticians,
Bethesda, Md., May 25-26, 1955*

DEVELOPMENTS in the field of mental hospital statistics and plans for future activities were the major areas of discussion at the Fifth Annual Conference of Mental Hospital Statisticians in Bethesda, Md., May 25-26, 1955, held under the sponsorship of the National Institute of Mental Health, National Institutes of Health, Public Health Service.

The conference was attended by delegates from the 17 member States forming the Model Reporting Area for Mental Hospital Statistics, and by unofficial observers from 7 other States and a representative of the Veterans Administration (see inset).

Emphasizing the contribution of State statisticians in collecting and publishing data, Dr. R. H. Felix, director of the institute, called attention to signs of the Nation's awakened interest in the whole area of mental health. The legislature in New York State has appropriated a considerable sum of money to be matched with local funds, for the development of a large-scale community mental health program. Other States may follow this precedent. Indications of increased interest are also seen at the Federal level, he reported.

Prepared by the Current Reports Section, Biometrics Branch, National Institute of Mental Health, National Institutes of Health, Public Health Service. The 1954 conference was reported in the September 1954 issue of Public Health Reports, p. 809.

This heightened desire to do something about an age-old problem has brought the realization that trained personnel, particularly biostatisticians, are in short supply. It is urgent that State mental hospital administrators provide statistical programs with much needed personnel and equipment and that they recognize the key position of the statistician in the fight against mental illness.

Recommended Cohort Studies

The Cohort Study Committee, appointed at the 1954 conference, reported on the types of uniform cohort studies to be produced by members of the model reporting area and the types of tabulations which should be required of these States.

Cohort studies, in a mental hospital, are studies in which groups of patients with common characteristics—these might be first admissions of a specified year with given age, sex, and diagnosis—are followed from the date of admission through their hospital experience to a specified end point, such as trial visit, discharge, or death, in order to determine their disposition within specified periods of time after admission.

The committee agreed that the analytical procedures involved in cohort studies are appropriate to the mental hospital situation and that all approaches to these studies are based on simple, basic movement data, which can be calculated manually—a particular advantage if

the hospital does not have access to machine tabulation equipment. Cohort studies permit development of a series of release, death, retention, and readmission rates; they permit more accurate prognoses on groups of patients for the benefit of the medical staff, the patients' families, and others.

Properly designed cohort studies can be used by a State desiring to evaluate its mental hospital operations, for program evaluation and budget justification, for evaluation of different therapeutic programs, for interhospital and interstate comparisons, and for many important areas of research.

The committee recommended that all model reporting area States attempt to develop cohort studies. Earlier in the conference only a few delegates had reported preliminary attempts to analyze data on hospital admissions on a cohort basis.

The recommended studies would be studies of first admissions over a 3-month period (preferably April, May, and June) in a given year or longer, if the longer time is required for adequate sample size. The committee suggested that all States adopt the cohort study approach used at the Warren State Hospital, Warren, Pa., and that States with adequate mechanical facilities and sufficient staff undertake in addition the types of studies made by the Ohio Department of Welfare. When data are recorded in sufficient detail, States might consider producing cohort studies where both the Warren and Ohio approaches are used.

By tracing the outcome of hospitalization of patients admitted over the past 40 years, the Warren study has furnished a veritable gold mine of information to the hospital, the State legislature, and the public. The approach is that of followup from date of admission to date of first significant release, with tabulations by number of months of hospital residence. With this type of study, one can answer the question: What proportion of first admissions will have attained their first significant release within the first 12 months following admission? Date of first significant release is defined as date of placement on convalescent leave (indefinite leave), direct discharge or escape from which the patient does not return within 30 days, whichever comes first, or death in the hospital.

From the cohort studies in Ohio, which determine the status of the patient at stated intervals of time irrespective of his movement to and from the hospital during the intervals covered by the period of observation, one could answer these questions: What proportion of such admissions 1 year after admission and on subsequent anniversaries have been in the hospital continuously? What proportion are in any State mental hospital subsequent to release? What proportion are on leave? What proportion are discharged without subsequent return to a hospital? What proportion died in or out of a State mental hospital?

Routine Tabulations Desired

The committee recommended that, if more and more resources—personnel, time, and money—were to be put into cohort studies, the number of routine tabulations now requested from member States should be reduced. Certain routine tabulations would, of course, continue to be necessary for the State's own administrative use and for the institute to use in compiling its national summaries.

The committee recommended that only certain tables be prepared and submitted to the institute every year and that other tables be submitted once every 5 years, commencing with 1955. A total of 9 tables would be submitted annually.

On an annual basis, a member State will submit a financial statement and a statement of personnel for each of its State mental hospitals so as to provide the institute with data for comparing maintenance costs and personnel ratios in the model reporting area. In addition, States are to submit an annual tabulation on the movement of patient population, by sex.

Separate tabulations for males and females are to be submitted for the following tables, the first group on an annual basis, the second on a 5-year basis:

ANNUALLY

First admissions during the year by age at admission and by mental disorder.

Readmissions during the year by age at current admission and by mental disorder.

Resident patients at end of year by age at end of year and by mental disorder.

EVERY 5 YEARS

Discharges by net length of time in hospital and by mental disorder—first admissions.

Discharges by net length of time in hospital for current admission and by mental disorder—readmissions.

Deaths in hospital during the year by age at death, net length of stay for current admission, and selected mental disorder.

Deaths in hospital during the year by cause of death, age at death, and selected mental disorder.

Resident patients at end of year by age at end of year, time on books from date of admission, and selected mental disorder.

The report of the Cohort Study Committee was approved and accepted by the conference.

Statistics for Consumers

The Committee on Presentation of Lay Materials, another committee appointed at the 1954 conference, stressed the need for having the chief statistician in the State mental hospital system be responsible for the preparation of statistical materials from the point of collection through to the point of final presentation so as to assure valid interpretation. The statistician should not assume the role of a public relations expert. He should provide the basic statistical data needed to answer questions about various aspects of the mental health program and as much interpretative material as necessary to those persons preparing information materials for public consumption.

The committee specifically recommended:

That the National Institute of Mental Health give attention to the possibility of sponsoring in representative communities a number of surveys to obtain much needed data on the incidence and prevalence of mental illness and mental deficiency. Planning for needs and facilities makes it necessary that statistics be up to date, but the only data now available come from several outdated and noncomparable surveys.

That the institute require from each member State certain basic summary totals within 1 to 3 months after the end of the fiscal year in order to facilitate the prompt release of information to the press and national associations. The data of national interest would include total first admissions, readmissions, discharges,

deaths, patients in residence and staff personnel at end of year, estimated per capita maintenance expenditures, and estimated financial expenditures. States not members of the area might also be interested in submitting such information.

That the institute consider the sponsoring of studies that would help in determining the most desirable methods of presenting statistical information. Two types were specified—those concerned with evaluating types of presentation in the field of mental hospital statistics and those concerned with determining which particular formats, layouts, and other pertinent aspects of the presentations attract the greatest audiences, are longest remembered, and assist in effecting action.

In the discussion that followed it was pointed out that several new studies are being carried out on prevalence and incidence of mental illness. Among these are the studies by Redlich in the New Haven area, by Rennie in New York City, and by the New York State Mental Hygiene Commission in Syracuse.

There is a body of knowledge available in the studies that the Public Health Education Branch of the Public Health Service has made on evaluating the effectiveness of various types of health education materials as well as in studies which advertising and psychological research personnel have made on presentation techniques. Copies of some of these studies would be made available to area States to see whether the general principles embodied therein are applicable to statistical presentation.

Discussion centered on the problem of how differences in administrative policies among the States, kind of patients admitted, types of facilities available, adequacies of staffs, and so forth, can affect the various indexes used in interstate comparisons of mental hospital accomplishments. Traditionally, in the tabulations published by the Bureau of the Census from 1923 to 1947 and continued by the National Institute of Mental Health since 1947, data for State mental hospitals have not been combined with data from county mental hospitals and from the receiving or psychopathic type of mental hospital because of lack of comparability. However, since changes in function have

occurred in recent years so that some of these hospitals are now operating much the same as the State hospitals, the institute agreed to produce for 1954 and thereafter tabulations for public hospitals combining data for all of the institutions functioning in the same general way.

In discussing the difficulties of comparing improvement and release rates on an interstate basis, it was brought out that there may be considerable variation in the degree of psychiatric impairment at the time of admission as well as at time of release, and this, too, would affect interstate comparisons. A committee appointed to look into this problem will report to the 1956 conference.

The report of the Committee on Presentation of Lay Materials was approved and accepted by the conference.

Reporting Area Tabulations

The Biometrics Branch of the institute presented an analysis of tabulations based on 1953 material from eight member States. In view of some of the difficulties the staff had encountered in comparing this material, the need for the cohort type of analysis was again apparent, and the need for further information regarding administrative practices in the various States was pointed up. Perhaps some of the problems of noncomparability can be eliminated by selecting data pertaining to specific groups of patients rather than attempting to compare all patients in one State mental hospital system with all patients in another system.

Among the editing problems encountered by the biometrics staff working with the State tabulations were failure to convert the old diagnostic terms to the new psychiatric nomenclature, failure to give data in the age and diagnostic breakdowns requested, lack of correspondence between the time periods of the schedules submitted and the time periods specified on the instructions, and lack of agreement among the tabular totals for age, sex, or diagnosis, on the schedules submitted by a State.

The need for greater care and accuracy in preparing schedules was stressed.

The Progress Reported

The States represented at the conference last year had indicated the need for certain statistical data on residents who were receiving inpatient care for mental illness under the auspices of the Veterans Administration. As a result the Veterans Administration, through the institute, has supplied the area States with needed and useful tabulations on patients resident in and discharged from VA hospitals. This information gives a more complete picture of the hospitalized mentally ill resident in a member State regardless of place of hospitalization. It was agreed that data on resident patients by claimed residence of the veteran would be the most useful material to be obtained on a yearly basis and that other data might be made available, as needed, at less regular intervals.

Delegates reported on developments and operating problems in their State statistical departments. Additional personnel, space, equipment, and duties have been added in some of the departments. The hospitals in one State now use mark-sense punchcards for routine reporting to the central statistical office, thus making it possible to gather more information per patient with less personnel. The statistical forms for hospital reporting in another State have been revised so that much information can be precoded, thus saving clerical time.

Illustrative of the view expressed at the conference that States have learned to work together for mutual benefit is the fact that since 1951 the model reporting area has grown from 11 to 17 States. Two States, Minnesota and Oklahoma, have joined the area since the 1954 meeting. Seven other States are in the process of developing their central reporting systems. Before too long, it can be expected that at least one-half of the 48 States will have satisfied the criteria for membership in the area.

Milk Sanitation Honor Roll for 1953-55

Fifty communities have been added to the Public Health Service milk sanitation "honor roll" and 71 communities on the previous list have been dropped. This revision covers the period from July 1, 1953, to June 30, 1955, and includes a total of 257 cities and 64 counties.

Communities on the "honor roll" have complied substantially with the various items of sanitation contained in the Milk Ordinance and Code recommended by the Public Health Service. The State milk sanitation authorities concerned report this compliance to the Public Health Service. The rating of 90 percent or more, which is necessary for inclusion on the list, is computed from the weighted average of the percentages of compliance. Separate lists are compiled for communities in which all market milk sold is pasteurized and for those in which both raw milk and pasteurized milk is sold.

The recommended milk ordinance, on which the milk sanitation ratings are based, is now in effect through voluntary adoption in 419 counties and 1,594 municipalities. The ordinance also serves as the basis for the regulations of 34 States and 2 Territories. In 11 States and the 2 Territories it is in effect statewide.

The ratings do not represent a complete measure of safety, but they do indicate how closely a community's milk supply conforms with the standards for grade A milk as stated in the recommended ordinance. High-grade pasteurized milk is safer than high-grade raw milk because of the added protection of pasteurization. The second list, therefore, shows the percentage of pasteurized milk sold in a community which also permits the sale of raw milk.

This compilation is from the Division of Sanitary Engineering Services of the Bureau of State Services, Public Health Service. The previous listing was published in Public Health Reports, March 1955, pp. 337-340. The rating method was described in Public Health Reports 53: 1386 (1938). Reprint No. 1970.

Although semiannual publication of the list is intended to encourage communities operating under the recommended ordinance to attain and maintain a high level of enforcement of its provisions, no comparison is intended with communities operating under other milk ordinances. Some communities might be deserving of inclusion, but they cannot be listed because no arrangements have been made for determination of their ratings by the State milk sanitation authority concerned. In other cases, the ratings which were submitted have lapsed because they were more than 2 years old. Still other communities, some of which may have high-grade milk supplies, have indicated no desire for rating or inclusion on this list.

The rules for inclusion of a community on the "honor roll" are:

1. All ratings must be determined by the State milk sanitation authority in accordance with the Public Health Service rating method, which is based upon the grade A pasteurized milk and the grade A raw milk requirements of the Public Health Service milk ordinance. (A departure from the method described consists of computing the pasteurized milk rating by weighting the pasteurization plant rating twice that of the raw milk intended for pasteurization.)

2. No community will be included in the list unless both its pasteurized milk and its retail raw milk ratings are 90 percent or more. Communities in which only raw milk is sold will be included if the retail raw milk rating is 90 percent or more.

3. The rating used will be the latest submitted to the Public Health Service, but no rating will be used which is more than 2 years old. (In order to promote continuous rigid enforcement rather than occasional "cleanup campaigns," it is suggested that when the rating of a community on the list falls below 90 percent, no resurvey be made for at least 6 months. This will result in the removal of the community from the subsequent semiannual list.)

4. No community will be included on the list whose milk supply is not under an established

program of official routine inspection and laboratory control provided by itself, the county, a milk control district, or the State. (In the absence of such an official program there can be no assurance that only milk from sources rating 90 percent or more will be used continuously.)

5. The Public Health Service will make occasional check surveys of cities for which ratings of 90 percent or more have been reported by the State. (If the check rating is less than

90 percent, but not less than 85, the city will be removed from the 90-percent list after 6 months unless a resurvey submitted by the State during this probationary period shows a rating of 90 percent or more. If the check rating is less than 85 percent, the city will be removed from the list immediately. If the check rating is 90 percent or more, the city will be retained on the list for 2 years from the date of the check survey, unless a subsequent rating during this period warrants its removal.)

Communities awarded milk sanitation ratings of 90 percent or more, July 1953-June 1955

NOTE: In these communities the pasteurized market milk shows a 90-percent or more compliance with the grade A pasteurized milk requirements, and the raw market milk shows a 90-percent or more compli-

ance with the grade A raw milk requirements, of the Milk Ordinance and Code recommended by the Public Health Service.

Note particularly the percentage of the milk pasteurized in the various

communities listed. This percentage is an important factor to consider in estimating the safety of a city's milk supply. All milk should be pasteurized, either commercially or at home, before it is consumed.

public health pioneering

A Southern Heritage

APHA SOUTHERN BRANCH CONFERENCE REPORT

To commemorate a pioneering heritage and a history of progress, the Southern Branch of the American Public Health Association chose for its 23d annual meeting in New Orleans on May 11, 1955, the occasion of the 100th anniversary of the establishment of the Louisiana State Board of Health.

Several hundred delegates attended from Alabama, Arkansas, District of Columbia, Florida, Georgia, Kentucky, Louisiana, Maryland, Mississippi, Missouri, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia, West Virginia, and nations to the south.

In a review of the southern heritage, Dr. Ben Freedman, director of the public health training center, Louisiana State Department of Health, pointed out that many health regulations were applied in the early Spanish settlements and that the

Virginia, Maryland, and Carolina provinces pioneered with health measures under the British Crown. In the history of the United States, the people of the States now comprising the APHA Southern Branch appointed the first health officer, the first local board of health, and the first State board of health.

Other speakers pointed out that southern economic progress, handicapped for years not so much by climate itself as by diseases peculiar to a warm, humid climate, has been accelerated by control of such diseases. By such means, public health services have released southern energy and enterprise to break the vicious circle of illness that begets poverty that begets illness.

Seventeen of the papers read at the meeting are briefed here. Several others will be published in full at later dates.

The Past is Prologue— Theme of Address

brief My title comes naturally to one from a State facetiously referred to by us natives as "a vale of humility between two mountains of conceit." Our past achievements serve well only as they spur us to build even more soundly, never when they lull us into complacency.

Edwin A. Alderman, 50 years ago, set the goal of the south when he said that its supreme need is for trained men, men with prevision to see things before they happen, men who think with their brains and not their emotions, men who find out about things before settling them instead of settling them first and finding out about them afterward, men eager to build for the future rather than to chant the requiem of a past age.

It is definitely not disrespectful or ungrateful but actually necessary to orientation and alertness when we take frequent looks all around, including a quick glance backward, as we move forward. It is unfortunate that even a few health workers assume that the really important services in public health began the day he or she was hired. Since an appreciation of history tends to dispel such arrogance, we need more of such appreciation, and only then can we safely admit that we are doing more and better work than the early pioneers.

The Southern Branch of the American Public Health Association is entirely dependent on volunteer and drafted service for its activities and growth, and all have come through magnificently in spite of the many handicaps of heavy responsibilities in various types of jobs. In our large organization no one per-

son could ruin it, but it takes devoted service from many to succeed day by day.

Our Southern Branch area has pioneered in environmental sanitation, control of intestinal parasites, State and local—and particularly rural—health department organization, immunizations, school health services, oral hygiene, control of insect pests in a subtropical area. All of these achievements have been under medical leadership. Some we did because we had to.

Our pleasantly warm climate, heavy rainfall, and soil types encourage outdoor living and certain disease hazards. The relative backwardness in and near the tropics has been due more to insect enemies than to climate. In the Tennessee Valley it was demonstrated that the former heavy morbidity and mortality from malaria around tropical and subtropical impoundments is controllable. The growth of tribes or towns and cities has been limited sharply to their ability and willingness safely to dispose of human wastes. As we in our lovely area bring insects and environmental pollution under effective control, progress will become limitless—agriculturally, industrially, and in human health and efficiency.

Private medical practitioners in our area have stimulated and promoted the development of sound local health departments. They have given of their time to serve on State and local health boards and to cooperate in case finding and other services. Private practice and public health have jointly brought communicable diseases under relative control.

We now have the organization, the experience in medical leadership, and cooperative teamwork to pioneer in the field of chronic disorders and accidents, and to prepare for providing public health services to our aging population.

To develop the ideal child, Socrates is said to have advised starting with the grandparents. For better control of chronic degenerative disorders, we should at least begin with sound parenthood, careful prenatal guidance, and early infant and pre-

school health protection and development.

As we set our sights on the future we can learn much from, and can deservedly be proud of, our pioneering past. Louisiana led the way with the first State board of health; Maryland with the Baltimore City Health Department; Virginia with her smaller type city health department, at Petersburg; Kentucky and North Carolina with early county health departments, in Jefferson and Guilford Counties; and North Carolina with the first strictly rural county health department, in Robeson. Alabama and South Carolina were among the first to attain full State coverage by local health departments—and we might go on. May we do our utmost to become worthy successors to our pioneer predecessors.

An Era of Responsibility Typifies Public Health

brief The era into which we are moving is still too confused to have a single adequate label. Depending on one's point of view, it can be described as the chemical era or the social era or the era of physics or radiological energy.

If we classify the present era as social or an era of social medicine, there is much to substantiate our case. The great variety of names dealing with mental health, the whole person, holistic medicine, and so on merely reflect the scope of the expanded interests which public health has developed.

Louisiana created early a unit of social work in its State health department. New York State now has an anthropologist on the staff of its health department. Departments of preventive medicine in the medical

By J. W. R. Norton, M.D., M.P.H., secretary and State health officer, North Carolina State Board of Health, and president, 1951-55, of the Southern Branch of the American Public Health Association.

By Roscoe P. Kandle, M.D., deputy commissioner, New York City Department of Health.

schools have anthropologists, sociologists, and medical and psychiatric social workers on their staffs doing research in social medicine.

The traditional separation of preventive and therapeutic services is slowly disappearing. Public health is concerning itself increasingly with both secondary and primary prevention of the chronic diseases. The State health department in Idaho has full responsibility for mental health. Public health nurses in Georgia have demonstrated their skill in helping families with post mental hospital experience. On the other hand there has been a further fractionation of many mental health services in many States.

In New York City 11 union-operated health centers provide high-grade diagnostic and ambulant therapy services and are quite successful in getting people to take advantage of periodic physical examinations. In Windsor, Ontario, the Ford Company and the union have negotiated a contract whereby all employees and their dependents will get prepaid hospitalization and complete medical care in the hospital, office, or home. The same care is assured after retirement.

The time has come when public health nursing care of the sick at home must be considered a normal part of the public health program. Visiting nurse associations and health department nursing staffs are uniting to form a single comprehensive nursing service. Certainly, a combined nursing agency can be a means to a better family service.

Family Health Center

The 3-year project now being conducted in Washington County and Hagerstown, Md., by Community Research Associates will give us a better perspective of the intricate complexities of family problems in this era of public health. The project combines research, demonstration, and direct service with the prevention and control of the heavy community burden presented by indigent disability.

During January 1954 about 13 percent of the families in Washington County received service from one of

the community-supported agencies which deal with health, dependency, and maladjustment. About 6 percent of this group were designated "multiproblem" in that they were families with recognized problems, receiving care from agencies working in 2 or more of these 3 fields.

Studies elsewhere have shown a remarkable consistency of this 6 percent of multiproblem families—in getting service as they do from many agencies, in absorbing an enormous and disproportionate amount of community funds and professional staff time. In Washington County these multiproblem families comprise 88 percent of the public assistance caseload, 63 percent of the organized indigent medical care caseload, and 43 percent of the caseload of the agencies dealing with maladjustment.

To a high degree these community agencies—13 local voluntary, 18 local tax-supported, and 24 State—are treating the same families and individuals.

Washington County is in the process of attacking the basic behavioral, social, mental, and environmental problems presented by its problem families through a family health center and a unit of chronic disease control in which rehabilitation will have major emphasis. The center will unite the skills of medicine, public health, rehabilitation, public health nursing, family case work, and will integrate its mental hygiene service with that of the health department.

Ingenuity, Courage, Vision

A 5-year project with similar objectives is under way in Lafayette Parish, Louisiana. It is a remarkable project, stemming from the work of a State interdepartmental committee, which all agencies are pledged to work through. Each agency is to support its part of the plan within the framework of its responsibility to prevent the waste of human resources occurring from the social breakdown of families.

It should be clear to all of us that every health unit is carrying many of these multiproblem families. The children all too frequently repeat much of the pattern of asocial behavior and chronic illness of their

parents. Even superficial reflection will impress us with the great amount of advice, pressure, needling, and direct action which these families receive from many workers, many agencies. Undoubtedly they get conflicting specific directions and counsel.

Few of us will have the opportunity to participate in trials such as those in Maryland and Louisiana, but everybody can take a crack at this tough basic problem. The logical approaches, in actual practice, are simple: recognition of multiproblem families as such, a comprehensive family diagnosis, comprehensive treatment based on this diagnosis, and the kind of leadership and machinery of synthesis necessary to make this treatment possible by a single plan. The difficulties lie in actually working out a way for functioning together to benefit our communities. When we have solved this problem by combining ingenuity, courage, and vision with hard work, we will have realized the most significant of the changing aspects of public health.

Local Agency Programs For Accident Prevention

brief Home and farm accidents have emerged as a leading threat to health and personal welfare in the United States in the second half of the 20th century. Home and farm accident deaths outnumber all communicable disease deaths in most States. As a killer andcrippler of children, home accidents outnumber the next five leading causes of death including motor vehicle accidents. The other large

By Charles M. Cameron, Jr., M.D., M.P.H., acting chief, accident prevention section of the North Carolina State Board of Health, and associate professor of public health administration at the University of North Carolina.

group experiencing unusual incidence of home accidents are the aged, and United States figures for 1953 show that 1 out of every 2 persons killed in home accidents was over 50 years of age.

Resistance to Program

In introducing the idea of home accident prevention to the local health departments of North Carolina, the State board of health's accident prevention section staff has found that the misgivings expressed by the local public health personnel fall into two general classes.

The first is the feeling that home accidents and other types of accidents do not actually constitute as real a health problem as do those conditions which can be related more closely to the traditional areas of medical and public health endeavor.

Accidents are, and should be, widely recognized as the concern of those engaged in the manufacture, maintenance, and operation of motor vehicles, the construction and use of highways and public roads, the operation of industrial plants, the conducting of occupational health and safety services, and those with interest in water safety, fire-arm safety, and the host of other safety specialty interests. The public health worker in some instances appears to feel that accidents to the individual in his home environment are not as worthy of the worker's time and attention as are the health problems related directly to bacterial etiology, degenerative conditions, clearly unhealthy physical and mental environment, and other conditions for which it is easier to demonstrate a cause and effect relationship.

The second area of misgiving is perhaps not so easily encompassed. It is expressed in the concern displayed by a number of health department staff members who believe that home accident prevention activities, to be effectually conducted, must be defined in concrete terms within the comprehension of all the staff.

This dubiety seemingly pertains not only to the etiology of accidents where terms such as "accident prone," "accident susceptible," and

"accident liable," are hard to reduce to day-to-day fundamentals, but also to the methods of prevention. In the latter area, one frequently hears much about "education," "motivation," and "integration," and in some instances these terms seem peculiarly nebulous in the light of everyday health department operations.

The conceptions of accident prevention also are colored in many instances by the mass educational and promotional programs which have characterized the focus of over 90 percent of all safety programs in the United States in recent years. That home accident prevention involves more than the mobilization of press, radio, television, and other mass educational media has been hard for some public health administrators to grasp.

Health department reluctance to undertake home safety activities has stemmed from a failure to recognize the rising importance of accidents as a threat to health, a hesitancy to redraft program content to meet these new needs, and the difficulty public health safety leaders have experienced in demonstrating down-to-earth¹ easily assimilated accident prevention techniques which can be adapted to existing health department programs.

Causes of Accidents

Home and farm accidents can be shown to result from a combination of two factors: human failing, such as physical, mental, or emotional conditions, and environmental hazards, either "built-in" the dwellings or "imported" by way of appliances and furnishings.

Physical conditions such as defective vision, loss of auditory acuity, dizziness, immaturity, feebleness, or other physical incapacity resulting from acute or chronic diseases or conditions easily can be pictured as causing many accidents, particularly among the elderly. That accidents can be ascribed to transient physical conditions such as fatigue, overindulgence, hunger, and sleepiness has been established.

The mental and emotional states which can be related to accidents are perhaps less well understood than

the physical, but again certain examples can be elicited which can be applied readily to accidents or near-accidents within the experience of most health agency employees. These encompass the accidents which result from failure to exercise usually observed precautions due to anger, frustration, anxiety, depression, and preoccupation. These mental and emotional circumstances, existing almost wholly on the conscious level, can only serve to suggest the significance of less clearly defined influences operating within the subconscious. The etiological relationships concerned in accident proneness or susceptibility are within this less well-defined area. However, the existence of such individuals has been demonstrated in a variety of accident research studies.

It seems obvious, however, that home accident prevention programs need not be delayed until all facts pertaining to the so-called prone individual have been established fully.

Face-to-Face Education

Successful home accident prevention activities must combat both human failings and environmental hazards. The approach to the individual and to his home must progress simultaneously on a communitywide front and an individual basis. Health department opportunities for a combination of the face-to-face teaching of safety in association with the mobilization of community resources offer an approach to safety in the home unique in the history of the safety movement in the United States.

In attempting to gain the interest and cooperation of the family members to conduct effective education on home accident prevention, several channels are open to the health department. Certainly, the utilization of mass media, audiovisual aids, displays, posters, exhibits, contests, and other educational enterprises should not be overlooked for whatever value they may have. However, through public health nurses, sanitarians, and other field workers who daily enter hundreds of homes in the community, public health agencies are in a position to mobilize perhaps the most potent educational force yet

brought to bear upon the accident problem.

The public health worker has entered into the home where he or she is received as a family friend who can speak with authority on health matters. With each entry into the home, a situation for learning is created, and in no other setting could the teaching of home safety be more effective. Far-sighted public health authorities have been quick to recognize the implications for safety in almost all of the program areas where health departments are now active.

Maternal and infant supervision, geriatrics, nutrition, environmental sanitation, the hygiene of housing, mental health, insect and rodent control, radiological health, chronic disease control and many other activities have real concern for safety in one or more aspects.

Health workers sensitized to safety objectives and techniques have stated that usually it is not necessary to seek the opportunity to integrate home safety teaching into the home visit. Such opportunities frequently present themselves, and the worker need only be alert to develop the opportunities to their fullest potential.

In some areas, home visits by all disciplines have been used as an opportunity to gain valuable statistical information on family accident experience and to record hazards existing in the home. Such activities not only add to the epidemiological knowledge of home accidents, but also afford another opening for family education.

Group teaching has been demonstrated as a type of interpersonal relationship wherein valuable information may be imparted to all participants. Meetings of public health workers with mothers, parents, and other organized community groups afford an additional chance for home safety teaching to be achieved at its most receptive level.

Cooperating Groups

The health department launching safety activities will find a host of other official agencies and volunteer organizations and individuals with a related safety interest or activity.

The department of motor vehicles, the public schools, the agriculture extension service, industrial commissions and labor groups, welfare departments, city planning and development organizations, housing authorities, and police and fire departments all have a vested interest in some phase of accident prevention. Coordinated planning and action with these official groups and the volunteer agencies can result in economy not only in funds but also in effort.

The precise depth and direction of the community centered safety program will depend in large measure upon the individual community's needs and resources. One single plan effective in all localities is beyond the realm of reasonable expectation. Important, however, is the thought that some organized plan must be formulated to involve actively all those concerned with the solution to this serious health problem.

Educating for Home Accident Prevention

brief The National Safety Council's "Accident Facts" informs us that the majority of persons over 65 who die as a result of home accidents are victims of falls. This information seemingly provides the key to the problem of preventing home accidents among the aged, for if we eliminate the causes of falls, it follows that we can cut the home accident death toll in half at one stroke.

A brief look at some of the causes of falls among the aged soon dispels any hope of easy victory, however, for these causes are both physical and environmental in nature. With advancing age, persons are less able

to foresee and protect themselves from accident hazards, and accidents which may cause slight injury to the young very often result in serious injury and death when occurring in later life.

We know, too, that among the aged, feebleness, chronic disease, senility, or acute physical disorders are major contributors to accident incidence. Elderly people, especially those suffering chronic diseases, are affected by errors of judgment and personality changes. Coupled with malfunctioning joints, susceptibility to accidental injury is greatly magnified. Visual and auditory activity is also often diminished, increasing vulnerability to accidental injury.

In a 1954 survey of fatal home accidents in Maryland counties, senility and chronic disease or disability were listed as the most frequent physical factors contributing to accidental injury. Miscalculation, poor or faulty judgment, loss of balance, inability to avoid obstructions, stumbling over objects, unsteadiness, fainting, or just seeming to fall without reason were listed as primary causes of these accidents.

These findings take on new significance when we see that out of a total of 119 fatalities in the 65 and over age group, 91 fatal accidents occurred to persons more than 75 years old. The need for close and continued supervision is obvious.

Emphasis on Education

The most realistic approach to the problem of preventing home accidents among the aged is to determine ways of reducing exposure to unsafe conditions in their environment. Education, with emphasis on educating persons responsible for the care of elderly folk, is the best method. Engineering and enforcement are important to a lesser degree.

Prospective operators of facilities for the care of the aged often consult the health department before beginning to build or remodel. By offering suggestions which take legal standards into account and also reflect understanding of the needs and problems of both operator and patients, we can eliminate many hazards. A similar service to prospec-

By J. Charles Judge, chief, home accident prevention unit, Maryland State Department of Health.

ve builders of private residences might also be productive of goodwill and increased safety.

In these contacts and in our work with individual families we can suggest adapting home surroundings to the needs of elderly members of the family. Such relatively simple changes as arranging living quarters on one floor, providing a central place for personal belongings, keeping passageways clear and lighted at night will reduce exposure to falls hazards.

More difficult is interpretation to family and community of the emotional needs of the elderly. The older individual needs to feel that he is valued and loved and that he makes a useful contribution to family and community life.

In addition, there is urgent need for codes and regulations which assure the "building out" of safety hazards in the individual home or the institution.

In Maryland, the State board of health has vested responsibility for the licensing of hospitals, nursing, convalescent and care homes in the bureau of medical services and hospitals. The hospital licensing law establishes basic principles of hospital and nursing home construction and operation so as to assure safe and adequate care of patients in places other than their own homes or those of relatives.

The contribution of the health department sanitarian in promulgating and carrying out these regulations is of real value. The Maryland sanitarian inspects the hospital or home before the issuance of a license and annually thereafter on renewal.

Health Department Sanitarian

Much thought is being given to the part sanitarians might take in helping prevent home accidents aside from their institutional activities and general sanitation inspections.

Seagle has pointed out in the *South Carolina Sanitarian* that the sanitarian has good opportunity to observe hazardous conditions or unsafe actions on his daily rounds and that a program of inservice training and a checklist of home hazards would help prepare him to discuss unsafe conditions on the spot and make rec-

ommendations for practical means of correction.

What are some of the points which the sanitarian might keep in mind as he inspects private residences and nursing or care homes?

In connection with construction, he should determine whether electrical, plumbing, and heating installations have been inspected for compliance with local codes, manufacturers' specifications, and the minimum standards set by national boards.

He might call attention of the homeowner or nursing home operator to the need for elimination of dangerous changes in floor level, the need for sufficient electrical outlets to avoid overloading circuits and to eliminate long extension cords.

He might check switches and outlets to see that they are located at sufficient distance from sinks, showers, bath and laundry tubs and yet are accessible to the bedside, doors of entry and exit, and at the head and foot of stairs.

He might look for such booby traps in the environment as doors opening into stairwells, inadequate lighting of stairways and hallways, insecure or missing handrails, loose stair treads, risers that are not of uniform width or height.

He might recommend that scatter rugs be backed with a nonslip material or substance, that they not be placed at the head of stairs, and that flooring have a nonskid finish. He might recommend grab bars for tubs or showers. He might suggest a traffic plan to rid passages or walkways of obstruction.

In the handling and storage of medicine, the sanitarian might ascertain whether containers are clearly and properly labeled and whether medicine cabinets are located near running water to facilitate preparation of prescribed medicine. Are narcotics, sedatives, and other dangerous or habit-forming drugs in a safe place? Are medications no longer in use being promptly discarded?

In connection with fires, which next to falls lead in causing accidental death and extended morbidity, the health department sanitarian

can augment the safety precautions required by the local fire authority or the State insurance commission. In many areas stoves and individual room heaters or space heaters are not acceptable and are a fire hazard. The sanitarian can work with county fire marshals who share our interest in saving lives.

Preventing accidents to the aged is not a task for one agency alone. Its solution will require the contribution of many—every member of the health department, engineers, architects, builders, teachers, individuals responsible for care of the aged, communities responding to the need for providing care facilities for their older citizens. Through such an approach it is reasonable to expect a steady reduction in the accidental injury and death rate among persons in the older age groups.

The Relation of Housing To Accident Incidence

brief In Augusta, Ga., a housing study was correlated with an accidental injury study to determine if the accident rate increases as housing standards become poorer.

The housing survey, made by the Richmond County Health Department in 1952 and 1953, classified the housing in two census tracts in the southeastern part of Augusta into five groups—A through E. Class A indicated the best housing and class E, the poorest. This section was selected for the survey because of the varied types of housing it contained. The class of housing was determined by inspection of the structure, dwellings within the structure, and the premises. The dwellings were graded by the penalty point method.

Also available was an up-to-date file the University Hospital of Au-

By Henry C. Steed, Jr., B.S., director of the home safety unit, Georgia Department of Public Health.

gusta keeps on all accidents treated in the emergency room. Ninety-five percent of the emergency cases in the area are treated by this hospital.

For its analysis, the home safety unit of the Georgia Department of Health selected from the hospital data the accidents occurring in 1953 to the residents of the two surveyed census tracts, V and VI.

The total estimated population of the census tracts was 8,283—6,204 white and 2,079 nonwhite residents. An extremely high percentage of the nonwhite population lived in the lowest class of housing. Eighty-eight percent of all the persons living in class E housing were nonwhite; in class A housing, only 3 percent were nonwhite.

General Rate Upward

Home injuries treated in the hospital's emergency room were the leading type of injury. They almost doubled the rate for motor vehicle injuries—20.9 to 11.8 per 1,000 population.

Although the study found no clear-cut rise in injury rates as the housing, maintenance, occupancy, and dwelling scores decreased, the general rate trend was upward as the housing conditions became poorer.

The total treatment rate for all types of accidents increased steadily through the first four classes of housing—from 43.4 for class A to 76.1 for class D. But for class E housing the total rate showed a sudden drop to 55.5 per 1,000 population.

For home injuries, the rates by class of housing were: A—17.7; B—21.2; C—17.9; D—31; E—25.8. Thus, home accident rates dropped slightly for class C housing, turned back up sharply in class D, and dropped again in class E housing.

Two factors possibly responsible for the differences in injury rates, such as the drop in the rates for class E housing, are the large proportion of nonwhite persons living in class E housing and the lower socioeconomic status of residents in this class of housing. Possibly, they made less use of hospital facilities.

The rates by manner of injury showed the same general trend as in

other comparisons, except for the categories "hit by person or objects" and "animals." These were considerably higher for class E housing. The category "falls," generally associated with poor housing, also showed a definite rise—from 8.4 per 1,000 for class A housing up to 17.2 per 1,000 for class E housing. This finding is another indication that there is possibly a relationship between housing and incidence of accidents.

Effect of Housekeeping

In another study, a sample survey of home injuries was conducted in Ware County, Ga. Data were collected on nonfatal injuries occurring in the 12 months preceding August 1954 according to: major causes of the injuries, by age, race, and sex; nature and manner of injury; and environmental and human factors associated with the accidents.

To discover if the type of housekeeping influences the home injury rate, the interviewers were asked to observe the condition of the housekeeping both on the inside and the outside of the house and to classify each according to one of five classifications: (1) very well kept, (2) well kept, (3) so-so, (4) carelessly kept, and (5) very carelessly kept. Although the recorded observations were strictly the opinions of the interviewers, the tabulated results did indicate a relationship between condition of housekeeping and home accident incidence.

For estimated major injuries outside the home, the rate per 1,000 population was lowest (26) for premises very well kept and highest (47.7) for premises classified as carelessly kept.

The rates for major injuries occurring inside homes rose in almost a straight line from 28.6 for very well kept homes to 40 for those carelessly kept.

The relationship was similar for minor injuries, although the estimated rates were somewhat higher. The inside and outside rates of 62.3 for homes very well kept rose to 100 for homes very carelessly kept inside and 87.7 for those very carelessly kept outside.

Aborigine Influence On the Southern Diet

brief Diet is an integral part of the culture of any people, and thus in the southern United States the dietary pattern is a part of our cultural heritage.

Generally, the southern diet is characterized by an excess of starchy foods; an ample supply of meat; a near absence of green, leafy vegetables; overcooking of all vegetables; frying in fats; and a general unvarying fare in season and out.

The food list is dominated largely by an Indian heritage. The diet of the indigenous Indians in the 16th century varied locally throughout the south but predominated in meat, corn dishes, beans, and perhaps squash.

The food preparation habits of the southerners are of mixed origin. The southern Indians were boilers and broilers, rarely bakers and never fryers. Long, slow boiling typified the preparation of plant foods other than maize. In fact, most tribes customarily kept a fairly large pot brewing and stewing at all times, and one dipped food from the pot when hungry. Only rarely were green, leafy vegetables used as salads.

On the other hand, frying is common throughout Africa, especially on the Guinea Coast and in the Congo Basin that contributed most of the American Negro slaves. In Colonial and pre-Civil War days, cooking was largely a function of the slave, and it is possible that various frying techniques would thus enter the cooking complex of the southerner. In addition, such cooking would soon attain a cultural value that would make it desirable to those who could not afford slaves.

Also in the Gulf Coast area large populations of West Mediterranean peoples, such as the French and

By William G. Haag, Ph.D., associate professor of anthropology, Louisiana State University.

Spanish, have introduced many dishes that involve frying in fats and oils. The American Indian had no domesticated animal comparable to the pig in the Mediterranean area and thus had no surplus fats to use as a food preparation agent.

No "Natural" Diet

There is nothing "natural" about the diet of man, and in the course of his development he has changed from a wholly herbivorous animal to an omnivorous one. He has developed various patterns of food habits that run from extremes of all meat to all vegetable. Like the American Indian, what he eats has been largely dictated by available foods and has often consisted of anything he could obtain. Only incidentally have man's dietary habits coincided with his basic needs.

Diet is often thought to be a matter of conscious selection, although certainly Lewin and Dickins have well supported the contention that "people like what they eat rather than eat what they like." Likewise, people often cannot eat what they do not like, and it is illusionary to think that man rationally selects his likes. The diet of several primitive peoples support this.

For example, nutritionists formerly thought that a balanced diet was virtually essential to existence, yet often Eskimos subsist their entire lives with not one item of vegetable food ever entering their diet. In fact, many Eskimos never eat anything in their lifetime that may be even remotely construed as vegetable food. Occasionally, a lucky hunter may be allowed to eat the stomach contents of a slaughtered whale or seal. In this "stomach spinach," as it has been called, he may get some partially digested vegetables. Certainly, there is nothing to suggest that a craving for vegetable food ever enters his head. On the other hand, it is certainly true that the Eskimo has a rather monotonous diet consisting of frozen fish, seal, walrus, or whale. This is seldom varied, and when something new enters the diet it is meat. It is not surprising that the Eskimo searches through the meat box in the house for a piece

that is somewhat on the "high" side to vary this bland diet.

When an economic status supports the luxury of eating what one likes, man may be fairly selective, but at the subsistence level maintained by most primitives, one eats what is available. Australian natives eat vast quantities of the larvae of a certain moth that they eagerly seek each year. Several California tribes collect and store hundreds of bushels of acorns, and some inhabitants of Nevada and Utah spend nearly all of their waking hours collecting roots and tubers. Their habitat offers little else.

Some Asiatics exist almost wholly on a single plant—rice. In several spectacular instances, men have learned to use plants that are very poisonous in the unprepared state; yet these become a staple food. Manioc, or cassava, is such a plant—the most frequent food used by millions of Amazon peoples. In the fresh state, it is so charged with prussic acid that an unsuspecting bite into a tuber will puff up and blister the whole mouth, and to swallow a small portion usually is fatal.

Approach to Nutrition

Since diet is part of the culture of a people and one cannot change an aspect of culture very readily, a nutritionist should approach changes in the diet of a locality in a spirit of compromise.

Millions of people in China look upon milk with abhorrence, and most West Africans are horrified at the thought of eating fresh eggs. Many a northern visitor to the south finds eating grits incomprehensible as well as unpalatable, and simple lessons in home economics do not remove these taboos. Man rarely behaves in a rational manner, and the simple truth that one food is better for him than another is hardly sufficient. Deliberate educational approaches, such as inviting people to a prepared feast of nutria dishes, may have only slight success; perhaps nutria gumbo has a chance, whereas baked nutria may not—the former being more closely allied to existing practices.

In the Louisiana State University cafeterias, the nutritionists

are constantly accused by the incoming students of failure to cook the vegetables. Hence, they now cook the vegetables to a cellulose pulp early in the academic year and gradually adjust the cooking time so that by spring the vegetables are properly prepared. This gradualism in vegetable cooking certainly pays bigger dividends than if the student is confronted with strange, but properly cooked, vegetables from the start.

Finally, a wholly humanistic approach is demanded. If the nutritionist presents a too-professional, oversophisticated front, the recipient of the instruction is likely to be repelled. A home economics teacher or a county demonstrator does not have the status that the local physician may have. A physician may accomplish some things simply by prestige. Dickins has shown that most new recipes were introduced to southerners by their friends, and this entree should be exploited by cultural participation on the part of the home economists.

Perhaps an anthropologist, untutored in the culinary skills and lost in the sea of nutritional data, is presumptuous in offering suggestions to the professional food preparer. Nonetheless, this paper is a success if it offers only "food for thought."

Leptospirosis Diagnosis In North Carolina

brief In order to carry out epidemiological investigations of leptospirosis, it is our conviction that the State public health laboratory must provide a reliable diagnostic test for this disease. This

By Martin P. Hines, D.V.M., chief of the veterinary public health section, North Carolina State Board of Health; Nell Hirschberg, Ph.D., bacteriologist, and Lynn G. Maddry, Ph.D., assistant director, North Carolina State Laboratory of Hygiene.

service was initiated in the North Carolina State Laboratory of Hygiene in January 1954.

The need for the service was brought to a focus in North Carolina in late 1953. At that time, blood specimens were being sent to the Public Health Service Communicable Disease Center in Chamblee, Ga., and reports were often delayed from 1 to 3 months because of the great demand from all sections of the country for the service. For example, the report on a specimen found to be positive in a high titer was not received, it was learned on investigation of the case, until several weeks after the patient had been discharged. The patient had been seriously ill with a jaundicelike disease believed to be infectious hepatitis, although leptospirosis had been considered in the differential diagnosis. A visit to the patient's home after receipt of the laboratory report elicited the information that he had cared for several bird dog puppies when they were ill with leptospirosis.

The response from physicians and veterinarians to the initiation of the diagnostic service has been gratifying, although many physicians do not yet recognize leptospirosis as a disease entity prevalent in North Carolina. The most important reasons for this are: (1) the limitation of instruction on leptospirosis in medical schools to the classical Weil's disease; (2) the widespread publicity given to the viral type of infectious hepatitis; (3) the so-called catarrhal jaundice known for generations to be associated with mild colds and influenza; and (4) inadequate diagnostic service before 1954.

Two points should be kept in mind in dealing with leptospirosis: (1) There are specific laboratory tests for this disease (although a real need for improvement exists), and (2) the reservoir for *Leptospira* organisms is in the lower animal kingdom. Therefore, control of leptospirosis requires the combined efforts of the physician, laboratorian, veterinarian, and health officer. Any member of this team may find the first clue. The others complete and confirm the diagnosis, treat the patient,

and carry out epidemiological studies directed toward finding the source of infection and initiating control measures.

Diagnostic Tests

The most specific test for leptospirosis is isolation of the organism, but most laboratories are not equipped to carry out this procedure routinely. The detection of specific antibodies in the serum of ill or convalescent patients, however, is a procedure that can be done by public health laboratories. Because the complement fixation test is not yet standardized, the agglutination-lysis test or the agglutination test with killed antigen is used.

For the agglutination test, two specimens of clotted blood, collected about 10 days apart, are required. A rise in titer of agglutinins is considered a reliable basis for a diagnosis of leptospirosis. However, with samples taken late in the disease, when the patient is finally jaundiced or is making a slow recovery from an illness thought to be infectious hepatitis without jaundice, the titer will not rise and may even come down. Since native antibodies do not appear in the normal person, the presence of antibodies indicates present or previous infection with leptospires.

The difficulties encountered in providing a diagnostic test for leptospirosis make it a task for experienced bacteriologists only. Temperature requirements for growing the organisms are strict. The organisms may disintegrate spontaneously and without warning. Since maximum growth takes place in 5 days, multiple cultures must be maintained if a source of supply for antigens is to be available, the choice of cultures depending on the types of infection in the locality. Antigens must be prepared regularly, and the tests must be carefully controlled to insure good results.

Examples of Cases Diagnosed

A high percentage of the human and animal serum specimens examined in North Carolina since January 1954 were positive. Many specimens

were positive with more than one strain of *Leptospira*, indicating cross-agglutination between strains. A few examples follow:

Specimens from several herds of cattle which were experiencing breeding difficulties, including abortion, and which were negative to *Brucella* tests were positive in high titers to *Leptospira pomona*.

A few mule blood specimens have been found positive to *Lept. pomona*. One specimen that reacted in a very high titer was taken from a mule suffering from periodic iridocyclitis, a condition recently recognized as a delayed and uncommon sequela of leptospiral infection in men and horses.

Among the specimens from humans was one which showed a titer of 1:2,048 for *Lept. pomona*. It was taken from an 8-year-old Negro boy with an illness diagnosed by his family physician as leptospirosis. An epidemiological investigation revealed that the boy had had no contact with animals suspected of having the disease. However, a goat was kept on the farm premises where the boy lived, and rats were prevalent. Drinking water was obtained from a shallow well that could easily be contaminated with goat urine. A blood specimen from the goat showed a titer of 1:2,560 for *Lept. pomona*. Later, the goat was killed and *Lept. pomona* organisms were isolated.

Rabies Control Plan For South Carolina

brief In September 1950, a statewide survey was made in South Carolina in an attempt to determine the extent of rabies within the State. Between September 1950

By Frank M. Lee, D.V.M., State public health veterinarian, South Carolina State Board of Health.

and March 1951, after numerous consultations with veterinarians, county health officers, and county health sanitarians, the South Carolina State Board of Health drew up a master rabies control plan.

The first step in the plan was a statewide publicity campaign, which was conducted for 30 days prior to a designated period of animal vaccination and stray dog control. The radio, daily and weekly news releases, and pamphlets distributed through schools, churches, and civic organizations were used in the campaign.

The second step was the operation of vaccination clinics for a 6-day period, in April 1951. The clinics, a total of 1,042 of them, were manned by county health department personnel and members of civic groups, the boy and girl scouts, and similar organizations. Practicing veterinarians performed the vaccinations. Vaccine and tags were furnished by the local veterinarians, who collected \$1.00 per animal. State rabies certificates were furnished each veterinarian by the State board of health. During this period, 57,739 dogs were vaccinated.

The third step was a followup publicity campaign to further educate the public regarding rabies and its control. Stray dog control and the reporting of rabies cases were stressed. The public was kept rabies conscious throughout the year and was continually requested to take pets to the local veterinarian for vaccination.

The rabies control plan, with a few minor changes, was carried out again in 1952, 1953, and 1954. The results of the program from 1950

through 1954, are shown in the accompanying table.

Morbidity Reporting

In August 1951, a morbidity reporting system for rabies was initiated by the State board of health, the reports originating with the practicing veterinarians and routed direct to the vital statistics section of the State board of health. The percentages of cards returned were as follows: 1951, 98.7 percent; 1952, 83 percent; 1953, 78.3 percent; 1954, 67.4 percent.

In 1953, the State board of health received complete investigation reports on 631 persons who were given rabies treatment. Of the 373 animals involved, 319 of them were dogs, showing definitely that dogs constitute the major rabies problem as far as human beings are concerned. Of the 631 persons, 539 were white and 37 were Negro, a finding which suggests that Negroes in the State do not report possible exposure to rabies unless the exposure is a severe bite.

The investigation reports revealed, further, that puncture wounds caused by teeth was the method of exposure for 281 of the persons treated. Wounds caused by scratches was reported for 125; and handling of animals, for 162. For 56 of the persons treated, there was no exposure, and for 7 the method of exposure was not stated. From these data, it would seem that 350 persons were treated for rabies when exposure to the disease was doubtful. We believe that a more extensive history of the case should be obtained before humans are given rabies treatment.

Matched Data on Births And Neonatal Deaths

brief

With the introduction of the birth weight item on the birth certificates of all but one State by 1950, it became possible to obtain much needed information on the incidence of prematurity and mortality among prematures for the general birth population. Data on incidence of births by weight are now being tabulated regularly by the National Office of Vital Statistics and by many States. A special NOVS study covering births in the first 3 months of 1950 will provide detailed national and regional data on mortality by birth weight. The NOVS can make studies of this type only occasionally and will require the assistance of the States in the matching phase of the operation.

Many States match births and infant deaths routinely, and data on mortality by weight can be obtained as a byproduct. Information for individual States is of interest to many people because public health programs for the special care of prematurely born infants are now operating in several States. To make State data available in one source, the Public Health Conference on Records and Statistics—a permanent organization providing for coordination among Federal, State, and city registration executives and vital statisticians—sponsored a cooperative program to send data on matched births and neonatal deaths to the NOVS for processing and publication. This program was initiated with the collection of data for 1950.

Specifications for the tabulations to be collected from the States were worked out jointly by the NOVS and the States through the mechanism of the conference. Table forms prepared by the national office are sent to the participating States. In the

By Everett H. Williams, Jr., M.S., director, bureau of vital statistics, Florida State Board of Health.

first 2 years of the program detailed data were collected on birth weight by race, sex, attendant at birth, period of gestation, plurality of birth, cause of death, and age at death. At the last conference meeting, it was agreed to continue collecting data on an annual basis but to schedule detailed tabulations only cyclically. Thus, for 1952-54 the data have been or will be requested by race, period of gestation, and birth weight; for 1955-57, it is planned again to obtain tabulations by cause of death and age at death.

Participation in the program has increased markedly. In 1950, 11 areas (including 1 city and a Territory) and in 1951, 19 areas (including 2 cities, 1 Territory, 1 possession) submitted tabulations; and about 25 areas are expected to participate in 1952 and 1953 (see table).

In formulating the program, only general principles for tabulating the data were set down. These principles were:

1. Neonatal death records included in the tabulations for an area should relate to all infants born in that area.

2. Tabulations on neonatal deaths prepared on the basis of year of birth are preferable to those based on year of death. However, this is not an important issue and tabulations prepared on either basis should be accepted.

3. Unmatched neonatal deaths should be tabulated along with matched neonatal deaths.

Answers to inquiries on the data submitted for 1950 and 1951 indicated in what ways the States departed from these principles. The only significant difference was the omission of unmatched neonatal deaths.

Information was not requested of the States on other procedures related to the coding and tabulating of the data. The consequent inability to evaluate the comparability of the data creates one of the main problems in the use of pretabulated data. In 1950 and 1951, birth data tabulated by the NOVS were used in conjunction with mortality data prepared in the States for computing mortality rates. The decision not to request the birth data from the

States in these years was made in the belief that the burden of tabulating might act as a deterrent to the participation of some States. Experience with the use of data from the States and the NOVS for 1950 showed inconsistencies in the coding of certain items. Another problem which arose in 1951 was related to the 50-percent sampling of birth data for that year. This was of significance at the very low weights. Beginning with 1952, the States have been requested to supply birth data if available, as well as mortality data. Most States have indicated this could be done.

A report on data collected for 1950 and 1951 will be published later this

year. This report will contain birth weight statistics for births by race, sex, and plurality and for neonatal deaths by race, sex, cause of death, and age at death. Data on a few additional items on which statistics were collected were not included because of the apparent lack of comparability of the birth and death data for some areas. Subsidiary information for each area on completeness of birth registration and mortality based on data tabulated wholly by the NOVS is to be shown. Because of the biases in the reporting of weight for very small infants who die soon after birth, special procedures, utilizing available data on gestation age, were set up for the

Progress in Prevention Of Diarrheal Diseases

brief Although acute diarrheal diseases have been brought under control in the United States, Canada, and a limited number of other economically favored countries, available mortality data

distribution of births and deaths with weight not reported for each of these diseases must be acknowledged as a major current public health problem in most of the countries of Latin America.

It is of historic significance that these diseases are at last to receive concentrated special attention from organized international public health. Within one decade there may be attained in the countries of the Americas that progress in the control of diarrheal diseases which in the United States came slowly over a period of 50 years.

Multiple Factors in Prevention

There is no clear evidence as to what preventive measures were effective in the United States. There was no vaccine, no new medication. There was no biologic vector to be eradicated by an intensive program. Multiple factors apparently were involved. Perhaps of chief importance were the safer disposal of human feces, better personal cleanliness, the control of flies, and marked improvement of infant hygiene in the home.

These changes were brought about by community, social and industrial development, as much as by direct public health activities. The introduction of the motor car, for example, with the disappearance of stables in urban centers and the elimination of this prolific source of fly breeding presumably contributed to the control of diarrheal diseases.

Data now available indicate that the serious diarrheal diseases of infants and children are chiefly specific enteric infections. Shigellae are the major etiological agents. Salmonellae are of lesser importance, though the infections caused by these organisms have been reported to be prevalent in some rural areas where animals and humans live in close proximity. Other infectious agents such as *Entamoeba histolytica* and specific types of *Escherichia coli* are probably of limited quantitative importance as a leading cause of death.

The role of viruses has not been established. The important role of predisposing causes, and particularly of deficiencies in nutrition, is generally acknowledged even though the

The chief responsibility for the prevention of diarrheal diseases must rest with organized public health. There is the evidence of history that the severe diarrheal diseases are almost totally preventable. There is no single point of attack. For their prevention, multiple

International Focus

In antibacterial treatment, the sulfonamides and many of the antibiotics have been found to be rapidly effective in shigellosis although specific therapy has little or no value in salmonellosis. These advances in treatment provide a means for the successful therapeutic management of a very high percentage of all cases of diarrheal disease provided treatment is begun without delay.

Successful replacement therapy commonly is and adequate fluid and electrolyte case. Regardless of etiologic diagnosis, in almost all cases of diarrheal disease for the prevention of deaths therapeutic knowledge is now adequate for the prevention of deaths.

Present techniques have markedly increased the sensitivity of bacteriological tests for shigella and salmonella and have made it practicable to handle relatively large numbers of these diagnostic examinations. Bacteriological tests on representative samples of the normal population have established the common occurrence of carriers of shigella. They have served also to reveal the broad range of clinical manifestations of shigellosis and the frequent occurrence of clinically mild cases in adults. These observations must be considered in planning for effective control.

New Advances in Control

Epidemiological studies have led to the conclusion that the dissemination of shigellosis commonly involves a more or less direct transfer from one person to another of human feces containing shigella, and the role of flies in this transfer has been seriously established. In salmonellosis most of the infections have their origin in lower animals and fowl, and dissemination occurs predominantly through the medium of foods.

tiple procedures are indicated, and a well-balanced program is necessary.

The nature of the problem must be accurately diagnosed—this requires the participation of the public health laboratory, epidemiology, and vital statistics.

Environmental preventive measures must be applied through programs of community sanitation, with emphasis on the availability of water, the safe disposal of human feces, garbage disposal, and fly control—this calls for the services of sanitary engineers and sanitarians.

Knowledge must also be applied directly to individuals—this is the responsibility of public health physicians, public health nurses, and health educators.

All these broad control measures must be organized and coordinated by the public health administrator. These goals will not be attained easily, but it has been adequately established that difficult public health programs can be carried out when they are given due emphasis.

Heretofore, major attention by international health agencies has been directed toward such diseases as yellow fever, malaria, typhus, and yaws, and only scant attention has been given to the diarrheal diseases, recognized as an even greater cause of death than malaria, for instance.

In view of this history the recent activities of the 14th Pan American Sanitary Conference at Santiago in October 1954 are highly significant. During 5 half-day sessions representatives from all of the countries of the Americas considered together problems in the control of the diarrheal diseases. By resolution the Pan American Sanitary Bureau was requested to implement the technical recommendations which grew out of the technical discussions.

From that point the matter is being carried forward by critical planning. A series of international regional seminars will give attention to the newer scientific advances in the knowledge of the diarrheal diseases. A demonstration area to apply and evaluate a broad preventive program is deemed essential. As an immediate life-saving program, the easily applicable measures to

prevent dehydration and resulting death will be promoted widely.

The effectiveness of these and other procedures can be measured only by time, but it may be anticipated that there will be an increased emphasis on the control of diarrheal diseases at national and local levels in our sister countries.

Prematurity Program In North Carolina

brief Premature birth is the greatest single factor associated with the deaths of infants in North Carolina as well as in the United States.

The reduction of infant deaths in the first 28 days of life has not kept pace with the decline in mortality in the later infancy period, 1 month to 1 year. Approximately 60 percent of the infants who die in the first month are premature—that is, they weigh $5\frac{1}{2}$ pounds (2,500 grams) or less at birth.

If progress in the lowering of infant mortality is to continue, steps must be taken to reduce the number of deaths among prematurely born infants. To this end, a premature infant care program was established in North Carolina in July 1948. The program, sponsored by the North Carolina State Board of Health, the North Carolina Pediatric Society, and the Children's Bureau, is designed to reduce the infant mortality rate in the State through:

1. Prevention of premature labor by the methods known to prolong gestation.
2. Care of the premature infant by lessening risk of delivery, early case finding, hospitalization in approved centers, and followup.
3. Education of nurses, physicians,

By Elizabeth M. Macfarlane, M.P.H., supervisor of statistical analysis and reports of the North Carolina State Board of Health.

and the laity in the care of premature infants.

In 1952 a special report form was initiated for collecting detailed information on each premature infant born in the six participating hospitals or referred to them for care. This form calls for information on prenatal care of the mother, previous pregnancies, complications of pregnancy, type of delivery, and use of anesthesia and analgesia. Information on treatment and progress is requested for infants whose care is paid for by the State.

These records, along with consolidated birth and matching mortality data kept since 1952 on a statewide basis supplied the information for analyzing the effect of the program.

During the study period 1952-53, there were 16,378 single premature births in North Carolina; 1,307 of these births occurring in the six participating hospitals are compared with the 15,071 births in other places.

Analysis showed that a significantly larger proportion of the premature infants in the lower weight groups, 2,000 grams or less, were born in the premature centers—38 percent compared with 31 percent.

The greatest weight difference was found for nonwhite infants in the previsible group of under 1,000 grams. The percentage of babies (9.1) in this group in the premature centers was almost twice the corresponding percentage (4.6) for all other nonwhite prematures.

Because of a higher proportion of early premature babies and the referral of obstetric problem cases, the centers had a higher neonatal mortality rate—156.8 per 1,000 live births compared with 146.7 for all other prematures. Actually, with the exception of the lowest weight group, the weight-specific mortality rates in the premature centers were much lower than for other premature births.

Immaturity, unqualified or subsidiary to other conditions, was the most important cause of death for both groups of prematures—80.3 per 1,000 live births in the centers compared with 71.3 for all other births. For nonwhite births the difference

Single premature live births according to birth weight, North Carolina (exclusive of premature centers) and premature centers, 1952 and 1953

Birth weight (in grams)		Rate per 1,000 live births									
North Carolina	Total	Live births					Neonatal deaths				
		Number		Percent			Number		Rate ¹		
Premature centers	Total	Total	White	Non-white	Total	White	Non-white	Total	White	Non-white	Total
		15,071	8,786	6,285	100.0	100.0	100.0	2,211	1,296	915	146.7
		758	467	291	5.0	5.3	4.6	361	200	160.2	22.5
		1,284	719	565	8.5	8.2	9.0	364	245	197.7	27.6
Premature centers	Total	10,393	6,087	4,306	69.0	69.3	68.5	287	222	187.7	57.6
		2,636	1,513	1,123	17.5	17.2	17.9	284	222	192.0	57.6
		1,501-2,000	1,284	565	8.5	8.2	9.0	364	245	197.7	27.6
		1,001-1,500	758	467	5.0	5.3	4.6	361	200	160.2	22.5
Premature centers	Total	Under 1,000	100	74	26	7.6	9.1	82	57	45.6	168.4
		1,001-1,500	132	106	26	10.1	10.4	51	38	358.5	500.0
		1,501-2,000	261	206	55	20.2	19.3	39	33	149.4	109.1
		2,001-2,500	814	636	178	62.3	62.2	29	25	40.5	22.5

was more striking—105.3 per 1,000 live births in the centers compared to 75.1 for all other nonwhite premature births. These differences in mortality rate might be accounted for again by the difference in the weight distribution. With a large proportion of early prematures in the center one might expect a larger proportion of deaths due to immaturity. Death rates due to asphyxia and atelectasis for white babies and birth injury for nonwhite babies were considerably higher among premature center births.

Maternal Factors

Analysis of maternal factors related to prematurity revealed that type of delivery, use of anesthesia and analgesia, and complications of pregnancy are closely related to the survival of the premature infant.

Type of care received by the mother was reported for all but 10 of the 1,307 premature births in the hospitals. Of these 29.4 percent received clinic care, 68.3 percent private care, and only 2.3 percent normal, instrument, cesarean, and

unknown—was stated for all but three births. For 66 percent of the cases the delivery was normal, prenatally without operative intervention. Another 21.1 percent were delivered by instrument—low, mid, or high forceps.

Mortality rates were highest for babies with an abnormal presentation delivery and those delivered by cesarean section—33.3 per 1,000 live births for abnormal and 24.6 for cesarean. However, each of these rates is based on less than 100 cases and is subject to great variability. Anesthetics used were classified according to three types: general, local, and spinal or caudal. The analgesias administered were barbiturates, demerol, scopolamine, or other specified analgesia.

It is known that both an anesthesia and an analgesia were given for 60.5 percent of the deliveries. In 63.4 percent of these cases a general anesthesia was given, and demerol was the most frequently used companion analgesia.

In comparing the causes of death that for babies born to mothers with various types of anesthesia administered, it was found that for deaths due to asphyxia and atelec-

sis the mortality rate for this group was 198.5 per 1,000 live births while that for babies born to mothers with out complications was 128.1. The difference between these two rates is statistically significant. Deliveries

Complications Affect Survival

The following classes of complications were arbitrarily set up on the report form: toxemia—mild, severe, and eclampsia; hemorrhage; infection tuberculosis, syphilis, and general measles; premature rupture of membrane 24 hours prior to delivery; and other specified complications.

Of the 1,307 premature infants 41 percent were born to mothers with complications of pregnancy. Also 52 percent of the 205 neonatal deaths occurred among the births to mothers with complications.

The mortality rate for this group was 198.5 per 1,000 live births while that for babies born to mothers with out complications was 128.1. The difference between these two rates is statistically significant. Deliveries

complicated by hemorrhage exhibited the highest mortality rate.

Infants born to mothers with complications comprise about 60 percent of the weight group of 2,000 grams or less. In the lowest weight group, under 1,000 grams, 63 percent of the births were to mothers with complications. The risk of a previable or early premature baby was greatest for the mother with a complicated pregnancy.

Further study will be necessary to determine the relationship of certain maternal factors to prematurity and survival. Data presently available are insufficient for any definite conclusions to be drawn, and 1954 and then 1955 data will offer additional evidence. However, we are confident that many premature babies that would have died have been saved as a result of this program.

Congenital Disorders— A Problem for Research

brief Events of the past two decades present public health statisticians with an opportunity to help solve the problems of congenital malformation, cerebral palsy, epilepsy, and mental deficiency. These disorders have perplexed both professional and lay thinkers throughout the period of recorded medical history.

The occurrence of malformation at birth has commonly been thought to be the result of some defect in the germ plasm and thus hereditary. Recent clinical observations and experimental demonstration in animals indicate, however, that the hereditary hypothesis is not a sufficient explanation of these disorders, and the concept of environmental determination has evolved. If proved true as a general mechanism, this

concept provides great hope for the prevention of these tragic abnormalities.

There is a pressing need for extensive statistical research to examine a set of hypotheses which are consistent with the concept of environmental determination. Since the public health statistician already has, by his custody of vital records, possession of much of the information required for this task, he stands in a particularly fortunate position to produce useful information.

Hypotheses To Be Tested

The principal questions that need clarification are:

1. Does the presence of infection during pregnancy affect the risk of congenital anomaly? Two further questions apply here: (a) Do all diseases exhibit teratogenic properties or only specified types? (b) Is the time of onset a determinant of the teratogenic potential of a disease?

2. Does the presence of noninfectious disease—toxemia, hypertension, anemia, diabetes—affect the risk of congenital anomaly? (Questions 1-a and 1-b also apply here.)

3. Does the presence of nonspecific insults—vaginal bleeding, accidental injury to mother, dystocia, malpresentation—affect the risk of congenital anomaly? (Question 1-b, when applicable.)

4. Do cultural and socioeconomic variables directly affect the risk of congenital anomaly?

5. Is the increased risk of mongolism and gross malformation in babies born to older mothers independent of cause-effect mechanisms under investigation as outlined in questions 1, 2, and 3?

Information Required

The basic data required to compose a meaningful and useful body of knowledge on congenital disorders may be listed as follows:

1. Frequency of malformation, total and by type, among stillbirths and live births.

2. Time trends in the incidence data, by year and by season.

3. Geographic variation in incidence by type of malformation.

4. Variation in incidence by socioeconomic status, age of parents, and birth order.

5. Presence of infectious disease, by type and by date of onset during pregnancy for each live birth and each stillbirth.

6. Presence of specified complications of pregnancy for each live birth and each stillbirth, with specific reference to anemia, hemorrhage, and toxemia.

7. Presence of specified complications of labor for each live birth and each stillbirth with specific reference to malpresentation, placental abnormality, and dystocia.

8. Presence of symptoms of respiratory difficulty in the infant at birth.

Sources of Data

The public health statistician has an instrument in the form of vital records which is clearly without equal for establishing the characteristics of the study universe. There is little question that birth records can provide useful working information on distribution of infants at risk according to area of residence, season of gestation, weight at birth, age of mother and of father, birth order, and, by deduction, occupation of father, residence of parents, and socioeconomic status.

A number of health departments have attempted to secure significant elements of the prenatal history, including labor, and an indication of the presence or absence of congenital malformation and birth injury by the use of a medical supplement to the birth certificate. Experience with this procedure appears to be fairly uniform. In areas in which hospital births approximate 95 percent of the birth experience, gross understatement of complications of pregnancy and labor has been noted when the findings are compared with data as found in the hospital history.

In my experience, I have found no insurmountable difficulties to securing accurate and complete data on specified segments of the prenatal and labor history of the mother and on the physical state of the newly born infant. The medical supplement to the birth record is a useful instrument for obtaining the birth

By Matthew Tayback, Sc.D., director of the statistical section, Baltimore City Health Department.

complicated by hemorrhage exhibited the highest mortality rate.

Infants born to mothers with complications comprise about 60 percent of the weight group of 2,000 grams or less. In the lowest weight group, under 1,000 grams, 63 percent of the births were to mothers with complications. The risk of a previable or early premature baby was greatest for the mother with a complicated pregnancy.

Further study will be necessary to determine the relationship of certain maternal factors to prematurity and survival. Data presently available are insufficient for any definite conclusions to be drawn, and 1954 and then 1955 data will offer additional evidence. However, we are confident that many premature babies that would have died have been saved as a result of this program.

Congenital Disorders— A Problem for Research

brief Events of the past two decades present public health statisticians with an opportunity to help solve the problems of congenital malformation, cerebral palsy, epilepsy, and mental deficiency. These disorders have perplexed both professional and lay thinkers throughout the period of recorded medical history.

The occurrence of malformation at birth has commonly been thought to be the result of some defect in the germ plasm and thus hereditary. Recent clinical observations and experimental demonstration in animals indicate, however, that the hereditary hypothesis is not a sufficient explanation of these disorders, and the concept of environmental determination has evolved. If proved true as a general mechanism, this

concept provides great hope for the prevention of these tragic abnormalities.

There is a pressing need for extensive statistical research to examine a set of hypotheses which are consistent with the concept of environmental determination. Since the public health statistician already has, by his custody of vital records, possession of much of the information required for this task, he stands in a particularly fortunate position to produce useful information.

Hypotheses To Be Tested

The principal questions that need clarification are:

1. Does the presence of infection during pregnancy affect the risk of congenital anomaly? Two further questions apply here: (a) Do all diseases exhibit teratogenic properties or only specified types? (b) Is the time of onset a determinant of the teratogenic potential of a disease?

2. Does the presence of noninfectious disease—toxemia, hypertension, anemia, diabetes—affect the risk of congenital anomaly? (Questions 1-a and 1-b also apply here.)

3. Does the presence of nonspecific insults—vaginal bleeding, accidental injury to mother, dystocia, malpresentation—affect the risk of congenital anomaly? (Question 1-b, when applicable.)

4. Do cultural and socioeconomic variables directly affect the risk of congenital anomaly?

5. Is the increased risk of mongolism and gross malformation in babies born to older mothers independent of cause-effect mechanisms under investigation as outlined in questions 1, 2, and 3?

Information Required

The basic data required to compose a meaningful and useful body of knowledge on congenital disorders may be listed as follows:

1. Frequency of malformation, total and by type, among stillbirths and live births.

2. Time trends in the incidence data, by year and by season.

3. Geographic variation in incidence by type of malformation.

4. Variation in incidence by socioeconomic status, age of parents, and birth order.

5. Presence of infectious disease, by type and by date of onset during pregnancy for each live birth and each stillbirth.

6. Presence of specified complications of pregnancy for each live birth and each stillbirth, with specific reference to anemia, hemorrhage, and toxemia.

7. Presence of specified complications of labor for each live birth and each stillbirth with specific reference to malpresentation, placental abnormality, and dystocia.

8. Presence of symptoms of respiratory difficulty in the infant at birth.

Sources of Data

The public health statistician has an instrument in the form of vital records which is clearly without equal for establishing the characteristics of the study universe. There is little question that birth records can provide useful working information on distribution of infants at risk according to area of residence, season of gestation, weight at birth, age of mother and of father, birth order, and, by deduction, occupation of father, residence of parents, and socioeconomic status.

A number of health departments have attempted to secure significant elements of the prenatal history, including labor, and an indication of the presence or absence of congenital malformation and birth injury by the use of a medical supplement to the birth certificate. Experience with this procedure appears to be fairly uniform. In areas in which hospital births approximate 95 percent of the birth experience, gross understatement of complications of pregnancy and labor has been noted when the findings are compared with data as found in the hospital history.

In my experience, I have found no insurmountable difficulties to securing accurate and complete data on specified segments of the prenatal and labor history of the mother and on the physical state of the newly born infant. The medical supplement to the birth record is a useful instrument for obtaining the birth

By Matthew Tayback, Sc.D., director of the statistical section, Baltimore City Health Department.

weight and information on operative procedures and complications of labor, but recourse to additional sources is necessary for a more complete measurement of several of the variables to be considered. For example, malformations often are not discovered until after the birth record is filed. When these conditions result in death, they will be noted on the death record, which can be matched with the appropriate birth record. Also, the public health nurse's visit to the home of the infant a few weeks after birth can be made the occasion of an examination for malformation and a report thereof. Another source is the program for crippled children.

The recorded birth universe is also an excellent source for the selection of a control population. In a study of the relationship of prenatal and parnatal factors and the development of epilepsy, for example, Lilienfeld and Pasamanik secured their case population from the available clinic registers and known institutionalized patients. For each case, they selected as a control the next infant in the birth register born in the same institution and matched for race and maternal age. They abstracted the hospital records for both series for certain variables of interest and compared the two groups.

These two methods—the use of the medical supplement to the birth record and the matched control hospital record survey—for obtaining data on factors associated with congenital disorders both involve to some extent a retroactive type of investigation. Essentially, at birth or following birth, an attempt is made to record the prenatal history of the infant or child. There are two serious limitations to this approach. If one is concerned with a known case of malformation, there is some tendency to search in the prenatal record or to query the mother about prenatal events with more care than in a case where no malformation is present, thus producing a bias that makes it impossible to construct any useful inferences. The second difficulty arises out of the fact that the records may not uniformly contain the detail required when we set about to an-

swer questions based on past experience.

A Course of Action

Assuming that research in congenitally determined disorders suggests itself as worthy of statistical research by a health department, what is a practical course of action?

First, the birth record, including the fetal death record, should be used to describe the population at risk, the distribution characteristics of prematurity, and, to the extent that local conditions permit, the incidence of complications of pregnancy and labor. To obtain uniform coverage of prenatal history, summary sheets for inclusion in the hospital record can be provided.

Second, the birth record plus the fetal death record, the death record, and data on malformations from public health nurses, well baby clinics, and crippled children services should be used as a basis for estimating the incidence of congenital malformations and some of their distribution characteristics.

There are, no doubt, areas where the procedures given above will require years of nurture before data of value can be produced. It may be that, as a universal system is being developed, it would be desirable to construct a study area within a given jurisdiction consisting of the prenatal clinics administered by the local health departments, the teaching hospitals, and such other large obstetrical services willing and capable of participating in longitudinal studies. Each birth within the study area would be reported by the usual live birth certificate or fetal death record supplemented by a record of the prenatal life, the labor history, and a statement based upon an examination of the newborn for evidence of malformation. The public health statistical unit should be prepared to provide consultation on the study design and assistance in collation and interpretation of data.

At present, the most practical method for probing into the prenatal determinants of cerebral palsy, epilepsy, and mental deficiency remains the retroactive study, for these conditions are rarely apparent

at birth. But this type of study would nevertheless benefit from the proposed universal collection scheme. The population as a whole would be described and known. The cases under study could be matched back to the appropriate birth record, and their characteristics thereby established.

Integrated Rehabilitation Of Cleft Palate Patients

brief Because of the variety of problems presented by the person with a cleft palate, no one specialty can attempt to deal with them all. A cleft palate is not just a "hole in the head" to be closed up in any fashion, or just a speech defect, or just a malocclusion. All of these conditions, along with the emotional and intellectual aspects, are related and interdependent. Hence, the team approach is gaining wide acceptance as the most productive way of rehabilitating these patients.

The essential services in rehabilitating the cleft palate patient are pediatrics, surgery, dentistry, orthodontia, prosthodontia, speech therapy, otolaryngology, psychology, and social service. Other services are added as the need arises. Each member of the team has a particular responsibility, but all members must work together for maximum effectiveness.

Pediatrics, Surgery

The pediatrician is in a position to guide the parents as soon as the baby is born. The manner in which he handles their attitudes and reactions toward the condition is all-important in the later adjustment of the parents to the child and, consequently, in the adjustment of the child himself to the handicap.

By Jeanette Laguaite, Ph.D., assistant professor of speech pathology, Tulane University School of Medicine.

The pediatrician can steer the parents' thinking toward the positive aspects of what can be done, rather than letting them dwell on the negative questions of what has not been done. He can reassure them that the baby can be provided with a cosmetically normal facial structure and with adequate oral structures for speech and nutrition.

It is the responsibility of the pediatrician, therefore, to acquaint the parents with a cleft palate team or with whatever agencies or resources are available in the community for cleft palate rehabilitation.

There is not much controversy concerning the surgical closure of the cleft lip. This procedure is usually carried out as soon as the baby is judged strong enough, usually about the third or fourth month.

Surgery on the palate, however, is another question, one that can best be answered through the team approach. The traditional treatment of cleft palate was by surgery. However, because surgery has so often been unsuccessful, many workers have felt that a reevaluation of surgical procedures, and especially of the timing of surgery, should be undertaken.

With the help of the orthodontist, prosthodontist, and speech therapist, the surgeon can better decide how and when to operate. The following criteria are now being used to judge whether or not a palate should be closed surgically and, if so, at what age:

1. Adequacy and vitality of tissue.
2. Spatial configuration of anatomic segments of the cleft, that is, width and shape of the cleft.
3. The relationship of the palate to contiguous anatomic structure in the pharynx.

Dentistry

Good general dental care is even more important for the cleft palate patient than for the average person. The successful use of a prosthetic device often depends upon the amount of retention which can be provided. Teeth should be cared for so that they do not become carious nor the gums diseased.

The influence of the deciduous teeth on the eruption of the permanent teeth and the consequent development of facial structures cannot be overemphasized. There is a direct relationship between the size and shape of the dental arch and the health of the baby teeth. Good habits of oral hygiene are a necessity for the cleft palate patient and must be instilled early and followed faithfully.

Through orthodontia, it is possible to restore teeth to their proper positions and to maintain them in their correct relationships. The orthodontist must have a thorough knowledge of growth factors and must know when to use appliances and what types to use to achieve the maximal results in alignment of structures. He aids the surgeon or prosthodontist by retaining the parts in the desired position or by repositioning structures so that they can work more effectively.

Prosthesis and speech appliances were formerly viewed as a last resort, after surgical failure. Subsequently, some workers developed the philosophy that prosthesis was the method of choice and that surgery should never be used.

It is now generally accepted that surgery and prosthesis offer complementary procedures for the rehabilitation of the cleft palate patient. When tissue is inadequate and a poor surgical result is almost a certainty, an appliance may be indicated from the beginning. Sometimes the surgeon can repair the hard palate but is unable to construct a functional soft palate. Then a speech appliance can be used to improve articulation. Young children may be fitted with a training appliance until they have reached the optimal age for surgery.

Speech Therapy, Otolaryngology

Among the several duties of the speech therapist, the most obvious one is the evaluation of the speech. In some patients, defective speech is due to causes other than the cleft, and the therapist must be able to differentiate these cases.

The therapist then must evaluate the structures in the light of the speech. Is the velo-pharyngeal clo-

sure adequate? Are there barriers to good tongue movement, such as orthodontic appliances? All these points must be assessed so that the advisability of further surgery, further orthodontia, or other procedures may be decided upon.

With a child who has not yet begun to talk, the speech therapist assumes the role of counselor to the parents. Ways in which to foster normal speech development and behavior to be avoided are discussed. As the child begins to talk, the parents are given specific suggestions for working with him at home until formal speech therapy is indicated.

Children with cleft palates are more susceptible to respiratory infections and more often have ear infections and accompanying hearing loss than normal children. They need careful periodic checkups to reduce the incidence of middle ear pathology.

Since much middle ear involvement is caused by blockage of the eustachian tube with hypertrophied lymphoid tissue, the otolaryngologist is faced with a problem in advising tonsillectomy and adenoidectomy. Often, the velo-pharyngeal closure which provides adequate speech is achieved because the palate rests against a large pad of adenoid tissue on the back wall of the pharynx. Removal of this adenoid pad may cause serious consequences speechwise. The otolaryngologist must decide whether an operation is indicated, how much tissue to remove, and the possible consequences to speech.

Social Service, Psychology

The social worker serves as a liaison between the team and the patient or his family. He interprets to the patient the decisions as to type of treatment, steps in the program, and the like. Also, he can help the team to plan by informing them of the attitudes and feelings of the family and the ability of the patient to cooperate and carry out recommended procedures.

In a total rehabilitation program, the mental and emotional factors are of vital importance. It is necessary to know the capacities of the patient so that a realistic policy can be pursued. Sometimes a patient, because

of intellectual capacity or economic, social, or emotional influences, is incapable of sufficient cooperation to make a prosthetic device practical. Therefore, surgery may be a better choice for him, although it is not the better one structurally.

The psychologist can be of value not only in testing, but in counseling and guiding both the patient and his family. A realistic, objective attitude to the handicap, an acceptance of the limitations of therapy, and a healthy emotional atmosphere can be as helpful as good surgery or a perfect appliance.

Excess Water in Milk— Georgia's Experience

brief A program for the detection and control of excess water in milk through the systematic use of the refractometer and cryoscope in Georgia has resulted in a marked decrease in the number of samples containing excess water. During the first year of the program, 1950, over 32 percent of the 2,623 milk samples examined showed excess water as compared to only 3.3 percent of the 16,176 samples examined during 1954. The results suggest that other States might find more water in their milk supplies if greater emphasis were given to this important examination.

Important in the success of the program was the excellent cooperation between State and local health department personnel in their work with milk plant operators and dairy farmers. Authority for milk control is not vested in the Georgia Department

of Public Health. This department acts only in an advisory capacity to local health departments. The local departments have adequate authority to enforce regulations adopted by their boards of health. However, it is to the Georgia Department of Public Health that local health departments turn for assistance, advice, and guidance on milk sanitation, and for laboratory services.

The State laboratories first offered laboratory services for the examination of milk and dairy products during the latter part of 1948. From the beginning, a sufficient number of low lactometer readings were obtained to indicate the need for a thorough investigation of excess water in milk. Consequently, when the central laboratory milk unit began operating in April 1950, the detection of excess water was emphasized. The findings indicated that either adulteration or gross carelessness, or both, was a common practice.

In July 1950, the central laboratory instituted the cryoscopic method of determining excess water in milk as a routine laboratory procedure. The results obtained aroused widespread interest throughout the State and accelerated the demand for this service.

Methods

At the beginning of the program, the equipment and procedure outlined in Standard Methods for the Examination of Dairy Products was closely followed. This involved the use of the Hortvet cryoscope or its equivalent. It soon became apparent that the freezing of all samples with the cryoscope would be too time consuming for routine application. The other official procedures outlined were then investigated. From these, a modified sour serum method was developed for screening all samples for possible adulteration with water.

A Bausch and Lomb juice refractometer was selected as the instrument for this screening job. With it, the percentage of dissolved serum solids could be read after filtering a small amount of milk which had been rapidly soured by adding 25 percent acetic acid and subsequently heating

in a 70° C. water bath to speed the separation of milk curd and serum.

In 1952, Vandiviere, Brooks, and Sunkes reported a comparison of results obtained in a parallel study of 2,898 milk samples examined with both cryoscope and refractometer. This data indicated that a screening point of 7.55 percent dissolved serum solids, or greater, by the Bausch and Lomb refractometer reading, could be used to eliminate a large number of samples from cryoscopic examination.

It was then policy to report excess water in all samples in which the cryoscope indicated 3 percent or more excess water. This tolerance of 3 percent is allowed in the official procedures. Later, the policy was altered to allow for an operational error in addition to the 3 percent allowed for variation in the freezing point of normal milk.

Data on 7,115 milk samples examined during November 1951 through December 1952 revealed a definite break in the percentage of positive samples observed to lie between the refractometer readings of 7.40 and 7.35. Of the 1,628 samples with refractometer readings of 7.40 or higher, only 71, 0.9 percent of all samples, showed reportable excess water of 5 percent or greater when examined on the cryoscope, and only 23 had greater than 6 percent. Hence, most of these 71 samples were borderline cases considered to be of little significance.

The screening point for milk to be reported as "free of excess water" was set at 7.40. All samples showing a lower percentage of dissolved serum solids were then subjected to cryoscopic examination. Excess water is reported only when the cryoscope examination shows 5 percent or more present and is reported to the nearest 0.5 percent.

Evaluation Control

From the beginning, a monthly evaluation of the procedure has been maintained. The evaluation samples involve the use of a herd sample milked under the surveillance of a health department official. Milking machines and other containers are inspected to see that no excess

By G. T. Knowles, Jr., M.A., J. R. Culp, B.S., and E. J. Sunkes, Dr.P.H., chief of the milk laboratory, chief milk sanitarian, and director of laboratory services, respectively, Georgia Department of Public Health.

water gains entrance to the milk. Known amounts of water are then added to portions of this milk and samples in iced cases are shipped to reach the regional laboratory on the following day.

The evaluation samples are examined by all cryoscope operators routinely making examinations. The central laboratory, which acts as a control, performs its tests on the same day as the regional laboratories. By means of this evaluation program, the work done in the central laboratory and three regional laboratories is closely coordinated, and any need for restandardization of freezing-point thermometers is promptly indicated.

Education

Much of the success of this program can be attributed to the educational approach of the sanitarians in dealing with those in whose milk excess water has been found. Only in a few instances, where there was no response or indication of cooperation in keeping excess water out of the milk, have local health departments had to revoke the permits of offending dairymen.

Whenever excess water is found in milk, the laboratory report is accompanied with a slip of paper on which it is pointed out that "it is believed that in the majority of cases an excess of water is due to the lack of knowledge of the condition rather than willful adulteration on the part of the dairymen." Then, the following list gives possible causes of excess water in milk:

1. Utensils not thoroughly drained before use.
2. Leaking cooling boards which allow the cooling water to enter the milk when it is flowing over the board.
3. The use of leaking milk cans which, submerged in water, allow the water to enter the milk.
4. Haste to cool milk by placing ice directly in the milk.
5. The addition of water to milk by employees in an effort to impress the owner of the dairy with their ability to maintain or increase the volume of milk production.

Results

During the 5 years of the program, the incidence of watered milk has sharply dropped. During 1950, the first year of the program, 2,623 milk samples were examined with the cryoscope. Of these, 846, or 32.3 percent, contained excess water. However, since many of these examinations were made on repeat samples in which excess water was suspected, this did not mean that 32 percent of the milk being sold on the Georgia market was watered.

During 1951, 9,074 samples were screened with the Bausch and Lomb juice refractometer; 3,823 of these, plus 831 others, were examined with the cryoscope. Of the 9,905 samples submitted to screening or direct cryoscopic examination, 1,264, 12.8 percent, were found to contain 3 percent or greater excess water. Thus, in the second year of the program, the positive findings were reduced by almost two-thirds.

In 1952, only 9.0 percent of the samples examined contained excess water. Part of this decrease was due to the change in policy from reporting 3 and 4 percent findings. However, in 1953 the positive findings were further reduced to 4.7 percent. The extent of watering appears to have leveled off now, for examinations on 16,370 samples in 1954 yielded only 3.3 percent positive for excess water.

The Anthrax Epizootic In Louisiana in 1954

In 1954, Louisiana experienced its first significant anthrax epizootic since 1949. Outbreaks of the disease have been recognized in limited areas of the State each year since about 1880, but epizootics have occurred at infre-

By H. B. Elliott, D.V.M., director of laboratories, Louisiana Livestock Sanitary Board, Baton Rouge.

quent intervals. Until the 1954 epizootic, anthrax appeared to occur in 30-year cycles. The first was recognized about 1890, the second in 1927, in the delta section; and the third in 1949, in the northwestern corner of the State.

Anthrax vaccine was used in each of the epizootics. Still in the experimental stage in 1890, the vaccine was adjudged to have had some bearing on the epizootiology of the disease, but when the supply was exhausted, the infection continued for only a short time. It appeared to burn itself out in northern Louisiana, several miles north of the last vaccinated areas. After the 1927 epizootic, when considerable research on the vaccine was conducted, several types became established on the market. Two types, the subcutaneous spore and the intradermal spore, have become traditional tools in increasing herd immunity to anthrax.

The 1954 epizootic in Louisiana apparently started in the relatively inaccessible delta region during June. The outbreak was recognized as a potential epizootic by July 18 and was confirmed as such by September 7. The last case was proved in the laboratory on October 20. Subcutis spore vaccine (No. 4) had been used extensively, but apparently it was not effective as administered.

Investigation of the epizootic was hampered by the type of terrain in the delta region and to some extent by the nature and customs of its people. The season, the temperature-humidity ratio, the sucking insect population, and the spread of the disease in a northerly direction appeared to be similar in all the epidemics that have occurred in the State so far.

The anthrax bacillus was isolated from a horsefly removed from a dying horse in the Venice area and from a fly taken from a febrile cow in the New Orleans area. Horsefly cultures were especially pathogenic for mice and displayed heavy capsular formation either directly from mice or when inoculated from first and second subcultures. However, no unusual cultural characteristics were observed.

Orientation of Dentists In Administration

brief In mid-20th century, the dentist is a highly skilled technician in an intensively specialized health practice. Throughout his 4 years of study, the pressure is on to develop, simultaneously, scientific background and judgment and the manual skills of dentistry. In recent years patient education, regimens of treatment, and certain techniques of prevention have occupied an increasing but inadequate segment of the dental school curriculum. Yet in practice the dentist must meet community responsibilities as well as responsibilities for individuals. As a professional health practitioner, he must accept this role cast for him by the public.

To successfully accomplish these things within 4 years is a credit not only to the students but also to the pedagogical abilities of the school faculties. To be able to enter the competent practice of a profession upon graduation from school and licensure is evidence of the intensiveness and effectiveness of the course.

More important, however, to this discussion is the fact that such an intensive experience in health science, in methodology, and in technique makes for a high degree of specialization focused on the individual and his pathology.

Orientation

Like the physician, particularly one trained in a medical specialty, the dentist in public health has the double problem of unlearning the attitudes of individual care and developing the philosophy of the community as the patient. Yet, both the physician and the dentist undertook their course of study because of a real interest in the practice of the chosen profession.

The role of the dentist in public health administration must, there-

fore, be predicated on adequate public health orientation or training through which he has had opportunity to redirect his interests and philosophy to a different type of patient—the community. No longer should the correction of defects or disappearance of pathology in an individual be the objective, but rather the dental health of a group of people for all of their lives becomes his aim.

The second prerequisite for the dentist in public health administration, growing out of this change, must be the concept of family and communitywide service. Not only the potentiality of resources in a community to solve its own problems but the requirement of professional teamwork to exploit this strength must become a way of life for each public health worker. How the specialized professional skills of doctors, nurses, engineers, dentists, sanitarians, clerks, and so forth are integrated and coordinated determines to a great extent the effectiveness of the public health team. And effectiveness cannot be achieved without full realization of these facts by each member of the team.

The physician is ordinarily the leader of the public health team, and, in fact, by law in most States, the responsibility for local and State health departments must lie upon a physician. To meet this responsibility and to serve adequately as leader of the organization, he must become a generalist in many other public health sciences. His basic profession becomes only a part of the spectrum of skills which he and the community must use to create a state approaching complete well-being. The less provincial he remains with respect to medicine, the more effective he is as a public health administrator. And this holds true for one who is to assist in administration.

For any professional person in public health, therefore, a basic decision must always be made, usually early in his experience—do I wish to be a public health or a program administrator? For the former the entire field becomes the generalist's bailiwick. For the latter, the program becomes the specialist's area in which his profession may remain his

primary interest, though it must still be seen in proper relation to the other fields of public health.

Public Health Duties

The dentist may effectively be an administrator of the dental public health program. In this responsibility he must solve such problems as competence of professional individual care in the community; availability of care to all members of the community; development of the attitudes and philosophy of health maintenance and promotion, as well as correction; and the application of preventive measures, such as nutrition, topical fluoride, and fluoridation of public water supplies. He should be delegated the authority to represent the health department in dental matters; to expedite dental health education activities, and to serve as liaison with dentists and their organizations. He must be able to evaluate dental programs, promote professional growth in the dentists, and insure the application of community resources to all of the community needs. And in doing these things he must have a sympathetic appreciation of the entire public health program, supporting it even as he works within his own field.

A second possibility for the trained and experienced dentist is in general public health administration. The educational background in the health sciences, once the transition to public health philosophy has been attained, should make the dentist invaluable in public health administration provided he can be comfortable in this relation to the health officer. Medical people need training and experience in the matter of delegation and sharing responsibility but can make this transition. The dentist, like a physician, must become a generalist, leaving behind the concentrated interest in one profession for the overall team approach. Yet, like the physician with the minimum of clinical medicine as a taproot to his profession, so would the dental administrator wish to keep contact with his parent profession.

In either instance, the dental public health administrator, who has successfully made the transition

By John H. Venable, M.D., M.P.H.,
director, division of training, Georgia
Department of Public Health.

from individual to community for a patient, and to health maintenance and promotion and prevention of disease as an objective rather than the correction or repair of disease, will derive deep satisfaction from his practice.

And satisfaction in the job he has done and the consciousness of important service rendered leave little for a professional to want.

Inter-American Health Program Since 1942

brief Competent observers agree that there has been startling and thrilling improvement in the health of people living south of the Rio Grande. That this is so, they also agree, is due to the aggressive activity of public health workers in the countries of Latin America, living and working in a land with a future.

Real help in the form of stimulation and technical assistance has come from foundations such as Rockefeller and Kellogg and more recently from international and national official agencies such as the Pan American Sanitary Bureau and the International Cooperation Administration—the new agency assuming the functions of the Foreign Operations Administration.

Since 1942 the United States Government, through the Institute of Inter-American Affairs, has been offering technical assistance to the ministries of health of Latin America. The IIAA, as it has become well known, now continues its

work as part of the International Cooperation Administration.

As of today there are cooperative bilateral health programs with 18 sovereign republics in Latin America and with the 3 semi-independent governments of Surinam, British Guiana, and Jamaica. This work is carried on by 135 United States professional health workers and more than 2,000 professional workers from the Latin American countries. An additional 5,000 subprofessional and clerical workers are employed in the operational phases of the programs.

The work is financed by an annual appropriation on the part of the United States of approximately \$5 million. The United States contribution is more than matched by the Latin American governments. Last year they appropriated more than \$12 million in local currencies.

It is unnecessary to describe in detail all the activities that have taken place since 1942. Programs of basic sanitation, community health promotion, and professional education have received priority by common consent.

Within the past 18 months some important changes have been made in the orientation of some of the cooperative programs with the separate countries. Characterized in the early years by operational projects, often turned over completely to United States technicians for professional management, more and more the operational phases are properly being assumed by the Latin American ministries of health. Technical advice and consultation continue to be offered by our technicians working directly with the ministries. This encouraging trend is receiving the active support of the International Cooperation Administration.

During this same period, in addition to continuing work in all of the original fields of health activity, an effort has been made to expand into new fields in order to keep up with the needs of a rapidly developing region. Work has been started in health education, nutrition, industrial hygiene, and medical education. Assistance has been given in organizing a model State health department in Brazil, the largest and one

of the more decentralized countries of Latin America.

A pleasant aspect of the inter-American health picture is the maturing relationship among the several agencies, public and private, working in this field of international health. The International Cooperation Administration is participating actively in efforts to improve this coordination. Joint planning with the Pan American Sanitary Bureau in medical education and mass disease control is part of this effort. The Pan American Sanitary Bureau has established, in Washington, D. C., a center for the exchange of information on medical education to which all interested agencies make contributions. By such formal means, and by means of frequent friendly informal exchange of ideas and information, a fine working relationship has developed.

This bright picture I have painted is not intended to convey the impression that all, or even most, of the problems are solved. Latin America still faces towering problems in public health, in many areas with grossly inadequate resources. The region supports only 1 physician per 3,000 population and 1 nurse per 15,000. Training facilities for both physicians and nurses need improvement. There are still mass disease control problems in such fields as malaria, diarrheal disease, and tuberculosis. Much remains to be done, but movement is occurring, and in the right direction.

Although the ministries of health have good leadership at the top, there are deficiencies in depth. Many more trained workers in the public health professions are needed at the local level. Considerable work still needs to be done in extending public health services to this level.

In moving to meet its needs, Latin America has available some fine resources. They are mostly governmental, however, since the voluntary health organization, as we know it in the United States, is not well represented in Latin America. For this reason a major effort of the cooperative health program is encouragement of voluntary health agencies to complement the work of official agencies.

By Charles L. Williams, Jr., M.D., M.P.H., chief, Latin America Branch, Public Health Division, International Cooperation Administration (formerly Foreign Operations Administration), Washington, D. C. Dr. Williams also is co-chairman of the Inter-American Health Problems Committee of the Southern Branch.

"History is simply the biography of the mind of man; and our interest in history, and its educational value to us, is directly proportionate to the completeness of our study of the individuals through whom this mind has been manifested."

—OSLER

Contributions by Medical Undergraduates to the Science of Preventive Medicine

By WILLIAM C. GIBSON, M.D., D.Phil.

THE AVERAGE student today is likely to greet with a mixture of amusement and pity any suggestion by his teachers that he might make a lasting contribution to medical science. Students have wallowed through mountainous academic seas for so long in convoy fashion—the speed of the fleet being set by the speed of the slowest ship—that their imagination has been blunted, if not embalmed. It is in the hope of resurrecting some of the keenness of students' first bright days in medical school that the following essay on student contributors of the past is presented. The inquiring, restless mind of the uninhibited undergraduate is still our greatest asset in medicine and the greatest deterrent to smugness in research.

Educators and administrators also would do well to review in retrospect the lives of past contributors in the field of preventive medicine, for in such a study there may be found the key to further recruiting and development of exceptional personnel. I mention educators because

the critical ingredient—gray matter—passes through their hands. Their attitude, as we shall see throughout this paper, can be absolutely determinative. They can foster discovery, or they can impede it. I mention administrators, for they face a dilemma—they have to make existing methods work while insuring that they are not brushing aside as a "nonconformist" some potential discoverer.

Smallpox

Appropriately, this review is opened with a reference to Edward Jenner, who combined early vision, fortitude in the face of powerful critics, and a life-long delight in clinical investigation. Jenner found himself, in 1768 at the age of 19, a quaking medical apprentice noting down a patient's history, possibly one of his first. The patient was a milkmaid who, on being questioned about any possible smallpox in her history, replied, "I cannot take that disease for I have had the cowpox." Thus, the fledgling Jenner encountered early in his career the common belief among the country people of Gloucestershire that there was a harmless preventive of smallpox. Perhaps his newness to the study of medicine caused him to listen

Dr. Gibson is Kinsmen professor of neurological research at the University of British Columbia, Vancouver, Canada.

long enough to this patient's replies to gain something of value. His countryman William Withering was to stumble on the virtues of digitalis in a similar rural setting in Shropshire.

Jenner became, as have many since, a student unpopular with his teachers, for he kept bringing up his fantastic theory, as from the back pasture. However, he lived in John Hunter's house while studying in London, and his patron greatly encouraged the thoughtful undergraduate. Hunter's philosophy was couched in his immortal advice to Jenner, "But why think, why not try the experiment."

Jenner graduated at the age of 22, and, despite an offer to accompany Captain Cook on a world-circling expedition, he returned to his native Gloucester to practice and to build up a set of records on simple, clear observations. So cautious was Jenner that he vaccinated no one for 30 years after his undergraduate conception of vaccination. Then came Sarah Nelves—the source—and James Phipps—the subject. And Jenner's campaign, for he was a campaigner, was launched.

John Hunter had been dead 5 years by the time Jenner was ready to publish the results of his inquiry. Jenner turned to the Royal Society in 1798 for an audience and was rebuffed with the advice that he "should be cautious and prudent . . . and ought not to risk his reputation by presenting to the learned body anything which appeared so much at variance with established knowledge, and withal so incredible."

The same advice had been given Franklin by the same body in 1752 when he reported on his derivation of electricity from the clouds. The type of advice offered Jenner, who happens to have been a keen balloonist, was 140 years later to be tendered another aeronaut Frank Whittle, the jet propulsion pioneer, on the grounds that he was still a Cambridge undergraduate and his theory was "incredible."

Tuberculosis

In another area—that of tuberculosis—one is struck by the student contributions of the impecunious, observant, and industrious René Theophile Hyacinthe Laennec. Before graduation in Paris in June 1804, he had written papers on mitral valvular disease and on "in-

flammation of the peritoneum" under the stern and powerful Dupuytren. He had discovered the subdeltoid bursa and had also shown that hydatid cysts were due to parasites. In March of 1804, he gave an address on what he called "pulmonary tuberculosis," in which he showed "phthisis" to be tuberculosis of the lungs.

Laennec learned of percussion from Jean-Nicolas Corvisart, who brought this clinical application of an innkeeper's barrel-tapping technique into use 47 years after Leopold Auenbrugger had first described it. Laennec's great book on auscultation appeared in 1819, and by 1825 we find William Stokes, as an Edinburgh medical undergraduate, singing the praises of the method in his book, the first work in English on auscultation, entitled "An Introduction to the Use of the Stethoscope with its Application to the Diagnosis in Disease of the Thoracic Viscera; Including the Pathology of Various Affections."

An unsung American contributor in the history of tuberculosis is James Jackson, Jr., of whom Osler wrote: "Jackson's name . . . will always be associated with the studies on emphysema, and he is the discoverer of the prolonged expiration in pulmonary tuberculosis." As an undergraduate Jackson studied with the great French clinician and pathologist Louis. In 1832 he sent home to New England an article on cholera based upon his experience with Louis in an epidemic in France. While preparing to write his M.D. examinations at Harvard, he was stricken with dysentery and died at the age of 24. Louis' letters to Jackson's father asking if the son could not spend another year in his clinic in Paris are very touching.

Another American pioneer in tuberculosis was James Blake (1815-93). In 1860 he was recommending and practicing the open-air rest treatment in a sanatorium on the summit of Monte Sol in California to the east of Mount St. Helena where Robert Louis Stevenson later lived. Blake's student contribution had been the arranging of the elements into a periodic table on the basis of their physiological effects. This was done when Blake was an undergraduate in London, aged 23. Mendelejeff, usually credited with the periodic table, was 4 years old at the time of Blake's publication. Blake's student discovery was made under the benev-

olent eye of William Sharpey, as were those by Lister and Huxley.

Puerperal Fever

Ignaz Philipp Semmelweis and Oliver Wendell Holmes had interesting student preparations for their eventual encounter with puerperal fever. As an undergraduate Semmelweis was experimenting on rabbits with tartar emetic, at that time a preferred "remedy" for

man must take physic because he is sick. . . . My aim has been to qualify myself . . . not for a mere scholar, for a follower after other men's opinions, for a dependent on their authority—but for the character of a man who has seen and therefore knows, who has thought and therefore has arrived at his own conclusions." Holmes, the Bostonian, a nationally known poet at 21, little suspected that a fiercely independent Hungarian practicing in Vienna unknowingly would be his ally. Holmes' pen was mightier than the swords of his obstetrical compatriots. Semmelweis maintained his doctrine against frightful persecution because he knew he was right and he had the support of his teachers Rokitansky, Skoda, and Hebra.

Cellular Pathology

One of the great concepts introduced in the last century was that of "cellular pathology." Rudolf Virchow as an undergraduate in Berlin decided to test the prevailing theory that inflammation was vascular in origin by studying it in the cornea, a nonvascular tissue. His graduation thesis, written in 1843, was entitled, "De rheumate praesertim corneae." We believe from a letter of 1841 written to his father in the country, asking for more rabbits, that he had been engaged on it at least 2 years prior to graduation. Virchow's student work on the cornea determined his later opinions on the cellular basis of inflammation and doubtlessly influenced his outlook on the fundamentals of pathology.

The distinguished physician-educators Sir James Paget and Sir William Osler were student investigators, strangely enough, in the same field. As an undergraduate at St. Bartholomew's Hospital Medical School, London, Paget in 1835 discovered the cysts of *Trichinella spiralis* in the muscles of the cadaver he was dissecting. In 1870, William Osler, a first-year medical student at the University of Toronto, was removing these trichinae from a cadaver and trying to infect cats, dogs, and rabbits with them. Osler entered medicine with training in the preparation of biological specimens, received at the skilled hands of James Bovell and Father Johnson at their school in Weston, Ontario. On graduation at McGill Medical

"... not to take authority when I can have facts, not to guess when I can know . . ."—Holmes.

pneumonia. Holmes, like Semmelweis, had spent a brief apprenticeship in law—a discipline which was to serve them, and humanity, well in the struggle to which their methodical investigation brought them. Holmes began the study of medicine under James Jackson, Sr., in Boston and continued it in Paris, along with Jackson's son already mentioned. In a letter sent to his home in Boston, he alluded to his student "discoveries": "I have more fully learned at least three principles since I have been in Paris: not to take authority when I can have facts; not to guess when I can know; not to think a

Faculty in 1872 his thesis was accompanied by such excellent histological preparations that he was awarded a special prize. Osler's early bent toward pathology was evident throughout his long clinical career. It remained for an undergraduate at Johns Hopkins Medical School, Thomas R. Brown, to discover in 1898 the eosinophilia seen in trichinosis.

David Gruby, the father of medical mycology and discoverer of the cause of favus, was in 1835 an undergraduate protégé of Carl Rokitansky, the celebrated teacher and pathologist at the University of Vienna. Gruby wrote his first paper on "The Morphology of Pathological Fluids." His study concerned the cell forms in pus from different diseases. The story of the hardships faced and overcome by this remarkable spirit are well-nigh unbelievable. He acquired his early schooling by listening outside a classroom from which he was barred on religious grounds. He was apprenticed to a lens grinder, and as a result he was able to make his own microscope when he entered medical school. Despite the fact that he earned his passage through medicine by tutoring, he nevertheless found time for research under Berres and Rokitansky, the latter permitting him to use his "best microscope" for it. Once again does Rokitansky, the teacher of pathology, enter upon our stage.

Oroya Fever

Daniel Carrion is probably the only medical student in history to have a medical school and several hospitals named after him. Separated as we are by a period of 70 years from his death from Oroya fever, administered to him in the course of his student research project, it is hard for us to realize the impression which his death made on Latin American medical and scientific circles. As early as 1858, a medical student named Tomas Salazar wrote in his graduation thesis, "Historia de las Verrugas," that this disease was waterborne. Since the Conquest it had been regarded as the equal of the "pest," and in the year 1870 alone had taken the lives of 7,000 workmen completing the trans-Andean railroad into Oroya, Peru. Carrion became interested in the problem and during va-

cations sought out cases and plotted them on a map of the area. Only near Oroya was the disease endemic. The clinical picture of high fever, profound weakness, joint pains, anemia, and leukocytosis was well known, but the cause was still a mystery. Some called it acute pernicious anemia, some atypical malaria, while others said it originated from the hot springs. On August 27, 1885, Carrion, against all advice, received an inoculation of blood from a 14-year-old boy suffering from the typical verruga peruana skin eruption. He was going to prove, once for all, the connection between Oroya fever and verruga peruana. After 3 weeks of excellent health he suffered muscular pains and prostration, with severe anemia. The post mortem was an important contribution to an understanding of the disease. The Peruvian student had answered the question of the connection between the two diseases.

Patrick Playfair Laidlaw as a Cambridge undergraduate, at the turn of the century, carried on an important investigation on hemoglobin derivatives in the biochemical laboratory of Sir Frederick Gowland Hopkins. This set the stage for his postgraduate work on histamine with Sir Henry Dale and for his lifelong researches into distemper and influenza. Hopkins must be listed among those who most encouraged young investigators.

William George MacCallum entered Johns Hopkins Medical School in 1894 bearing a gold medal from the University of Toronto for an important contribution on worm parasites. In his final year as a student at Johns Hopkins he reported on his studies of malarial parasites in birds. He supplied the missing link in the life cycle of the parasite, showing the flagellated form to be the sperm cell. Sir Ronald Ross, who had interpreted it as a flagellated spore escaping from a female cell, wrote years later: "I have ever since felt disgraced as a man of science!" MacCallum's later discovery of the role of the islet cells of the pancreas in diabetes became the springboard for Banting's revolutionary work, aided by the youthful Charles Best. In fact, as we shall see, the islet cells had been discovered by a medical student, Paul Langerhans.

that she once had cowpox and therefore could not get smallpox. The Royal Society reprimanded him for this "incredible" paper, "so much at variance with established knowledge."

Chemotherapy

The father of modern chemotherapy, Paul Ehrlich, stated his great side-chain theory as a medical student. Encouraged by one of his teachers, Waldeyer, at Strassburg, Ehrlich began in 1877, by testing the staining qualities of many of the aniline dyes just coming into commercial use in Germany. After transferring to the University of Breslau he had the opportunity of working in the laboratories of Conheim and Heidenhain. While still an undergraduate Ehrlich described, in the *Archives of Microscopic Anatomy*, his experiments on histological staining which brought him to the "idea of a chemical binding of heterogeneous substances to the protoplasm." The rest of Ehrlich's life was spent in developing this great generalization in the fields of immunity, bacteriology, and chemotherapy. The key to Ehrlich's research lay in the aniline dyes, the first of which was synthesized by an 18-year-old English chemistry student William Henry Perkin. Two years later Archibald Scott Couper, as a student in Paris, proposed a valency of four for carbon and showed that it formed long-chain compounds. It took the genius of Ehrlich, a chemist with great stereovisual powers and interest in tissues, to bring together into a fundamental concept all that had gone before.

Public Health

John Shaw Billings has been described as America's greatest contributor to scientific medicine. He was a born inquirer rather than the product of famous teachers. As a student, writing an essay on the surgical treatment of epilepsy, he came to realize the utter lack of any index to the world's medical literature. He lived to remedy this, through the Index Catalogue and its successors in the library of the Surgeon General of the United States Army.

However, our interest in Billings here stems from his campaigns in the fields of sanitation and hospitalization. As an impoverished student at the Medical College of Ohio in Cincinnati from 1858 to 1860, Billings paid his way by serving as caretaker of the dissecting rooms and by "living in" at one of the city's hospitals. This latter appointment caused him to think

more about the organization of hospitals—or possibly lack of it—than did contemporary administrators. He found out where things could "go wrong" in institutions and he developed a keen sense of smell with regard to these matters.

It is little wonder that on his first Army posting in the Civil War Billings excoriated Clifflburne General Hospital in Washington, D. C., as being "in an extremely filthy and dilapidated condition—no drainage whatever, . . . no sinks, no water within half a mile." He was later to describe the United States Army as "the best fed and the worst housed" in the world. His suggestions for reorganizing the marine hospitals and his sanitation reports on Army military posts were blunt and forceful. One of his interests was vital statistics, and in 1880 he suggested to the Government that the data compiled from the census "might be recorded on a single card or slip by punching small holes in it, and that these cards might then be sorted and counted by mechanical means according to any selected group of these perforations."

Billings' stimulating influence was to be felt in his work as director of the laboratory of hygiene at the University of Pennsylvania, as designer of the Johns Hopkins and Peter Bent Brigham Hospitals, and in medical education and libraries. When asked how he accomplished so much he replied: "There is nothing really difficult if you only begin. Some people contemplate a task until it looms so big it seems impossible. But I just begin and it gets done somehow. There would be no coral islands if the first bug sat down and began to wonder how the job was to be done."

Thomas "Phenomenon" Young, that many-sided genius who discovered in his first days at medical school that the lens of the eye varies its shape in accommodation was an early constructor of life expectancy tables and of insurance formulas. His first was published in 1826 as "A Formula for Expressing 'Decrement of Human Life.'" In his theory of color vision—rediscovered years later by Helmholtz—in his accurate measurements of the size of red and white cells of the blood, in the deciphering of the Rosetta stone, in developing the modulus of elasticity, in setting out a phonetic alphabet for all languages, in standardizing the imperial gallon, and in his writings on gaslighting,

"There is nothing really difficult if you only begin. . . . There would be no coral islands if the first bug sat down and began to wonder how the job was to be done."—Billings.

Young made himself one of the most celebrated scientific contributors of all time. If he were alive today we would find him, doubtless, energizing the Food and Agriculture Organization with reports of his observations on the production of better wool and meat through crossbreeding and of increased food production through irrigation, matters which he studied as a medical student. His drive to understand things was inexhaustible and his capabilities truly Newtonian.

Nutrition

The field of nutrition reveres the name of Sir Frederick Gowland Hopkins for his early researches on "accessory food factors" which we now call vitamins. Before graduation in medicine, Hopkins published a paper on the pigments in the wings of the English brimstone butterfly. He found the pigment to be a derivative of uric acid and, in his typical way, immediately improved the method for the determination of uric acid. This method was the key to his succeeding researches on nitrogenous

compounds. As he investigated the effects of artificial diets composed of purified proteins he became aware of "unidentified accessory food factors" and pursued them, with what great success we all know today.

To follow briefly this lead in nutrition one finds the field of carbohydrate metabolism bristling with student contributors. But, it is the disease diabetes which absorbs us as physicians interested in public health problems. Paul Langerhans discovered his famous "islets" in the pancreas 2 years before he graduated in medicine. Virchow had given him encouragement and laboratory space in 1867, and his graduation thesis, completed in 1869, is an historic document. In 31 pages he described his discovery, adding: "There is indeed hardly another organ in which there is such glaring contrast between the brilliant results of physiological research and the complete darkness in the realm of anatomic knowledge."

The deposition of calcium in the teeth and bones of the body was poorly understood until the Swedish medical student, Ivar Sandstrom, in 1877 discovered the parathyroid glands. True, it remained for W. G. MacCallum and others to demonstrate the physiological principles involved, but Sandstrom's investigation as a 25-year-old student at Uppsala was basic to further progress. His paper was returned to him by a German editor as being too long to publish. The fact is that the paper was so thorough that little has been added to the subject since!

At a time when cardiovascular disease is receiving such attention we would do well to review the student work of Jean L. M. Poiseuille. In 1828 he wrote his M. D. thesis in Paris on "Recherches sur la force du coeur aortique" and in it described his revolutionary mercury manometer for registering blood pressure. Using this instrument he was able to show the rise and fall in the recorded blood pressure with each heart beat, and he actually calculated the degree of dilation of the arteries with each systole.

Aviation medicine has had a number of interesting undergraduate devotees. Alphonse Gal, while a medical student in Italy, served in 1872 on a "mother ship" for sponge divers operating off the Turkish coast. He was the first

to describe the itching which goes with "the bends" in deep sea divers. The father of aerial photography, Felix Tournachon, was a medical student. Known as "Nadar," he, like Jenner, was one of the early balloonists. With this reference to the latest specialty we must conclude this account.

Certainly, one thing is clear from this brief review of 2 dozen student contributors of the past: Good seed can be helped greatly by good soil. The determining factor has often been the provision of facilities for a student investigator by a sympathetic teacher. The lesson for us

today would seem to be clear. Summer research scholarships in all fields of medicine and its ancillary sciences are likely to repay us handsomely as educators. Encouragement of original work by undergraduates is in the best tradition, as I have tried to show in this paper, and offers one method of offsetting the homogenizing influence of too many specialty boards. Student curiosity can be depended upon to bring to light new facts of major importance, as it has in the past. The shaping of the conditions under which such students will work and grow is a major challenge to all educated people.

Medical Research Fellowships

The Division of Medical Sciences is accepting applications for National Academy of Sciences-National Research Council postdoctoral research fellowships for 1956-57. The following programs, offered only—except as indicated—to American citizens under 35, are available:

Study in all branches of the biological, chemical, and physical sciences, and of clinical investigation applicable to the study of typical or malignant growth: also, exchange fellowships open to American and British scientists for advanced study in specialized fields pertaining to growth. These awards are sponsored by the American Cancer Society.

Fellowships in the basic medical sciences. These awards, also open to Canadian citizens, are supported by the Rockefeller Foundation.

Study in fields related to tuberculosis, supported by the National Tuberculosis Association. Applicants must be graduates of American schools.

Preparation for radiological research. Appointments to this program, sponsored by the James Picker Foundation, are not limited to citizens of the United States.

The closing date for applications is December 1, 1955. Forms may be obtained from the Fellowship Office, National Academy of Sciences-National Research Council, 2101 Constitution Avenue, NW., Washington 25, D. C.

by 22 American countries signify progress in neighbor nations.*

Report of Health Conditions in the Americas

By GUSTAVO MOLINA, M.D., M.P.H., and
RUTH R. PUFFER, Dr.P.H.

NEED for a numerical statement of facts, with precision and reliability, has been a matter of prime concern to persons interested in coordinated health planning in the Americas. Since establishment of the Pan American Sanitary Bureau in 1902, improvement in collection of statistical data has been one of the important objectives of the organization. Although achievement of this objective has been given impetus by the many requirements of the Pan American Sanitary Code in relation to statistics and reports, only in recent years has it received concentrated effort.

A major goal in fulfillment of the requirements in the Pan American Sanitary Code was

the publication of the Summary of Reports of Member States, 1950-53, which was prepared for the XIV Pan American Sanitary Conference held in October 1954. This document consolidates the statistical data on health conditions for the years 1950 through 1953 that were submitted by each of the 21 member states of the Pan American Sanitary Organization. Included are data on population, vital events, reported cases and control of communicable diseases, personnel and organization of health services, and various aspects of sanitation programs. Since release of the summary, similar reports have been received from Puerto Rico, Canada, and the territories in the Western Hemisphere, which will be incorporated in a revision of the summary. For the following discussion, selected data dealing with population, vital events, communicable diseases, and sanitation from the reports of the member states and Canada are presented. These data provide a basis for appraisal of general health conditions in the Americas.

Population

Nearly all the countries in the Americas conducted a census in or about 1950, and on July 1 of that year the population was estimated to be 326,415,000. Of this population, 216,443,000

Dr. Molina is chief of the division of public health of the Pan American Sanitary Bureau, and Dr. Puffer is chief of the division's epidemiology and statistics section. Assistance in presenting the vital statistics data in this paper was provided by Jean Peabody, a member of the staff of the epidemiology and statistics section. The paper was read at the 23d annual meeting of the Southern Branch of the American Public Health Association in New Orleans, May 10-13, 1955. It is scheduled to be printed in Spanish in the October 1955 issue of the Boletín de la Oficina Sanitaria Pan-Americana.

Table 1. Percentage of population in 4 age groups for 3 regions of the Americas according to recent census in 18 countries

Region	All stated ages	Under 15 years	15-34 years	35-54 years	55 years or more
Northern America----	100.0	27.2	30.5	25.5	16.8
Middle America-----	100.0	41.8	32.8	17.9	7.5
South America-----	100.0	40.0	34.3	18.4	7.3

lived in North America and 109,972,000 in South America. In Alaska, Canada, Greenland, St. Pierre and Miquelon, and the United States, which is called Northern America, were 165,110,000 people, and in the remainder of North America (including the islands of the Caribbean), which is designated Middle America, were 51,333,000.

Division of the population into age groups, as presented in table 1, demonstrates a sharp difference between Middle and South America and Northern America. In Middle and South

Table 2. Birth and death rates per 1,000 population and infant death rates per 1,000 live births in 20 American countries, 1952

Country	Birth rate	Death rate	Infant death rate

Figure 1. Live births per 1,000 population in 20 American countries, 1952.

¹ Federal District and State capitals, except city of São Paulo

America the proportion of the population under 15 years of age is substantially higher than the proportion in Northern America, 42 percent and 40 percent as compared to 27 percent. The proportion in the older age groups is considerably lower in Middle and South America, although the proportion in the age group 15-34 years is about the same in all three regions. These age distributions indicate that in Middle and South America greater priority at present should be given to health programs directed to problems of infancy, childhood, and young adult life.

Vital Statistics

Practices in registering vital events, definitions of terms, and tabulation procedures vary considerably from country to country. Although the reports on health conditions were not concerned with the technical details of the methods of collecting and analyzing data, certain explanations should be made.

The data provided by Haiti were considered too incomplete to be used because this country does not have a vital events registration system. Cuba did not provide any birth or death data. In Brazil, data were available only for the Federal District and capitals of States, except the city of São Paulo. In some of the countries, notably Paraguay, the low rates indicate incomplete registration of births and deaths.

The birth, death, and infant death rates reported by 20 countries for 1952 are given in table 2, and these rates are shown by rank order in figures 1, 2, and 3. Notwithstanding the difficulties involved in providing complete information for the hemisphere, the statistics presently available from birth and death certificates do give valuable clues to the health problems in the various countries. The need for improving vital statistics systems becomes increasingly evident as the data are used.

Very high birth rates were noted in many of the countries. In fact, in half of them the rates exceeded 40 per 1,000 population and in 3 countries of Central America they were

Figure 2. Deaths per 1,000 population in 20 American countries, 1952.

¹ Federal District and State capitals, except city of São Paulo

Figure 3. Infant deaths per 1,000 live births in 20 American countries, 1952.

¹ Federal District and State capitals, except city of São Paulo

in excess of 50 per 1,000 population. Such high birth rates indicate that maternal and child health programs are essential for proper care in the prenatal and postnatal periods and in childhood.

Likewise, high death rates were found in several of the American countries, the highest being recorded in Guatemala. Although death registration is incomplete in several countries and the true rates are probably higher, the data indicate excessive mortality in many areas. However, analysis of death rates from specific causes as well as by age group is clearly required for understanding of health conditions.

The range in infant death rates was great, from 28.4 per 1,000 live births in the United States to 184.6 per 1,000 live births in Bolivia. The fact that the United States and Canada have been able to bring their infant death rates down to relatively low figures gives promise that, with the development of health programs, improvement of environmental sanitation, and prevention of infectious diseases, rates can like-

Figure 4. The 5 leading causes of death in 9 countries of South America, 1952.

¹ Federal District and State capitals, except city of Sao Paulo

wise be reduced throughout the hemisphere. Forty years ago, at the time of establishment of the Birth Registration Area in the United States, the rate for the 10 States and the District of Columbia, although probably lower than for the rest of the country, was still around 100 per 1,000 live births. Reduction was steady but not even, with some States maintaining relatively high rates until very recent years. Similar unevenness can be expected in the declines in other countries. In those countries which have put into force vigorous public health programs, clear-cut reductions have been noted, and it is to be hoped that the downward trend will continue.

Principal Causes of Death

Eighteen countries provided data regarding the principal causes of death. In considering

these data, it must be kept in mind that not all countries used the International Statistical Classification of Diseases, Injuries, and Causes of Death (sixth revision of the International List) and that there was not uniformity in the title numbers used in ranking the causes of death. Moreover, it is known that there are deficiencies in registration and medical certification in certain countries, such as Bolivia, Paraguay, and Peru.

The 5 leading causes of death in 9 countries of South America are shown in figure 4. In the three northernmost countries—Colombia, Venezuela, and Brazil—the gastrointestinal diseases, that is, the diarrheas, which are probably due principally to shigella, were the leading cause of death. In four countries farther from the tropics—Peru, Bolivia, Paraguay, and Chile—influenza and pneumonia were the principal cause of death. In Uruguay and Argen-

Figure 5. The 5 leading causes of death in 9 countries of North America, 1952.

tina, the diseases in the older age groups, circulatory diseases and cancer, stood first.

Figure 5 gives similar data for 9 countries in North America. In Canada and the United States, the infective diseases did not appear among the 5 leading causes. In the other 7 countries, the infective diseases—the diarrheal diseases, malaria, and influenza and pneumonia—appeared frequently.

A summary of the data on principal causes of death is given in table 3. These data point up the importance of the infective and parasitic diseases, for in addition to the diarrheal diseases, which were the principal cause of death in 8 countries and among the first 5 causes in 12 countries, influenza and pneumonia, tuberculosis, malaria, and whooping cough appeared as leading causes. Even though there is lack of uniformity in classifying and ranking deaths

and variations in completeness of reporting and accuracy of medical certification, the data emphasize the need for active programs for prevention of death due to communicable diseases.

Communicable Diseases

As has been pointed out, the communicable diseases rank high among the first five causes of death in many countries of the Americas. They contribute heavily to infant mortality and mortality in early childhood. In addition to mortality, furthermore, these diseases are responsible for considerable illness and economic loss. The reports on health conditions provided detailed data regarding 15 communicable diseases, including the number of cases and deaths with rates per 100,000 population. In table 4 are shown the death rates for two of these diseases, malaria and whooping cough.

Table 3. Summary of the 5 principal causes of death by rank order in 18 American countries, 1952

Cause of death	Total	Number of countries by rank order of cause of death				
		1st	2d	3d	4th	5th

¹ Diseases of digestive system in two countries. ² Diseases of respiratory system in one country. ³ Includes bronchopneumonia in one country and pneumonia in two countries. ⁴ Diseases of nervous system in one country. ⁵ Intestinal infections. ⁶ Avitaminosis and anemias in one country and dropsy in one country. ⁷ Dysentery, helminths, and syphilis, each in one country.

Malaria is one of the communicable diseases that results in considerable morbidity and mortality in certain areas of the hemisphere. The six countries with the highest death rates are in North America—Guatemala, Honduras, Dominican Republic, Nicaragua, Mexico, and El Salvador. As is well known, malaria has also been a serious health problem in the southern part of the United States. An active eradication program in the United States had almost achieved complete extinction of the disease when the disturbed conditions of World War II and the return of soldiers from heavily infected areas resulted in an increase in cases and deaths. But decline is again in progress: In 1953 only 1,310 cases were reported, and the death rate was estimated to be less than 0.05 per 100,000 population.

The XIV Pan American Sanitary Conference recommended that "the Pan American Sanitary Bureau promote the intensification and coordination of antimalaria work, with a view to achieving the eradication of this disease in the Western Hemisphere; and that the Member Governments should convert all control programs into eradication campaigns within the shortest possible time, so as to achieve eradication before the appearance of anophelene resistance to insecticides." To carry out this resolution, a malaria consultant has been employed; headquarters for the coordination office of the

malaria eradication program have been established in Mexico; countries particularly involved are undertaking active programs; and the United Nations Children's Fund is considering a major increase in appropriations for malaria eradication. Through such coordinated activities, the Americas can be made free of malaria within a short period of time. The excellent antimalaria program in the United States has shown that eradication can be achieved through collaboration of all groups concerned.

The communicable diseases of childhood continue to cause many deaths in the Americas. The death rates for whooping cough, for example, in 5 countries exceeded 30 per 100,000 population in 1952. The rates for this disease were so high in a few countries that doubt has been expressed regarding the accuracy of the statements of causes of death, for it is easy in early childhood to confuse the death due to whooping cough and bronchopneumonia with the death due to bronchopneumonia caused by other diseases. But, even though the data may not be entirely accurate, the size of the whooping cough death rates indicates the need for investigations to determine the causes and for application of preventive measures. Triple vaccine (diphtheria, pertussis, tetanus) was reported to be in use in several countries. The high value and the low cost of this method of

prevention justifies the addition and expansion of programs of immunization against whooping cough.

The International Sanitary Regulations lists six diseases as quarantinable—cholera, plague, louse-borne relapsing fever, smallpox, typhus (louse-borne), and yellow fever. Smallpox continues to occur in several countries, and the case rates in Peru, Bolivia, and Colombia are relatively high. In Colombia, for example, 7,146 cases were reported in 1954. Fortunately, fatality rates for smallpox are generally quite low, indicating that the virus has relatively low virulence. In the light of existing knowledge about smallpox control and about methods of vaccine production and preservation, there is little excuse for continued appearance of this disease. Cases of plague or deaths from this disease occurred in 8 countries in the 4-year period 1950–53, and cases of or deaths from louse-borne typhus were reported in several countries.

Progress in the control of yellow fever and in

eradication of the *Aedes aegypti* has been highly gratifying in several countries. In fact, in six, eradication of the insect vector of urban yellow fever is either complete or in sight. In too many countries, however, much remains to be done. The *A. aegypti* is still present, for example, in many southern States of the United States. Perhaps not enough publicity has been given to the fact that the infested States have been officially reported by the United States Government to the World Health Organization as a yellow fever receptive area. The development in 1954 of yellow fever in Trinidad, an island heavily infested with the *A. aegypti*, and the northern extension of jungle yellow fever in Central America have been reminders that the insect vector must be eradicated from every area in the Americas if the threat of yellow fever is to be eliminated.

From the data on the principal causes of death and also from those on the 15 communicable diseases, the very great toll the communicable diseases are taking in the Americas is evident. The success that has been attained in regard to urban yellow fever and malaria indicates that eradication of malaria and the other diseases will depend on concerted efforts to apply existing knowledge and on determination to carry through such programs.

Status of Programs and Services

In addition to data on vital events and communicable diseases, data regarding the status of the various health programs being carried on, including disease control and environmental sanitation programs, were obtained in the reports on health conditions. To illustrate these data and to stress their value in program planning, an example is taken in the field of sanitation.

The fact that the diarrheal diseases were included among the 5 leading causes of death in 12 countries is evidence of the need for improvement in environmental sanitation. The data regarding the status of one of the programs in this field, the provision of water supply systems, for 13 countries are shown in table 5. In 5 of the 11 countries providing data for urban areas, three-fourths of the urban population was served by water supply systems in 1953—

Dominican Republic, El Salvador, Panama, United States, and Venezuela. In 5 others, more than half of the urban population had water supply systems. As would be expected, the percentages of the rural population having water supply systems were very low. Despite the obvious limitations of these data, they do point out the phases of water supply programs in which international help can be of greatest importance, and they serve to stimulate individual countries to raise standards to constantly higher levels.

Table 5. Percentage of population served ¹ by water supply systems in urban and rural areas in 13 American countries, 1953

Country	Total	Urban	Rural
Argentina-----	43	67	2
Bolivia-----		57	-----

United States-----	59	89	² 23
Venezuela-----		88	-----

¹ Percentages of population calculated using total population living in area.
² Communities of less than 5,000 population with water supply systems.

Although some information was provided regarding the organization of health services and personnel employed, summarization of the ma-

terial for presentation here is difficult. In general, it can be said that the data indicated a shortage of trained personnel, an absence of full-time health departments, and the necessity for data to evaluate resources as well as needs for health services.

Summary

Selected data from reports of the American countries, which were prepared for the XIV Pan American Sanitary Conference, have been presented to illustrate existing knowledge regarding health conditions and health services. Shortcomings of the data are great, but the very act of providing the data that are available has been a powerful impetus to improved reporting as well as to improved health programs.

In most of the American countries, there is a need for emphasis on communicable disease control and eradication and on programs for the predominantly young population. National initiative, along with the coordinated efforts of international collaboration, can solve these problems, as it has others. Through full utilization of the basic data on health conditions that appear in the Summary of Reports of the Member States, 1950-53, the countries of the Western Hemisphere, working together, will now go forward in eradicating communicable diseases, developing environmental health programs, providing maternal and child health services, improving case reporting and vital statistics systems and basic data in other programs, and in the overall strengthening of health services.

A psychologist concludes that more light would be shed by understanding human behavior factors than from complicated statistical analyses of the uncontrolled world surrounding accidents in everyday circumstances.

The Illusive Phenomena in Accident Proneness

By WILSE B. WEBB, Ph.D.

How shall we determine the presence or extent of accident proneness?

Granted the factor of accident proneness, how shall we come to know its character?

This, in a sense, will be a consumer's report—a report of occasionally desperate attempts to apply the cool logic of statistics to the fetid jungles of accident data. It is the result of some 5 years of delving into innumerable accident records (1-3). This faint blaze on my back tracks may help others avoid some of the morasses

in which I have floundered on a number of occasions.

The Extent of Accident Proneness

In view of the wide use and frequent abuse of the term "accident proneness," it would appear to be a required first step that I outline my concept of its meaning.

I conceive of an accident as a condition of liability, as an event subject to and contingent upon the existence of identifiable, at least in a theoretical sense, events.

This position would contend that a constellation of circumstances at the time of an accident determines the occurrence of that accident. Further, the presence of certain events increases or decreases the probability of any given accident. The summation of the probabilities represents accident liability at any given time. Finally, the position maintains that a knowledge of all of the pertinent events prior to the accident permits the prediction that the accident will occur. It, of course, follows as a corollary that increasing knowledge about the factors surrounding an accident will permit its prediction, or, if such factors are manipulatable, will permit the reduction of accidents.

Dr. Webb, head of the Aviation Psychology Laboratory, United States Naval School of Aviation Medicine, Pensacola, Fla., was formerly an assistant professor of psychology, University of Tennessee and Washington University, and visiting lecturer, University of Southern California. During World War II he was a commissioned research psychologist. Since then, on contract, he has directed research in aircraft accidents, for the Air Force, and in the selection and training of aviators, for the Office of Naval Research. Dr. Webb is associate editor of Psychological Reports and the author of some 50 papers in professional journals.

Here is an expository categorization of events which may be called the dimensions of accident liability.

Factors within individual:

Stable individual characteristics (accident proneness). *Examples:* psychomotor capacities, intellectual capacities, sensory capacities.

Transitory individual characteristics. *Examples:* fatigue, illness, hangovers, emotional states.

Changeable individual characteristics. *Examples:* low level of training, faulty training.

Factors outside individual:

Stimulus presentation. *Examples:* clarity of cues for response, speed of cue presentation, sequence of cue presentation.

Response demands. *Examples:* speed of response, direction of response, accuracy of response.

Equipment adequacy. *Examples:* materiel failure, calibration errors, response lag.

Activities of others. *Examples:* faulty maintenance, faulty instruction.

Consider accident proneness as a component part of this accident liability. Accident proneness, in these conditions of accident liability, is that category concerned with the stable characteristics within the individual. The other categories obviously could not be considered as proneness on the part of the individual since they either are not stable or not directly under the control of the individual.

Accident proneness, then, may be defined as the continuing or consistent tendency of a person to have accidents as a result of his stable response tendencies. For example, two individuals may fly in the same aircraft and in identical circumstances. Thus, they would have the same situational probability of having an accident. However, one may be inherently a poor pilot in regard to coordinative capacities. He will have, because of this lack of proficiency, a greater probability of having an accident in circumstances requiring coordination. He would then be called an accident-prone pilot.

How may we detect the presence of accident proneness in a population of accidents? Let us recognize certain conditions inherent in our definition of accident proneness. First, it has been described as a continuing factor, and, second, it has been described as increasing the liability of accident occurrence. It follows, then, that, if a group of individuals with varying

amounts of accident proneness were exposed to conditions which permitted the operation of these factors of proneness, the accidents of those individuals with high accident proneness would exceed beyond chance expectancy the accidents of those with low accident proneness, other things being equal. The problem is simply one of establishing the fact that certain individuals had accidents which exceeded those expected on the basis of chance, other things being equal.

The Poisson Method

Perhaps the most classical method is the Poisson method (4, 5). The method reveals the statistical problem as a relatively simple one. Given a relatively infrequent event, how will these events be distributed by chance alone? If such a distribution can be derived, a comparison may be made with an obtained distribution of accidents. If the distributions differ, an inference about the operation of non-chance factors may be introduced.

Thus, if 100 accidents are going to be distributed by chance among 10,000 people over a period of 1 year, what are the chances of these accidents occurring to 100 different people as contrasted with some individuals having 2 accidents, some only 1, and some none; or, some individuals having as many as 3 or 4 accidents, some having 2, some having 1, and some having none? Given a chance distribution, how does it compare with the actual distribution of accidents under consideration?

Mathematically, the Poisson distribution, which is merely the binomial distribution with low probability of occurrence, can be used to describe the chance distribution of infrequent events. If the distribution of accident events deviates from that expected on the basis of the prediction of the Poisson distribution, we may state that a beyond-chance factor is operating. This technique has been so sharpened that we may actually estimate the amount of predictable variance which exists above and beyond chance and may further estimate a correlation which could be obtained between perfect predictors and this variance in excess of chance.

The accompanying table presents a mathematically derived chance distribution and an obtained distribution of 7,288 accidents occur-

ring to 17,952 Air Force pilots during an 8-year period (2). Let us consider this table.

According to the Poisson method

Number of accidents	Chance distribution		Obtained distribution	
	Number of pilots	Number of accidents of pilots	Number of pilots	Number of accidents of pilots
0-----	11, 962	0	12, 475	0
1-----	4, 856	4, 856	4, 117	4, 117
2-----	986	1, 972	1, 016	2, 032
3-----	133	399	269	807
4-----	14	56	53	212
5-----	1	5	14	70
6-----	0	0	6	36
7-----	0	0	2	14

First, in regard to the chance distribution, if merely the repetition of an accident is to be taken as the definition of accident proneness, some 33 percent of the accidents could be so classified in a completely chance distribution. This is patently absurd.

Second, a casual comparison reveals that the obtained distribution contains individuals who did have accidents in excess of the distribution to be expected by chance. Only 1 pilot would have been expected to have had 5 accidents during this period on the basis of a chance distribution. In actuality, 14 had as many as 5 accidents. None would have been expected to have had 6 accidents if these accidents had been distributed on the basis of chance. In the obtained distribution some 6 individuals had as many as 6 accidents.

A comparison by the chi-square technique indicates the two distributions are significantly different. We must, however, reserve judgment as to the possibilities of inferring that this excess of chance occurrence can be attributed to accident proneness.

The Split-Period Method

Perhaps the most straightforward test of the consistency of accident tendencies over a period of time is the "split-period method." This is based on the determination of the relationship between a number of accidents had by indi-

viduals in 2 periods of time. The simplest method is to divide the total period of accident exposure into 2 halves and then determine if there is a relationship between the accidents had by individuals in the 2 periods. The statistical tool would be the correlation coefficient. In actual procedure, the time period is more typically divided into accidents occurring in odd and even periods in contrast to a first-half, last-half division so as to obtain better control of the external characteristics of the time periods.

A distribution of accidents on odd and even days, according to the split-period method, was obtained for the same Air Force population referred to previously. The obtained correlation is 0.107 and is correctable by a Spearman-Brown formula to 0.193 (2).

Since a correlation expresses the degree of relationship between two sets of measures, these figures indicate the degree to which the accidents had by a man during one period were related to the accidents he had in a second period. A correlation of 1.00 would indicate that the accidents during one period perfectly predicted the accidents in another period, or, one could infer there was a direct relationship between a man's accident behavior during the two periods of time. A 0.00 correlation would indicate that his accident behavior in the two periods was completely unrelated. The correlations obtained were small but significant, and it would be concluded that some beyond-chance factors were operative in the Air Force population.

It should be noted in passing that there has been, on occasion, differential touting of the Poisson method and the split-period method (6-8). It seems appropriate to point out that Jones and I (9) have shown that the two methods, derived from essentially independent assumptions, yield operationally identical estimates. We also found that mathematically the identity of the methods can be demonstrated. Practically, it would appear that the choice of the method becomes dependent only on convenience, ease of conceptualization, or personal preference.

External Correlation Method

A further statistical procedure establishing the presence of accident proneness may be la-

beled the "method of external correlation." This procedure would be dependent on the selection of a measure presumably related to accident proneness. The population would then be measured on this factor, and then these measures would be correlated against the accident occurrence. If this correlation was significant, it would indicate that accidents could be predicted on assumption of accident proneness, and, therefore, accident proneness could be inferred as existent. For example, suppose a measure of intelligence can be shown to be related to accident frequency. Since intelligence is a stable characteristic of the individual, it follows that accidents are to some extent a function of individual accident proneness as partially measured by intelligence.

Limitations of Methods

All of these procedures have their difficulties, however. The prime difficulty lies in the fact that the beyond-chance factors which may be demonstrated by these methods may not be attributed to the existence of a continuing factor of accident proneness alone. A considerable portion of the liability conditions outlined previously may exist commonly with the individual but not be attributed to his own within-person proclivities for accidents.

For example, 2 individuals with precisely the same capacities or proneness potential may be assigned throughout the accident period to 2 different situations which require different complexities of response. The individual who is consistently required to respond more effectively is likely to make more errors, and accidents would be more frequent throughout the situation, and yet he could hardly be considered more accident prone—consistently more accident liable, yes, but not more accident prone. In fact, quite frequently the converse is true since better men are frequently assigned to more difficult situations. Or, again, frequency of exposure may be different for different individuals during the accident period. A man exposed twice as frequently as another man is likely to have more accidents, but again this could not be called accident proneness.

All instance variations in liability throughout the period under study will result in beyond-

chance distributions, if they are systematically associated with certain individuals and not with others. It follows that the extent to which all factors, other than the accident-prone factors which are included in the listing of the dimensions of liability, are equalized among the population under consideration defines the extent to which the deviation from chance established by the methods described can be attributed to accident proneness.

As a point of fact, with each increasing restriction on the Air Force population previously used, there was a reduction in the significance of deviation from chance. Until, for example, training accidents (which impose maximum restriction in regard to age, training, exposure, and type of aircraft) revealed no deviation in their accident repetition from that which would be expected by chance. The same holds true for selected groups of jet accidents in which exposure was largely equalized (2).

The Clinical Method

One further method may be mentioned as a tool for probing the existence of accident proneness. It is not statistical, but may be described as the "clinical method," a method which involves very simply a post hoc detailed analysis of the characteristics of individual accidents and individual accident histories. If, for example, a man consistently has the same type of accident under varying circumstances, and these accidents may be attributed to some characteristic inherent in that man, at least these accidents and perhaps others are attributable to accident proneness.

The clinical method has its advantages and disadvantages, which have been, and are being, argued independent of the present problem. It yields no satisfactory estimate of the extent of accident proneness. I am somewhat frightened by the "seek and ye shall find" phenomena. In the typical complexity of the accident situation I can almost always find that which I am looking for if I know what I am looking for in the first place.

Perhaps the main advantage inherent in this procedure is the liveliness and convincing quality of the results and its usefulness in developing hypotheses to be further investigated.

The Nature of Accident Proneness

Let us assume that either on the basis of faith or fact we are convinced a significant proportion of accidents is determined by accident proneness in a particular population. What do we do next? The mere pointing to the fact of accident proneness is hardly more useful than pointing to sin. We must somehow know its characteristics to be able to deal with it.

Our basic paradigm is not difficult to conceive. We need measures which are presumably related to this intervening concept of accident proneness. We need measures of the accident event. Finally, we need to determine whether our measures of accident proneness are related to or predictive of accidents.

Certain difficulties typically follow from the nature of accidents and accident records. The definition of the accident is a difficult one, yet this is a first requirement in a reasonable test of the predictability of our concepts concerning accident proneness. It is a bit absurd to suggest that, for example, an intelligence test could predict an accident resulting from the breakdown of equipment, when this breakdown was independent of the operations of the individual. In other words, we should limit ourselves to accidents for which the operator could at least theoretically be held responsible.

Unfortunately, even a simple dichotomy of accidents into personal responsibility and non-responsibility is frequently unreliable. When we further try to dimensionalize accidents within a personal responsibility category, vast confusion tends to reign. Not long ago, on reviewing psychological coding systems for accidents, DuBois and I found that the commonality of classification of the nature of the accident usually ranged from about 33 percent agreement between 2 raters to a maximum of about 70 percent agreement between the 2 raters (3). The variations seem to be primarily related more to the number of possible categories to which the accident could be assigned than to any descriptive nature of the codings used. So long as the definition of an accident is not at all clear—and to date I know of no satisfactory, psychologically meaningful dimensionalization of this event—our designs will be weak.

On the other end, there are many problems inherent in obtaining measures which we are to relate to this chaos. Most of the problems at this end stem from the fact that accidents are infrequent phenomena. This means that, if measures are to be collected prior to the occurrence of an accident, the data collection must be an extensive one. Frequently, as many as 10,000 measures must be obtained on a population in order to yield measures on 10 individuals who are going to have accidents. An alternative procedure is the measurement of a limited number of individuals and then waiting for the passage of an extensive period of time until the low probability of accidents yields sufficient cases. This procedure is further complicated on finding that the measures taken may be quite meaningless by the time the accident occurs. Then, there is the post hoc method, the method of obtaining data after the accident has occurred. This method contains all of the faults of a posteriori reasoning noted in the clinical method.

Although there are ways around these problems, one becomes discouraged. Faith, frustration, tolerance, or funds are necessary to sustain us through the travails involved. There is also, of course, the question of what measures should be used, which involves an appraisal of the state of psychology itself. I will merely understate the case by saying that much more needs to be known about the nature of man.

The most adequate studies of the role of psychological factors in the development of errorful behavior, in short, a study of accident proneness, will best be performed in the laboratory situation even though there are inherent difficulties in translating laboratory findings to the operating situation. However, I personally feel that these difficulties will be far less the difficulties inherent in the rough and ready analysis required of the present complexities of the uncontrolled world surrounding operational accidents.

Nursing Home Project Approved

The first project to be constructed under the provisions of the Medical Facilities Survey and Construction Act of 1954 (P. L. 482, 84th Cong.) has been approved.

It is a 53-bed nursing home addition to the Pinal County General Hospital at Florence, Ariz., which will be used for nursing and medical care of the aged, and will be operated by the hospital.

At present, there are no nursing home facilities in the county, and patients who could be cared for in a nursing home are occupying more than 12 percent of the 86 beds in the general hospital. The nursing home will use the hospital's special services and personnel and will, when necessary, transfer patients to the hospital for medical or surgical treatment.

Estimated construction cost of the nursing home is \$240,000, toward which the Federal Government will contribute half and Pinal County the other half.

Parasitism in Southeastern United States

a symposium

The program of the Association of Southeastern Biologists, meeting in Charleston, S. C., April 21, 1955, included a symposium on parasite problems in the southeastern United States. The three papers of the symposium include a historical review by Dr. Faust, an appraisal of the progress made and the problem today by Dr. Wright, and a general summary of veterinary problems in parasitology by Dr. Bailey. The symposium moderator, Martin D. Young, Sc.D., director, Laboratory of Tropical Diseases, National Microbiological Institute, Public Health Service, Columbia, S. C., wrote the following introduction.

ABOUT three centuries ago the English successfully colonized the southeast coast of the United States. These colonists brought some exotic parasites, and later they imported slaves who also brought certain tropical parasites. In addition, the colonists encountered native parasites in the indigenous hosts. Confronted with a new set of epidemiological factors, the parasites behaved in different ways. Some became established to cause recurring epidemics. Others established endemic foci, of which some were to disappear gradually by attrition. Still other parasites were unable to maintain themselves in this area.

The parasites exerted a great influence upon the economic and social development of the people. Some of the more important para-

sitic diseases, such as malaria, were instrumental in causing the establishment of medical schools and influenced the type of culture evolved in the plantation low country, especially in the Carolinas. The investigation of hookworm disease emphasized the need for public health organizations and laid the foundation for the present-day county health systems.

Some of the parasitic diseases, namely malaria and filariasis, have virtually disappeared from this area. Others are still present. The symposium was held to review what has happened in the field of parasite problems in the southeastern United States and to estimate the current situation.

The eminent parasitologists in this symposium discuss their subjects authoritatively.

History of Human Parasitic Infections

By ERNEST CARROL FAUST, Ph.D.

A RÉSUMÉ of human infections from parasitic organisms in the southeastern United States from the earliest records until recent times is logically divided into four periods: infections in the American Indian before the coming of the white man; from the earliest colonial period until about 1850; from 1850 until the end of the 19th century; and from 1900 until recent times.

Before the Coming of the White Man

Very little is known about parasitic infections among the Indians. There is no indication that malaria was present (1), but by inference intestinal protozoiasis must have been relatively common since they have been found in all indigenous populations in regions where surveys have been made. The Indians must have had the common intestinal roundworms (*Ascaris* and *Trichocephalus*) for the removal of which the Cherokees employed crude oil of chenopodium, obtained from the seeds of the native plant *Chenopodium ambrosioides* var. *anthelminticum*, and possibly also the rhizomes of the pinkroot, *Spigelia marilandica* (2). Their dogs probably harbored *Ancylostoma braziliense* and possibly *Ancylostoma caninum*,

but the human hookworms are believed to have been introduced later from the Eastern Hemisphere.

When serious epidemics developed in Indian communities the inhabitants burned their homes and resettled on uncontaminated soil (3).

From 1607 to 1850

During early colonial days the explorers and settlers who came from Europe brought with them the white man's common communicable diseases, notably smallpox, measles, and tuberculosis and, to a lesser extent, malaria and hookworm infection (*Ancylostoma duodenale*). Much of the parasitic diseases were those imported by African slaves, including virulent strains of vivax malaria, malignant malaria, the subtly developing quinine-resistant tropical hookworm infection, Bancroftian filariasis, schistosomiasis, and probably also the parasitic diseases indigenous to Africa. In the latter it may be reasonably assumed that relatively virulent strains of *Entamoeba histolytica* were introduced.

Malaria

All three species of malaria require an appropriate mosquito host in the southeastern United States, and more prolifically as virgin soil for the cultivation of rice in the Carolinian lands and for sugar cane in the Louisiana country. The malaria-infected mosquito served as the reservoir for infection of the human. The mosquito in turn transmitted the

Dr. Faust is the William Vincent professor of tropical diseases and hygiene and head of the graduate department of parasitology, Tulane University of Louisiana. His most recent book, just published, is entitled, "Animal Agents and Vectors of Human Disease."

parasites to other Negroes and to the white population. This situation caused rapid development of highly malarious communities. Later, with people settling in the fertile Ohio and Mississippi Valleys, malaria spread rapidly. By 1850 there were almost solid areas of intense malariousness from Baltimore south to Georgia, Alabama, and central Florida, inland to Cincinnati and St. Louis, and down to the Gulf of Mexico. From these highly endemic areas vivax malaria became established throughout almost the entire United States except for mountainous and desert regions, while the more tropical *falciparum* infection remained entrenched in the southeast (1).

Hookworm Infection

Human hookworm infection caused by the more tropical parasite *Necator americanus* became gradually disseminated throughout the moist sandy humus soils of the southeast, extending from Virginia to southern Illinois and down to the gulf, and as far westward as eastern Texas. Here again the Negro was the source of the infection as he polluted the soil with his excreta which contained the eggs of the

people may have acquired in part from the In-
dians, and in larger part from the Negroes who
worked on the plantations. The evidence sup-

porting these conclusions is indirect but rela-
tively satisfactory, based on the descriptions of
roundworms in the American medical texts of
the late 18th and early 19th centuries and on the
prescription of many native plants which were
supposedly effective as intestinal vermifuges
(5) and listed in the early editions of the United
States Formulary (*Allium cepa*, *Allium sati-*
vum, *Angelica archangelica*, *C. ambrosioides* var.
anthelminticum, *Convolvulus jalapa*, *Ferula*
assafoetida, *Juglans regia*, *Laurus camphora*,
Melia azedarach, *Spigelia anthelmia*, *S. mari-*
landica, *Tanacetum vulgare*, *Valeriana offi-*
cinalis, and *Veratrum sabadilla*). Moreover,
persons who ate inadequately cooked beef must
have acquired beef tapeworm (*Taenia sagi-*
nata) infection and, similarly, those who ate
rare pork, infection with pork tapeworm
(*Taenia solium*). Likewise, they probably be-
came infected with *Trichinella spiralis*, which
was first reported from hogs by Joseph Leidy
of Philadelphia, in 1846.

Bancroft's filariasis, caused by *Wuchereria*
bancrofti, was introduced in the African slaves
(4) and became established in the domestic mos-
quito *Culex quinquefasciatus* as a biological
vector. However, there is no information dur-
ing this period as to the geographic distribution
or prevalence of this disease.

Blood fluke infections, caused by *Schistosoma*
mansonii and *Schistosoma haematobium*, which
were likewise introduced into the Western Hem-
isphere in African slaves (4), failed to find suf-
ficiently susceptible molluscan intermediate
hosts in North America, never became estab-
lished here, and did not survive the death of
the human hosts who brought them into the
country.

Primitive conditions for disposal of human
excreta, contaminated water supplies, infre-
quent bathing among the laboring and even
other classes, and various other defects in per-
sonal and community hygiene favored trans-
mission and high prevalence of infections pro-
duced by the intestinal protozoa. Yet there is
no direct evidence of their presence or frequency
although it seems justifiable to assume that a
considerable amount of the common dysentery
of these decades, referred to as "bloody flux,"
was due to the pathogenic ameba, *E. histolytica*.

By 1850 most of the parasitic diseases of the southeast and those transmitted by arthropods or due to bacteria had reached their peak, had developed formidable plateaus of incidence, or were subject to serious periodic epidemics (3). At least two of our medical schools, the Medical College of South Carolina at Charleston and the Medical College of Louisiana, later named Tulane, at New Orleans, were established to train physicians to combat malaria, yellow fever, epidemic typhus fever, cholera, and endemic intestinal diseases.

Today it is readily understood that all of the environmental conditions which favor many of the infectious diseases were present during those decades in the southeastern States, namely (a) for malaria—newly cultivated, poorly drained land for the breeding of the anopheline mosquito vector; (b) for yellow fever—prevalence of *Aedes aegypti* transmitters in cisterns and other fresh water containers around the home; (c) for typhus fever—infrequent bathing and washing of clothes, resulting in body lice among both the poor classes and the socially elite; and (d) for the intestinal diseases—improper disposal of human excreta, contamination of food and drinking water, and carelessness in personal hygiene. While the slaves and poorer whites suffered most, the better educated and well-to-do persons were by no means exempt and at times had proportionately higher morbidity and mortality rates.

From 1850 to 1900

During the years 1862–65, when Northern soldiers were quartered in the South, there was a notable increase in malaria and dysentery, particularly in and around the Army camps. During this quadrennium the annual malaria morbidity rate in the Federal forces in North Carolina was 1,087 per 1,000 mean strength; in Tennessee, 848; and in the gulf area, 803 (6). Moreover, there were nearly 2 million reported cases of dysentery in the Northern Army, with 44,558 deaths attributed to this cause (3).

Following Appomattox, the South was deprived of its agricultural labor, the land remained untilled, and malaria mosquitoes bred without restraint (1). As late as 1881 the malaria death rate per 100,000 population was

428 in Shreveport, 318 in Vicksburg, 171 in Baton Rouge, 100 in New Orleans, and comparably high in other malarious areas of the southeast.

Epidemics of yellow fever of major or minor proportions were reported from one or more southern port cities annually from 1850 through 1900, except for 7 years—1861 (during blockade of southern ports by Federal forces), 1881, 1885, 1886, 1891, 1895, and 1896 (7). There were severe epidemics of dengue during 1849–60, 1873–76, 1880, and 1896–98. Between 1847 and 1853 there were about 1,200 cases of louse-borne typhus fever annually in the New Orleans Charity Hospital, originating from importation of the disease from Ireland and Mexico (8). Cholera arrived on boats from Europe. During 1849–53 and again in 1873, it caused heavy mortality at the port of New Orleans and was spread to communities far inland through the Mississippi, Ohio, Missouri, and Platte River Valleys (9).

From 1900 to 1950

The etiology and natural history of many of the common parasitic and arthropod-transmitted diseases prevalent in the southeast became known during the 1890's and the following decade. These included the role of *Anopheles* in the malaria life cycle, of *A. aegypti* in urban yellow fever, and of the body louse in epidemic typhus fever. As early as 1876, Manson had demonstrated that the household mosquito *C. quinquefasciatus* was an intermediate host and vector of Bancroft's filariasis (10). By 1900 the life cycle of the human hookworms was likewise a matter of record (11), but it was not until the 1920's that specific information was provided on the epidemiology and life cycle of *Ascaris*, as well as the etiology of cutaneous larva migrans.

Amebiasis

Although *E. histolytica* had been described by Lösch in 1875 and its pathogenic role in the production of disease was conclusively demonstrated during the next 25 years by workers in Europe, Egypt, Philadelphia, Baltimore, and Texas, its life cycle involving man was first directly demonstrated in 1913 when Walker and

Sellards in the Philippines fed cysts of this ameba to 20 human volunteers and obtained infection in 18, with dysenteric symptoms in 4 (12). Epidemiological surveys were begun in 1913 to determine the prevalence of, and methods of exposure to, amebiasis in different groups of the population in the United States, that is, urban vs. rural, clinic patients vs. apparently well persons, children vs. adults, and institutionalized vs. noninstitutionalized groups. These studies demonstrated a higher average incidence among noninstitutionalized individuals in the southeast than in other areas, due probably to less careful personal and group hygiene (13).

Malaria

The first two decades of the 20th century saw considerable retreat of malaria along the northern border of the hyperendemic areas in the southeast, primarily as a result of better drainage of farmland. In contrast, there was no appreciable decrease in malariousness in the southeast (14). During the depression of the 1930's there were notable increases in morbidity and mortality from malaria in this area. Then widescale control was instituted by cooperation of Federal and State public health agencies, consisting of scientific drainage and other antilarval measures, screening of homes, chemotherapy, and more adequate diets among the poorer classes in the population.

Beginning in 1942 malaria vector control was carried out intensively within and around military training bases in the southeast, and, as soon as DDT was in supply, this insecticide was used effectively both as a larvicide (15) and an imagocide. More accurate blood film diagnosis of the malaria parasites so that malaria and typhoid fever were no longer confused (16), together with treatment of human carriers with quinacrine and later with chloroquine, practically terminated the chances for the remaining anophelines to pick up the infection and transmit it to other persons.

Although our local *A. quadrimaculatus* was shown to be readily susceptible to foreign strains of human plasmodia (17), as a result of effective control measures only a very few incidental transmission cycles developed in the United States following the return of many thousands

of American troops from malarious areas during World War II, and more recently from Korea. Thus, by 1950 malaria had ceased to be a public health problem in any previously malarious area in the United States (18).

Hookworm Infection

Soon after the discovery and naming of the hookworm *N. americanus* in 1902 by Charles Wardell Stiles, surveys were undertaken to ascertain the clinical and public health importance of hookworm infection in the southeastern United States. It was discovered that this parasite had extensive distribution, especially in the nonmountainous areas, and was responsible for much serious illness, an appreciable number of deaths, and untold economic loss.

In 1915 the Rockefeller Foundation undertook studies in the southeast to obtain more exact epidemiological information, with the objective of developing effective control (19). In cooperation with State public health agencies all of the endemic areas were surveyed, after which anthelmintic treatment was administered to the hundreds of thousands of infected individuals (20). Sanitary methods for disposal of human excreta were instituted, and education concerning hookworm epidemiology and its prevention became a part of the public health programs of all communities in which the disease was prevalent.

These measures were successful in reducing the heavy hookworm burden in all but a few localities (21) although incidental hookworm infection remained throughout much of the previously heavily endemic area (22).

Cutaneous Larva Migrants

The disease, cutaneous larva migrans or creeping eruption, is restricted mostly to the South Atlantic and the gulf coasts, particularly on both coasts of northern Florida. Clinical and experimental studies of Kirby-Smith and associates between 1917 and 1927 demonstrated that the etiological agent is a non-human strain of *A. braziliense*, exposure to which occurs when persons lie on beaches or otherwise come in contact with the infective-stage larvae in places where dogs or cats harboring the adult worms have previously defecated (23).

Ascariasis

Inquiry into the geographic distribution and epidemiology of ascariasis was undertaken in 1927 by Cort and his associates, a few years after the life cycle of the etiological agent, *A. lumbricoides*, had been elucidated by Ransom and his associates (24, 25). It was found that in the southeastern United States this was fundamentally an infection of young children, who seeded the dooryard with *Ascaris* eggs (26). Later, the same children and their playmates became infected by getting the embryonated eggs in their mouths—eating contaminated soil on play objects or fingers and then swallowing the eggs. With a few notable exceptions, ascariasis in the southeast was found to be predominantly prevalent in the southern extensions of the Appalachian highlands. Headlee (27), who studied the epidemiology of ascariasis in New Orleans, emphasized that it is primarily a familial infection. Up to 1950 no sustained or extensive programs had been undertaken to control this infection.

Visceral Larva Migrants

The dog ascarid, *Toxocara canis*, has been found to produce a serious childhood disease designated as visceral larva migrans. When a child swallows fully embryonated eggs of this parasite, the eggs hatch in the child's duodenum and undertake a lung journey, just as occurs in human *Ascaris* infection. However, since man is not a particularly suitable host for the dog ascarid, granulomatous tissue reaction almost invariably traps the migrating larvae, most frequently in the liver, but at times in other organs and tissues. A pronounced sensitization reaction results, with prolonged high eosinophilia. The infection is incapacitating but not usually fatal. Discovery of the etiology of this disease (in New Orleans) has been so recent that its prevalence and geographic extent are essentially undetermined (28).

Strongyloidiasis

Strongyloides stercoralis is prevalent in warm moist climates; in the United States it occurs mostly in the gulf coast areas where there is a relatively high ground water level, as in the bayou country of Louisiana (29); elsewhere throughout most of the southeast the infec-

tion is relatively sporadic. This nematode is biologically interesting since under favorable conditions it can carry out one or more complete life cycles as a free-living organism on the soil, while at other times it propagates exclusively by internal autoinfection (30).

Whipworm Infection

In connection with epidemiological studies on hookworm and *Ascaris*, infection with the whipworm, *T. trichiurus*, has been found to be widely disseminated in the southeast (31, 32). Most reports indicate that the average worm burden is relatively light, but young patients living in unsanitary rural environments occasionally have a high worm burden, with dysentery and other manifestations of severe colitis.

Enterobiasis

Infection with the pinworm, *E. vermicularis*, is common in children throughout the southeast, but is no more prevalent here than it is in cooler climates. The development of the NIH swab (cellophane) and more recently of the Graham swab (scotch tape) for recovery of the eggs deposited by the female worms migrating outside the anus, has provided much easier and more accurate diagnosis than fecal examination for eggs (32). In our area as elsewhere the infection is primarily familial or institutional.

Trichinosis

Surveys to determine the incidence of human infection with *T. spiralis* have been conducted in several localities in the southeast, usually employing digestion or pressed muscle examination of routine necropsies to demonstrate the larval stage. The percentage of positive cases has been relatively low (2.8 to 10.0) save for one report of 33.0 from Alabama. With few exceptions the larval count per gram of infected muscle has likewise been low (33, 34). This corresponds to the clinical findings in the southeast where the infection rarely produces severe manifestations.

Tapeworm Infections

The beef tapeworm, *T. saginata*, has become considerably less prevalent than it was 25 years ago, and the pork tapeworm, *T. solium*, has

practically disappeared from the native population of the United States. In contrast, both of these infections are increasingly common in continental Latin America.

The dwarf tapeworm, *Hymenolepis nana*, which requires no intermediate host and results from poor personal hygiene and lack of environmental sanitation, is widely distributed in the southeast and is most often found in children (35). Occasionally patients are so heavily parasitized that they are seriously ill as a result of these worms.

Human infection with the fish tapeworm, *Diphyllobothrium latum*, has been demonstrated to be indigenous in only one locality in the southeast, a rural community in Florida, where Negro boys and their dogs harbor the adult worms (36). The larval stage (sparganum) of a related tapeworm, *Diphyllobothrium mansonii* complex, producing somatic infection in man (sparganosis) has been reported in earlier decades—once from Florida and once from Texas. Recently, eight new cases have been discovered in Louisiana, Mississippi, and eastern Texas. As in fish tapeworm infection, species of *Cyclops* are the first intermediate host of the parasite, while frogs, snakes, birds, and mammals, but never fishes, are the second larval-stage hosts, and cats or dogs are the natural definitive hosts of this tapeworm. There is no specific evidence as to how man acquires the infection, but it seems likely from the case histories that he drank unfiltered water containing infected *Cyclops*.

Hydatid disease, produced by the larval stage of *Echinococcus granulosus*, has been demonstrated to be an autochthonous human infection in Virginia, Tennessee, Mississippi, and Louisiana.

Filariasis

During the 18th and 19th centuries Bancroft's filariasis may have been widely distributed throughout the southeast although there is no authentic record of the demonstration of the etiological agent, *W. bancrofti*. Charleston, S. C., was found to be an endemic center during blood surveys conducted in 1886, 1890, and 1915. Between 1915 and 1918 Edward Francis of the Public Health Service examined human blood films in 10 southern cities

(Charleston, Columbia, Beaufort, and Georgetown, S. C.; Savannah and Milledgeville, Ga.; Jacksonville and Tampa, Fla.; Mobile, Ala.; and New Orleans, La.) to determine the extent of the infection. Only in Charleston were positive individuals discovered (13 to 35 percent of inmates of the old folks' home) who had maintained residence exclusively in the United States.

Since the publication of Francis' report (37), the writer has learned of only one authentic diagnosis of an autochthonous case—in 1930 in a native of Georgia who was for a time a patient of the Public Health Service Hospital at Carville, La. The lack of any subsequent reliable reports of cases suggests that Bancroft's filariasis has disappeared from the southeast. Meanwhile there have been three recent findings of immature female filariae from subcutaneous nodules of white persons with long residence in Florida. While these worms conform to the criteria for *Dirofilaria conjunctivae*, it seems reasonable to believe that they are in reality young specimens of the dog filaria, *Dirofilaria immitis*, which were unable to complete their development in man (38).

Summary and Conclusions

The parasite problems of the southeastern United States have been presented from the perspective of history and epidemiology. Some of the common intestinal roundworms and probably most of the intestinal protozoa were indigenous in the American Indian. Other animal parasites were introduced from Europe by the explorers and colonists although diseases among them were relatively unimportant compared with the contagious diseases of viral and bacterial origin which were brought to the Americas. Many serious problems developed with the importation of slaves from Africa and the consequent propagation in the favorable environment of the southeast of tropical strains of malaria parasites and the hookworm *Necator americanus*. As families from the Atlantic and gulf coast areas settled in the fertile inland valleys, these and other parasitic diseases became more extensively distributed. Poor conditions of sanitation and primitive personal hygiene made of the entire southeast a hyperen-

demic area for a number of diseases of parasitic origin, of others transmitted by arthropods, and those caused by enteric bacteria.

With the discovery of the etiological agents and knowledge of their life cycles and their methods of transmission, came improvement in water supplies, drainage, and disposal of human excreta. Public health programs were instituted to control these diseases. Parasite control in the southeast presents less of a problem now than it did in 1850 or 1900.

EDITOR'S NOTE: The term, "*Trichocephalus trichiurus*," used in the above paper is synonymous with the term, "*Trichuris trichiura*," in the other papers of this symposium.

Special Committee on Medical Research

A Special Committee on Medical Research has been named by the National Science Foundation to review and evaluate the medical research program of the Department of Health, Education, and Welfare.

In requesting the review, the Secretary of Health, Education, and Welfare asked that the committee consider the rate of growth of the Department's health, medical, and related research program in the light of Federal responsibilities and appraise its present level of medical research support. Careful consideration was also requested of the proper balance of support for basic and applied research and the relative distribution of effort among the major special fields of health research.

The special committee is headed by Dr. C. N. H. Long, chairman, department of physiology, Yale University School of Medicine. Other members are Dr. E. A. Doisy, professor of biochemistry, St. Louis University School of Medicine; Dr. Ernest W. Goodpasture, Armed Forces Institute of Pathology, Walter Reed Army Medical Center; Dr. A. B. Hastings, department of biological chemistry, Harvard Medical School; Dr. Charles Huggins, director, the Ben May laboratory for cancer research, University of Chicago; Dr. Colin M. MacLeod, department of microbiology, New York University School of Medicine; Dr. C. Phillip Miller, department of medicine, University of Chicago; Dr. W. M. Stanley, director, virus laboratory, University of California. Dr. Joseph W. Pisani, on leave of absence from the State University College of Medicine at New York City, where he is assistant dean, is serving as executive secretary of the committee.

Current Status of Parasitic Diseases

By WILLARD H. WRIGHT, Ph.D.

THE past few decades have witnessed a remarkable advance in public health standards in the southeastern United States, and along with this advance changes have been recorded in the incidence of most parasitic infections. Other than the virtual disappearance of malaria, to which the insecticide DDT has contributed in no small measure, most of the gains have not been associated with any spectacular medical discovery.

The decline in hookworm disease is a case in point. Stiles (1), who awakened the consciousness of the south concerning this disease and who was responsible for much of the early control effort, believed that the important factors in the decline in hookworm disease were associated with the advent of the automobile, good roads, better schools, industrial expansion, higher economic status, and improved sanitation. These factors are even more potent influences today than they were more than two decades ago. Regardless of the responsible elements or the operative mechanism, it is interesting to trace the changes since 1910 and to analyze the present status of human parasitic infections in this area through such data as are available.

Sources of the Data

The more recent information concerning the incidence of intestinal helminths has been

Dr. Wright is chief, Laboratory of Tropical Diseases, and assistant director, National Microbiological Institute, Public Health Service, Bethesda, Md.

placed at my disposal by the directors of the State health department laboratories or other State officials. The data for 1930-38 have been taken from the extensive surveys conducted by the department of preventive medicine of Vanderbilt University School of Medicine and summarized by Keller, Leathers, and Densen (2). The figures for 1910-14 are from the reports of the Rockefeller Sanitary Commission. In certain instances, material has been abstracted from reports of State health officers.

Morbidity data on amebiasis and trichinosis have been extracted from records of the National Office of Vital Statistics, Public Health Service. Information concerning the incidence of *Trichinella spiralis* represents a summary of all diaphragm examinations reported by various investigators. The material covering malaria morbidity and cases appraised during 1948-53 was compiled by the Communicable Disease Center, Public Health Service.

The validity of some of the comparisons made in this paper is subject to question because of many variable factors. The surveys were made by many different individuals and different techniques were utilized. There is no certainty that the samplings came from the same areas in the various States or that similar population groups are represented. Regardless of these limitations, a comparative presentation of data for various periods is warranted, and in many cases the comparisons are of considerable significance.

Ascaris lumbricoides

The classic report of Otto and Cort (3) summarized the information regarding the dis-

tribution of *Ascaris lumbricoides* infections in the United States up to 1934. The high incidence areas were defined by these authors as the southern Appalachian plateau with its foothills and contiguous valleys, isolated areas in the coastal region of North and South Carolina, and areas in Florida, Arkansas, and central and south Louisiana. The highest incidences recorded have been from the mountainous regions of Kentucky, Virginia, and Tennessee.

The latest available data on the incidence of *A. lumbricoides* infections in certain southeastern States are summarized in table 1. The figure for Kentucky is strikingly higher than that for any other State, and Florida and Louisiana follow in order. These figures are then consonant for the most part with the summation of Otto and Cort 20 years ago.

A comparison between the recent incidence of ascariasis in various southeastern States and the data for 1929-38 also appear in table 1. The data indicate a decided improvement in the situation with regard to this parasite except in Florida, which now shows a higher incidence than that reported for 1937-38.

Zoonotic Larval Ascariasis

Zoonotic larval ascariasis is also known as visceral larva migrans. During recent years a number of reports, some from the southeast, of a clinical syndrome associated with hepatomegaly and pathological foci in the liver believed to be due to invasion by ascarid larvae

have appeared. In most cases an intermittent fever is present. There is usually a history of nausea, vomiting, anorexia, irritability, cough, and loss of weight. In cases with pulmonary involvement, roentgenograms may show transitory, shadowy infiltration. There is marked anemia, a striking leukocytosis, and a high eosinophilia. Liver function tests frequently show deviation from the normal. In cases in which laparotomy has been performed, the liver has been found to be studded with white plaques of scar tissue.

Perlingiero and György (4), Zuelzer and Apt (5), Mercer and associates (6), and Behrer (7) were the first to describe these cases, which have occurred mainly in young children. Most of these authors associated the condition with larvae of *A. lumbricoides*. However, Beaver and associates (8) were of the opinion that the three observed by them were due to the larvae of *Toxocara canis*, the most common of the two species of ascarids infecting the dog. Since that time, the larvae of the cat ascarid, *Toxocara cati*, have also been incriminated.

Wright (9) showed that the life cycle of *T. canis* is similar to that of *A. lumbricoides*. However, in abnormal hosts the larvae have a pronounced tendency to wander extensively in various tissues without necessarily completing the entire life cycle. According to Mendheim, Scheid, and Schmidt (10), the adult cat ascarid, *T. cati*, has been found 18 times in man, but only 1 authentic case involving a mature infection with the dog ascarid, *T. canis*, is on rec-

ord for man. Regardless of the fact that these worms seldom develop to maturity in man, children especially are no doubt often exposed to the infective ova. The potential exposure must be considerable since it has been estimated that there are in the United States some 22 million pet dogs and 11 million domestic cats, the majority of which at one time or another probably become infected with *Toxocara*.

Although perhaps not directly related to zoonotic larval ascariasis, the cases of nematode endophthalmitis reported by Wilder (11) present another indictment against nematode larvae as disease agents. Wilder reported 46 cases in which nematode larvae were found in 24 of the enucleated eyes and a characteristic reaction in the other 22. With few exceptions, the 46 patients were children, the greatest number being from the southeast. While Chitwood identified the larvae as hookworm larvae, recent findings concerning conditions due to *Toxocara* larvae would leave the suspicion that perhaps these larvae are involved in cases of endophthalmitis.

Trichuris trichiura

While the general factors responsible for the transmission of *A. lumbricoides* are applicable to *Trichuris trichiura*, the ova of the latter have a much higher moisture requirement for their development and are less resistant to desiccation (12). The incidence of *T. trichiura* infection is usually higher in tropical and subtropical areas with heavy rainfall than in the temperate zones, where conditions in the ex-

ternal environment are less favorable for the ova. Even in the mountains of Kentucky, where conditions were once extremely favorable for transmission of both parasites, Keller and Leathers (13) obtained an incidence of 40.8 percent for *A. lumbricoides* and an incidence of only 12.1 percent for *T. trichiura* infections. Recent data concerning the occurrence of the latter parasite in certain southeastern States and data for 1930-38 are shown in table 2. Relatively low indexes were recorded in all States represented, with the highest recent incidence in Louisiana. The relatively heavy rainfall and high humidity in parts of Louisiana may provide favorable conditions for the development of the ova of this parasite.

Hookworm Infection

At one time hookworm disease constituted a serious public health problem in the southeast and was responsible for much physical and mental retardation. The current incidence is relatively low (table 3). Florida shows the highest incidence of all southeastern States represented, followed in immediate order by Georgia, North Carolina, and Alabama. The marked reduction which has taken place in the incidence of hookworm infection since 1910-14, the days of the Rockefeller Sanitary Commission and since the survey conducted by Vanderbilt University in the 1930's is shown in table 4. It is not possible to arrive at any definitive evaluation concerning changes in the intensity of the infection over the past 40 years because efforts to ascertain the relative worm burden

were not made during the 1910-14 surveys nor are such data available for the recent period. However, the available evidence would indicate that there has been over the period in question a marked reduction in the worm burden. Keller, Leathers, and Densen (2) found that about one-fourth of the individuals in their 1930-38 surveys had infections sufficiently severe to produce clinical symptoms. Hood (14) stated that in Florida there had been a

Table 3. Incidence of hookworm infection in 9 southeastern States as revealed by examinations by State health department laboratories

State	Period	Number of examinations	Number positive	Percent positive
Alabama-----	1953-54	83,901	9,936	11.8

South Carolina-----	1951-54	25,239	2,022	8.0
Tennessee-----	1950-54	23,529	460	2.0

marked diminution in the intensity of infection during the 10 years previous, and noted that in western Florida only 7.7 percent of infected children had moderate to heavy infections. Hosty and co-workers (15) stated that in Alabama the typical clinical case is rarely seen.

Creeping Eruption

Creeping eruption is an annoying but not a serious condition caused by the migration, through the skin, of infective larvae of the dog and cat hookworm, *Ancylostoma braziliense*. It occasionally comes to maturity in man in certain parts of the tropics. The condition is associated with papular formation and tortuous or serpiginous, subepithelial burrows with later vesiculation. The larvae may continue to migrate for weeks or months. Infection is contracted when parts of the body come in contact with infested soil.

Since creeping eruption is not a reportable disease, the frequency of its occurrence is not known. However, physicians along the south

Atlantic and gulf coasts are called upon to treat many cases annually. In 1949 Donaldson, Steele, and Scatterday (16) sent questionnaires to 1,100 Florida physicians, of whom approximately 50 percent replied. These physicians had seen, within a 6-month period, more than 8,000 cases of the disease. These authors conducted surveys of hookworm infection in dogs and cats in Florida; of 495 dogs examined 44.2 percent were infected with *A. braziliense*. Seven of 26 cats were positive. Of the 495 dogs, 86.1 percent carried one or both hookworm species, *A. braziliense* and *Ancylostoma caninum*. The larvae of the latter species may also be involved in the causation of creeping eruption. The opportunities for exposure to dog and cat hookworm larvae would seem to be exceptionally good, particularly along the Atlantic and gulf beaches.

Amebiasis

In 1950, Wright reported on the public health status of amebiasis in the United States and pointed out the factors which account for a considerable variability in reporting (17). Because of these factors, there is some question whether morbidity reports accurately reflect the occurrence of the disease. At that time it was pointed out that amebiasis was more prevalent in the West South Central States, Arkansas, Louisiana, Oklahoma, and Texas, than in any other part of the United States. There was also evidence that the disease was more widespread in the southern States as a

whole than in any other section, with the possible exception of the Pacific Coast States.

The number of cases reported in certain southeastern States for various years since 1933 when the occurrence of the disease was first recorded by the Public Health Service is presented in table 5. If these figures could be relied upon at all, they would indicate a gradual reduction of cases in this part of the country. The erratic figures from Mississippi are accounted for by a change in reporting methods in 1947; reports prior to that time were probably inaccurate.

The results of stool surveys for *Entamoeba histolytica* in various population groups in the southeastern States prior to 1945 (table 6), may be compared with the findings of such surveys carried out since 1945 (table 7). Table 8 summarizes the data in tables 6 and 7. The overall incidence of the parasite prior to 1945 was 10.9 percent and that from 1945 to 1954 was 10.5 percent. Thus, insofar as stool examinations are concerned, there is no indication of any marked decline in the incidence of the infection in the population of the south-

eastern States within the past 10 years. These data are certainly not in conformity with the morbidity reports. Several explanations might be offered to account for this discrepancy, but since no factual data are available to support any one of them, they would constitute mere speculations.

Restudy of Intestinal Parasites

Because of the numerous variables which are recognized as influencing certain comparisons in this presentation, it is of interest to review the data presented by Jones, Smith, and Eyles (18) concerning a restudy of intestinal parasitic infections in a Tennessee community 21 years after a previous survey. Jones was responsible for the technical work in the recent investigation and was also largely responsible for the examinations in the 1930 survey (19). The samplings included many of the same people who were sampled in the former survey. Comparative findings of the principal parasites in the two periods are summarized in table 9. The figures indicate a substantial reduction in

parasite incidence over the 21 years. The difference in prevalence appeared to be due primarily to a lower current incidence in the adult population. No special efforts were made during the period represented to reduce the parasite burden of the community, and improvements must be regarded as accruing from economic and general sanitation advances.

Trichinosis

A number of surveys involving the examination of the diaphragm for *T. spiralis* among persons coming to necropsy in the southeastern States have been conducted by various individuals. The total number of diaphragms examined were 2,233, of which 323, or 14.5 percent, were positive for the parasite (table 10). This incidence figure is only slightly lower than that encountered by Wright, Kerr, and Jacobs (20) in 1943 in the examination of 5,313 diaphragms from 37 States and the District of Columbia, of which 855, or 16.1 percent, were positive.

<i>Entamoeba histolytica</i>	38. 1	22. 4

¹ Reference 19. ² Reference 18.

The number of reported clinical cases of trichinosis in the region is not impressive, as indicated in table 11, and is certainly not correlated with the infection rate as revealed by the diaphragm surveys. In fact, the southeastern States rank well below many other parts of the United States in the number of reported clinical cases of the disease. This may be due to failure of diagnosis or failure to report some cases but is probably more closely related to food habits and a lower incidence of the parasite in southern swine (21). At any rate, if we are to judge correctly from the available data, trichinosis would not seem to constitute an important health problem in the southeastern States.

Toxoplasmosis

Toxoplasmosis is still an obscure disease, and little is known concerning its prevalence or mode of transmission. Clinical cases have occurred in the southeastern States, but since the disease is not a notifiable one, there is no record concerning the number of such cases. The only available data which throw light on the occurrence of infection in this part of the country are those derived from the application of the Sabin-Feldman dye test. Feldman (22) tested 270 individuals from New Orleans, La., of whom 84, or 31.1 percent, showed a positive reaction in a titer of 1: 16 or greater. Gibson and associates conducted dye tests on 987 individuals from the rural Negro population of Fayette County, Tenn., of whom, he wrote in a personal communication, 27.5 percent were positive. Exclusion of positive serums with titers of 1: 4 or

Table 10. Incidence of *Trichinella spiralis* infections in the population of 10 southeastern States as indicated by findings on diaphragm examinations

State	Number diaphragms examined	Number positive	Percent positive
Alabama.....	434	148	34.1
Florida.....	15	2	-----

South Carolina.....	15	1	-----
Tennessee.....	250	29	11.6
Virginia.....	133	11	8.3
Total.....	2,233	323	14.5

below reduced the overall incidence by about 8 percent. In a personal communication, Jacobs wrote that he conducted tests on 207 individuals from Norfolk, Va., and found 42 percent positive with a titer of 1:16 or more.

If dye test results are indicative of past or present infection with *Toxoplasma gondii*, and the tests are believed to have considerable validity in this respect, the limited data would indicate that toxoplasmic infection is far from uncommon in the southeast. In addition to congenital toxoplasmosis and acquired post-natal disseminated clinical infections, the role of the organism in the production of chorioretinitis and uveitis (23) indicates that toxoplasmosis may well prove to be a disease of considerable public health importance.

Positives all confirmed by blood smear for 1948. ³ Clinically and epidemiologically consistent with malaria, confirmed by positive blood smear. ⁴ Clinically and epidemiologically consistent with malaria, not confirmed by positive blood smear. ⁵ Case records on file at the Communicable Disease Center. Many cases of foreign origin investigated by State epidemiologists are not included. ⁶ Provisional data through Dec. 18, 1954.

Malaria

The rapid decline and the virtual extinction of malaria in the United States should stand as a fitting monument for all time to those who participated in the campaign, and to all who were engaged in the research and development which contributed to its success.

Great strides were made toward control of the disease during the war years through the Office of Malaria Control in War Areas. The national malaria eradication program was activated on July 1, 1947 (24) as a cooperative effort on the part of the States and the Public Health Service. As the campaign gained momentum substantial reductions were made in the number of reported cases, a trend which was interrupted only during 1951 and 1952 following the return from Korea of military personnel infected with *Plasmodium vivax* (table 12). When this threat was removed, the number of cases continued to drop, so that by 1954 there were only 8 confirmed primary indigenous cases and 1 presumptive primary indigenous case in the entire country.

The southeastern States, formerly the hotbed of malaria, are now practically free of the disease. Thus there has been conquered, probably for all time, the most serious of the parasitic diseases which have plagued this part of the country since the earliest of colonial days.

Conclusions

The data presented certainly warrant the general conclusion that remarkable declines have been registered in the incidence and intensity of certain parasitic infections in the southeastern United States. In most areas, intestinal helminths are much less prevalent than they were two decades ago. On the other hand, there appears to have been no marked reduction in the incidence of *Entamoeba histolytica*, although the number of reported cases of amebiasis seems to be on the decline. Trichinosis does not appear to be important in this area. The virtual eradication of malaria has eliminated one of the most serious health problems of the southeast. Zoonotic larval ascariasis and creeping eruption, conditions which are due to larval forms of certain dog and cat parasites, are still prev-

alent in the area; the former will probably be recognized with increasing frequency. Nematode endophthalmitis and toxoplasmosis are known to occur and may also prove to be of increasing importance.

While improvements are obvious, the situation does not warrant complacency. Health is a relative state. A heavy parasite burden is no doubt deleterious, but we cannot be equally certain that a few parasites are entirely innocuous. There are probably many implications of parasitism of which we are not aware. There is increasing evidence, for instance, that certain parasites may be the means of transporting other disease agents. The classic discovery of Shope (25) that the swine lung worms, *Metastrongylus apri* and *Metastrongylus pudendotectus*, carry the virus of swine influenza; the findings of Syverton, McCoy, and Koomen (26) that the larvae of *Trichinella spiralis* are capable of transporting the virus of lymphocytic choriomeningitis; and the recent disclosure by Mochizuki, Tomimura, and Oka (27) that *Toxocara canis* larvae can open the blood-brain barrier and pave the way for the localization of the virus of Japanese B encephalitis should make us hesitate to deprecate too quickly the health hazards of even a modest parasitic invasion of the human body. As Hardy (28) has so aptly stated, "Optimum health, not the mere absence of obvious illness, is the objective of public health and obstacles to the attainment of this goal must be removed. The individual has a right to be free of parasites. . . ."

Veterinary Parasite Problems

By W. S. BAILEY, D.V.M., Sc.D.

PARASITISM has exerted a tremendous influence on the livestock industry of the southeastern United States. The story of cattle tick fever and its eradication is a familiar one. Other parasitic infections of a less spectacular nature have continued to plague our livestock, usually in the form of inapparent or undiagnosed chronic infections. Such infections tend to attract little attention until an acute clinical outbreak occurs. Certainly parasitism in the domestic animals is not a problem peculiar to the southeastern States, but a number of factors (1) contribute to make many of our problems of greater magnitude than in other areas of the United States.

The very large number of parasites of domestic animals in the southeastern States vary greatly in their distribution, incidence, and pathogenicity. It is difficult to present an accurate, brief account of the veterinary parasite problems. This is particularly true since our knowledge of these parasites is, in many instances, incomplete or entirely lacking. The task is seen to be more difficult when one realizes that the line of demarcation between clinical and subclinical, or latent, parasitism is variable, influenced by a number of factors in the host-parasite relationships. Consequently, many parasites not generally considered to be primarily pathogenic may be of importance in a particular disease of an individual or group of animals.

Dr. Bailey is head professor, department of pathology and parasitology, School of Veterinary Medicine, Alabama Polytechnic Institute, Auburn, Ala.

Specific parasite problems will be discussed by the host relationship. No attempt will be made to rank the infections according to importance or to catalog all of the parasites that may be present as major factors. Rather, a brief summary of internal parasitism in the different animals will be presented, and one or more entities will be discussed in greater detail because of differences in incidence, greater economic importance, or biological interest.

Cattle

During the past 10 years there has undoubtedly been a greater change in parasitism of cattle in the southeast than in any other host and probably than in any other area. The most striking aspect of this change has been the common occurrence of clinical parasitism in mature animals. The figures below illustrate the marked increase in clinical parasitism in southern Georgia as determined at autopsy by Andrews, Sippel, and Jones at the Tifton, Ga., experiment station (2).

Year	Percent of cattle with clinical parasitism
1945-50	Negligible
1950-51	6
1951-52	11
1952-53	17

From March 21, 1952, to June 2, 1953, 14 animals, aged from 6 months to 10 years, were found to have been suffering from clinical parasitism at autopsy. The animals were from 10 farms on which there was a death loss of 5 percent of 1,900 animals.

Although the criteria are not exactly the

same, and, no doubt, evaluators differ somewhat, these figures appear to be rather close to those given in the following table taken from the autopsy records of the department of pathology and parasitology, School of Veterinary Medicine, Alabama Polytechnic Institute. The diagnosis for 11.1 percent of 422 cattle autopsied was primary parasitism, and the diagnosis for an additional 5.6 percent of these cattle was secondary parasitism.

The results of Cooperrider's study (3) on the economic losses in cattle due to internal parasitism further emphasize the common occurrence and great importance of clinical parasitism of cattle in this area. We would be amazed if we could but know the magnitude of the loss resulting from combined clinical and subclinical parasitism of cattle in the southeast.

These losses are due primarily to infections with the stomach worms, *Haemonchus*, *Ostertagia*, and *Trichostrongylus*. These natural infections are almost always in the form of a parasitic gastroenteritis, with certain intestinal parasites contributing to the disease. In some instances the intestinal parasites are the primary cause of the syndrome.

There is relatively little information on the number of these parasites required to produce clinical parasitism and death. This is mainly because parasitic infections may be parts of more complex diseases in which malnutrition and concurrent or previous infections with

other pathogens play major roles. Rarely will one find infections with more than 10,000 *Haemonchus*, but as many as 300,000 immature *Haemonchus* have been reported. The presence of 50,000 to 75,000 *Ostertagia* or *Trichostrongylus*, or both, is apparently sufficient to cause severe symptoms and death in some animals. Recent reports include a number of cases with from 200,000 to 500,000 of these worms, and as many as 1,100,000 have been found. In these massive infections a large percentage of the worms often are immature.

All three of the stomach worms are blood-suckers and anemia of variable degree is a characteristic symptom of *Haemonchus* and *Ostertagia* infections. Digestive disturbances, usually in the form of a persistent diarrhea, are almost constantly present. There is a great need for additional information on the host-parasite relationships of these worms, especially with regard to pathogenesis and immunity.

The intestinal helminths contributing most to general parasitic gastroenteritis and which may be primarily responsible for the disease under certain conditions are: *Cooperia* spp.; *Bunostomum phlebotomum*, the cattle hookworm; *Nematodirus* spp.; and *Oesophagostomum radiatum*, the nodular worm.

There are a number of other helminths in the intestines of cattle, but they generally are of little pathogenic importance in the southeast. One or two of these should be mentioned, however. *Neoscaris*, the cattle ascarid, may be a problem in individual herds. It apparently is found more in scattered herds in Louisiana and Florida than in any other of the southeastern States. The anoplocephaline tapeworms, *Moniezia* spp., are quite common but appear to be relatively nonpathogenic. There is, however, the tendency to attribute damage produced by the minute parasites to these large ones.

Coccidiosis continues to be an important problem in many herds. Of the 10 species occurring in cattle in this area, *Eimeria zurnii* and *Eimeria bovis* are the most pathogenic, but some of the others may contribute to, or be primarily responsible for, the infection. As is true with the worm infections, older animals may also have clinical coccidiosis.

Fasciola hepatica infections have been diagnosed in a number of the southeastern States.

Primary and secondary parasitism as found at autopsy at the Alabama Polytechnic Institute, May 1, 1953, to Mar. 18, 1955.

Host	Number animals autopsied (all ages)	Primary parasitism ¹		Secondary parasitism ²	
		Number	Per cent	Number	Per cent
Dog.....	532	38	7.2	23	4.3
Cat.....	51	3	6.8	2	3.9
Sheep and goat.....	52	8	15.3	1	1.9
Cattle.....	422	47	11.1	24	5.6
Equine.....	46	3	6.5	2	4.3
Hog.....	186	5	2.6	7	3.7

¹ Considered the primary cause of death. ² Considered to be a contributing factor to the illness and death of the animal.

At the present time the only State east of the Mississippi River in which *Fasciola* infection is considered to be of any appreciable importance is Florida. *Fascioloides* infection is probably much more widespread than reports indicate. Although many deer in certain areas of Alabama are infected, the first bovine case came to our attention last year. It is not known if the case was an autochthonous infection.

Lungworm infection is quite widespread in the southeast, and is especially important in the low, wet areas which provide an ideal environment for the larvae. Heavy infections often result in severe bronchitis and death. We do not appear to have in the area the "atypical" lungworm infection of mature cattle described recently by the English workers (4), but the possibility of this should not be overlooked, especially in the wet areas.

Bovine genital trichomoniasis, caused by *Trichomonas foetus*, has been diagnosed in practically all the States. This disease does not appear to have caused as much trouble in most southeastern States as it has in the more heavily concentrated dairy areas of the midwest. In individual herds in any of the States, however, it may be of great economic importance. Until 1954 we knew of no definite diagnosis of this infection in Alabama. Our first diagnosis was made in a herd into which bred heifers were brought from a midwestern State. Since that time the infection has been diagnosed in three additional herds and probably exists in a number of others.

Although the exact classification of the etiologic agent of anaplasmosis is unsettled, it is included with the parasitic diseases in this discussion. In some of the southeastern States anaplasmosis is currently of only spotty distribution and little importance. However, South Carolina, Florida, Mississippi, and Louisiana may truly be referred to as enzootic areas. The incidence and distribution of this disease is intimately related to, but not limited by, the density of the several arthropod vectors which may transmit it.

Sheep and Goats

The prevalence of internal parasites was a major factor in the decline of the sheep in-

dustry in a number of southeastern States in years past, and the promise of better control measures has contributed to an increase in the sheep population in recent years. Since many of the problems are much the same as for cattle and are produced by the same or closely related species of parasites, no separate discussion for these hosts will be given in this general and brief review.

Swine

A number of the gastrointestinal parasites of hogs are not appreciably different in the southeastern States from most of the rest of the country, although the intensity of infection may be somewhat heavier. The stomach worms are widely distributed, but are not often primarily responsible for trouble. The hog ascarid is also widely distributed and of major importance. Undoubtedly many of the factors relating to the distribution and epidemiology of the human ascarid are also operative in this infection.

The thorny head worm of hogs is not as widely distributed as the ascarid but may be an important problem in given herds, in which control is difficult. Occasionally, death occurs from light infections due to peritonitis resulting from perforation of the intestinal wall by the proboscis. Of the several species of nodular worms infecting the hog, only one, *Oesophagostomum dentatum*, appears to be widely distributed in this country. The others are somewhat restricted to the southeastern States. Lungworm infection is quite common and is often the cause of respiratory symptoms and even death.

The kidney worm of hogs, *Stephanurus dentatus*, is of little importance outside the southeast. In fact it is only in the lower tier of States and up the Atlantic seaboard to Virginia that the infection is of any great significance. In these areas, however, it is still a major problem, and losses occur in a number of ways. The loss most easily determined is that due to condemnation or trimming of parts of carcasses at the killing abattoir.

According to a personal communication from J. A. Langford a heavy infection with the larval stage of *Diphyllbothrium* (*Spirometra*)

mansonoides was diagnosed in a range hog in Florida recently.

Poultry

Little will be said about poultry parasites. The common gastrointestinal helminths and protozoa are widely distributed and of variable importance throughout the southeast.

Leucocytozoon smithi infection of turkeys appears to be quite common in many parts of the southeast, as evidenced by the observations of a number of workers (5-8). Bierer (8) indicates that this is primarily a disease of the tide-water area along the eastern seaboard. Recent outbreaks in South Carolina have been particularly striking. Wild turkeys apparently served as a reservoir of infection. The disease may be very acute and highly fatal as described by Stoddard and associates (7), who reported 75 percent mortality of 1,600 birds in 7 days, or it may be more insidious and with low mortality. The latter outbreaks may be associated with the breeding season in which case there seems to be a greater mortality in toms than in hens.

Equines

With the decrease in the horse and mule population, a number of the parasite problems in these animals have become less marked but have by no means disappeared. Bot infections are still very common, and marked gastritis due to infections with *Trichostrongylus axei* is quite common. The latter is not surprising in view of the increasing importance of this parasite in ruminants, inasmuch as there is good evidence that cross transmission occurs. Cutaneous habronemiasis is seen much less than in earlier years. However, this disease may constitute a problem on even the best of farms if the animals are infected with the adult worms and there is a high transmission potential because of an abundant fly population.

The most important intestinal parasites are the ascarid, *Parascaris equorum*, and the strongyles, particularly the large strongyles, *Strongylus vulgaris*, *Strongylus edentatus*, and *Strongylus equinus*. Ascarid infections are usually of clinical significance only in young

animals. In addition to the bloodsucking activity of the large strongyles, the parasitic aneurysm produced by *S. vulgaris* is of great importance. This aneurysm, with the resulting thrombus formation, of the anterior mesenteric artery may cause a variety of intestinal disturbances, and frequently results in death. Pinworm infection may constitute a problem in individual or groups of animals, but it generally is of little pathogenic importance.

Dogs and Cats

Spirocerca lupi, the dog esophageal worm, appears to be very rare in this country except in the south. Over a period of approximately 4 years we have found slightly over 4 percent of 943 dogs of all ages infected (9). Since this includes a large number of puppies, the incidence in dogs old enough for the life cycle to have been completed would be appreciably higher. Only a small percentage of the dogs infected with *Spirocerca* show clinical symptoms. However, this infection takes on added interest and importance in view of the recent report by Seibold and associates (10) that it may be an inciting cause of the development of malignant esophageal tumors of the dog.

A number of intestinal helminths are very widely distributed, not only in the southeast but in much of the Nation, and some are highly pathogenic. We have no comprehensive figures on the incidence of *Strongyloides* in the dog in the southeast, but it is certainly more common than the reports indicate. It is often the cause of respiratory symptoms and intestinal disturbance, and the mortality rate in heavily infected puppies is quite high. Although the worm is apparently indistinguishable from *Strongyloides* of man, it is likely that man does not easily become infected with the dog form.

The hookworms, *Ancylostoma caninum* and *Ancylostoma braziliense*, continue to take a heavy toll of our young dogs. Prenatal infections are very common and highly pathogenic. Some of the heaviest infections have been in mature dogs concurrently suffering with some other disease.

Roundworm infections are very common, especially in young dogs, with prenatal infection

again being of great importance. *Toxocara canis* is the one most often encountered.

Light tapeworm infections are found in a high percentage of dogs, and heavy infections are common. *Dipylidium caninum* is the one found most often in this area, but *Taenia taeniaformis* and *Taenia pisiformis* are not uncommon and seem to occur most often in the cat. There is a recent report of natural infection of dogs with *Echinococcus granulosus* in Mississippi (11). The public health importance of this needs no elaboration.

Pseudophyllidean tapeworms appear to be rare in dogs in this area. *Diphylllobothrium latum* has been reported from Florida. *D. (Spirometra) mansonioides* has been reported from Louisiana and, during the past year, from the Alabama-Georgia area (12). Langford, who recently sent us the larvae of this parasite from a hog, in his letter reported finding a number of cases of *Diphylllobothrium* infection in dogs and cats.

Light to moderate infections with the whipworm, *Trichuris vulpis*, are common in the dog, and occasionally very heavy infections are encountered in which the parasite is apparently the cause of death. In such cases, not only is the cecum filled with worms, but the entire surface of the colon is covered.

A number of intestinal protozoa are commonly found in the dog. Eyles and associates (13) have recently reported finding 8.4 percent of 143 dogs in Memphis, Tenn., infected with *Entamoeba histolytica*, using cultural methods. We certainly agree with their observation that cysts of *E. histolytica* are almost never passed and that the trophozoites are passed in small numbers in the feces of dogs.

Shown below are the protozoan infections found by direct smear examinations at the small animal clinic, Alabama Polytechnic Institute, from September 1953 to May 1954. Of 871 dogs examined, 193, or 22 percent, were found to have protozoan infections, although there may have been more than one infection per dog.

	Number	Percent
<i>Giardia</i>	75	8.6
<i>Trichomonas</i>	57	6.5
<i>Isospora</i>	44	5.0
<i>Entamoeba histolytica</i>	7	.8
<i>Entamoeba coli</i>	1	.1
<i>Balantidium</i>	9	1.0

Each of the seven dogs infected with *E. histolytica* showed a characteristic profuse diarrhea, continuous or intermittent and often of long duration. In the *E. coli* infection, cysts were being passed, and this dog was concurrently infected with *E. histolytica*. Only a small percentage of the dogs infected with *Giardia* showed symptoms attributable to the organism. It is possible even in these cases that the symptoms are not due solely to the protozoan. There is evidence (14) suggesting that a combined *Giardia* (protozoa) and *Pseudomonas* (bacteria) infection may be quite pathogenic in the chinchilla. The intestinal trichomonads are common in the dog, and the incidence figure rises rather markedly when cultural methods are used in diagnosis. Here again the organism appears to be associated occasionally, apparently in some causal relationship, with a severe diarrhea, which may also be of long duration.

Even though occurring in a low percentage of dogs, *Balantidium* infection is much more common than we had earlier suspected. It appears to be pathogenic in the dog in practically every infection. Light infections with the dog coccidia are common, and when animals, especially puppies, acquire heavy infections, marked symptoms and death may result. In Georgia, 2 of 3 recently reported cases of human infection with *Isospora* appeared to be related to an infection in the family dog (15).

Although we probably have more information on the distribution of *Dirofilaria immitis*, the dog heartworm, than on almost any other of the parasites of veterinary importance in the southeast, its distribution still has not been well defined. The infection is obviously quite common in many areas where it is not present at disease-producing levels. The presence of adult worms in sufficient numbers to result in clinical infection is evidence of a high transmission potential. On the basis of current information this appears to be common in the southeast only along the seacoast. There are inland areas where the transmission potential is sufficiently high to result in the presence of moderate numbers of adults and even in some instances in clinical infection, as emphasized by Eyles and associates (16) in their recent study in the area of Memphis, Tenn. Auburn, Ala., is a good

example of an area with low transmission potential. In a recent limited survey it was found that microfilariae could be demonstrated, using concentration procedures, in approximately 37 percent of the dogs. Our autopsy records of the past 5 years have not been summarized to give the incidence of adult worms, but it certainly is appreciably lower than the 4 percent found in Memphis. The only clinical cases which have come to autopsy in recent years were sent to us from coastal areas where the infection is certainly a major problem.

There are a few reported cases of the giant kidney worm, *Diocotophyma renale*, in the southeastern States (17). There appears to be a small enzootic area in southeast Georgia.

We do not know how common canine toxoplasmosis is in the southeast. Serologic tests made elsewhere indicate that inapparent or otherwise undiagnosed cases are quite common, as in other animals. From July 1954 through March 1955 we autopsied 148 dogs, of which 6, 4 percent, were diagnosed as toxoplasmosis, or toxoplasmosis together with distemper. In addition to these cases from autopsy, all of which were from Alabama, we have made a diagnosis during this period of toxoplasmosis from at least one place in Florida, Georgia, South Carolina, Virginia, and Tennessee by the histological examination of tissues sent to us by practicing veterinarians.

The cat lungworm *Aelurostrongylus abstrusus*, has been reported from Maryland, Virginia, North and South Carolina, Georgia, Tennessee, and Alabama (18). In these States although there are few reports of the infection, mostly only 1 or 2, many of these are fatal infections. Probably the infection is much more common than published reports indicate, as suggested by the recent finding of the infection in 6 of 50 cats in a Virginia county.

Information Needed

There are many different aspects of these and other infections that could profitably be discussed. This very incomplete account will be closed by pointing out the general needs with regard to veterinary parasitology in the southeast.

1. More information on the distribution and

incidence of parasitic infections to determine more clearly the true nature and extent of the problem.

2. Better use of the information currently available in the control of these parasites.

3. More information on the biology and host-parasite relationships of the many parasites common in the southeast, for only on this foundation can we build truly effective control programs.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of PUBLIC HEALTH REPORTS, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

Not all our readers receive the journal on the delivery date. An official copy is trickled down to them through a series of other readers. Sometimes the trickle slows to a complete halt.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Silicosis and Dust Control

—Vermont's Granite Industry—

By HARRY B. ASHE, B.S.

VERMONT granite is a heterogeneous mixture of approximately 60 percent feldspar, 30 percent quartz, 15 percent mica, and 5 percent miscellaneous silicates. Quartz is, of course, the black sheep of the group of minerals which comprise this monumental stone.

Pneumatic tools came into general use between 1895 and 1900, accompanied by a tremendous increase in dust production over that produced by hand tools. Industrywide dust control for all dust-producing operations had its beginning in 1937. Hence, the period of greatest dust exposure in the Vermont granite manufacturing industry is about 40 years.

A Bench Mark

The year 1937 is a bench mark in the Vermont granite manufacturing industry. A program of dust control for all dust-producing operations was put into effect by the industry. A division of industrial hygiene was created in the Vermont Department of Health, and for

many years it concentrated most of its efforts in improving working conditions in the industry. The division purchased a portable X-ray machine and began a yearly X-ray program, which is still in effect.

During the period 1924-26, dust exposures in this industry were reported by the Public Health Service to be about 1 to 200 million particles per cubic foot of air. Granite cutters who suffered the most severe exposure averaged an exposure of about 60 million particles per cubic foot of air (1). Since the beginning of plant-wide dust control in 1937, the dust exposure has been gradually reduced.

Recent dust counts in the industry indicate a general air dustiness of 1 to 2 million particles per cubic foot of air, with few individual operators exposed to greater than 5 million particles per cubic foot of air. Recirculation of dust collectors has been completely discontinued, and dry dust-producing operations in the industry are provided with an approved type dust collector. Every exhaust unit in the industry is inspected by the division of industrial hygiene at least twice a year, and detailed reports are sent to the individual manufacturer with a mandatory compliance order wherever corrections or improvements are necessary.

During 1937 and 1938 there was a very definite effort to encourage men to visit the division office for an X-ray at any time during their free hours. During that period, the division X-rayed 805 granite workers for the first time.

Mr. Ashe, director of the division of industrial hygiene, Vermont Department of Health, since 1946, served as program chairman of the American Conference of Governmental Industrial Hygienists, 1953-54, and as chairman, 1954-55. This paper was presented at the 17th annual meeting of the conference in Buffalo, 1955.

Table 1. Number of granite workers X-rayed, Vermont Department of Health, 1937-54

Total.....	3, 020	8, 032	11, 052

From 1938 to 1950, evening clinics were held for granite workers in the division office. Results are shown in table 1. However, many men were not availing themselves of this service provided by the State of Vermont, and in 1950 arrangements were made with the various manufacturers to set up our portable X-ray machine in their establishments so that men could be X-rayed on company time. By this change of procedure, 937 and 994 men were X-rayed in 1950 and 1951, respectively.

Mobile X-ray Unit

During the summer of 1951 we conceived the idea of constructing a mobile X-ray unit whereby our X-ray machine could be transported to every shed in the area and our service offered to the men at a distinct saving to the manufacturer. This unit was put into service in the fall of 1951 with an increase in participation of about 400 men a year.

The 26-foot trailer consists of a small room in the rear for occupational histories, a dark-room for changing films, an X-ray compartment in the middle, and a dressing room in the front. A 3,000-watt, 220, 110-volt generator supplies the power, and a State-owned auto-

mobile provides the transportation. Lead-lined plywood is used in the interior construction to protect operating personnel from stray radiation.

This mobile X-ray unit, designed to X-ray men in dusty trades at their place of employment, was put into operation in September 1951. It has traveled 8,000 miles and taken 13,776 X-rays. The industries covered are granite, marble, slate (quarrying and finishing); asbestos (quarrying and milling); talc (mining and milling); copper (mining and processing); foundries (gray iron). The cost of the unit follows:

26-ft. Travelo trailer, custom built, with furnishings	\$3, 072
Pickier portable X-ray machine, 15 ma., 8-step voltage control. 14" by 17" plates.....	1, 350
Pass box, cassette holder, cassettes, and other accessories	805
3,000-watt Onan electric plant, installed.....	910
State-owned automobile, overload springs, trailer hitch, accessories.....	2, 727
Total cost.....	\$8, 864

1937-1938

Approximately 2,400 men were employed in the Vermont Barre Belt granite manufacturing district in each of the years 1937 and 1938. Of the 805 men X-rayed, 365 had silicosis (45.3 percent); and 143 had silicosis with possible infection (17.9 percent).

All cases with definite X-ray evidence of nodular silicosis, whether it be early, moderately advanced, far advanced, or complicated with infection, are grouped together. In the category "silicosis plus possible infection," the infection is presumed to be tuberculosis. However, in these data (table 2) there has been no attempt to prove the existence of infection. It is very probable that a number of the men listed in this category have nothing more than a conglomerate silicosis. Some of them may have cavitation and positive sputa. For the purpose of this paper they are likewise grouped together.

1952-1954

The 3 years from 1952-54 have been taken for comparison with 1937-38 inasmuch as the

Table 2. Number of granite workers X-rayed and found to have silicosis, Vermont Department of Health, 1952-54

mobile X-ray unit was in operation during these years, and the greatest cooperation was received from both employer and employee. The data in table 2 indicate the proportion of persons in the Vermont granite manufacturing industry who were X-rayed during these years and found to have silicosis.

The gradual decrease in the incidence of silicosis from a high of 45.3 percent in 1937 and 1938 to a low of 16.2 percent in 1954 may be attributed to two causes: dust control and silicotics leaving the industry for one reason or another. The incidence of silicosis with possible infection has been reduced from 17.9 percent to 2.3 percent over the same period.

The X-ray program began in 1937. Consequently, there could be no backlog of X-ray data then. Hence, the data for the years 1937 and 1938 cannot be compared on the same basis with data for the years 1952-54. However, we believe, the data presented here demonstrate an apparent striking decrease in the incidence of this occupational disease in a very hazardous industry. The majority of the 2,400 men employed in the industry in 1937 probably had more than 10 years experience; only 34 percent of these were X-rayed, and 45 percent of those X-rayed were found to have silicosis. It is gen-

erally believed that if it had been possible to examine the chest X-rays of every man employed in the industry at that time the incidence of silicosis might even have been higher. In 1954, for contrast, of all the men on the payroll, 18.4 percent were found to have silicosis (or 19.8 percent of those who had X-rays). Participating in the program, however, were 90.6 percent of the employees.

Summary

Our X-ray program started in 1937. Dust control started the same year and has gradually improved ever since. The State health department has not to this day discovered a case of silicosis in any man who has worked only in the Vermont granite manufacturing industry since 1937. It is our contention that this remarkable record is mainly due to effective dust control within the industry.

Venereal Disease in Migrant Workers New Jersey, 1954

By ADELE C. SHEPARD, M.D., M.P.H., and WILLIAM J. PAGE, Jr., B.A.

ABOUT 18,000 migrant workers are required each year to supplement local labor in agriculture and in the food processing industries (1), the New Jersey Department of Labor and Industry estimates. This does not include the seasonal labor force necessary to meet the needs of resort areas, race tracks, and other industries which utilize migrant labor. In 1954, approximately 9,000 persons from Puerto Rico, 6,000 southern Negroes, and 3,000 workers of various types from neighboring cities came into New Jersey as migrant workers.

Examination of 3,401 migrant agricultural workers in New Jersey in 1953 showed a very high incidence and prevalence of venereal disease (2). The serologic survey of this group was continued in 1954 and, in addition, a survey was made of migrant race track workers and itinerant workers in the seafood industries. This report presents the results of the latter survey.

Generally speaking, migrant workers do not receive regular medical services (3). At best, the rural areas where they find employment usually have inadequate public health facilities

so that the extension of existing services to include migrant workers is minimal. Furthermore, the training of migrants is such that they often do not take advantage of even such assistance as is made available to them. The special migrant health program provided in New Jersey, therefore, is a product of necessity (4). The program is largely one of venereal disease control, although some attention is given to other health problems.

The first large groups of agricultural workers begin to arrive in New Jersey in May, although the majority do not appear until July. Permanent clinics have been established in three areas of heavy concentration of migrants, and a mobile unit operated for about 6 weeks during the peak season reaches more than half the persons tested each year. The remaining workers are tested at the permanent clinics. The staff of each clinic consists of professional, technical, and clerical personnel. During the period July 15–September 15, two additional persons are usually employed to contact farmers, contractors, and workers in order to promote clinic attendance. Although there is a legal requirement that workers obtain physical examinations, few of them actually apply for medical service until they are motivated by a personal visit from a member of a clinic staff.

In 1954, a total of 3,288 farm migrants were examined for venereal disease during clinic sessions. All persons over 12 years of age were tested serologically for syphilis and an inspection of mouth and genitalia was ordered on all

Dr. Shepard is chief of the bureaus of venereal disease control and acute communicable disease control, New Jersey State Department of Health. Mr. Page is health program representative in the bureau of venereal disease control.

males. All females with positive serologic tests for syphilis (STS), all contacts of both sexes to cases of venereal disease, and all individuals complaining of or manifesting obvious signs or symptoms of disease had a more complete examination. A presumptive diagnosis of venereal disease was permitted on the basis of objective clinical findings or one positive or doubtful result of the STS. No spinal fluid examinations were done. Routine treatment for syphilis was 4,800,000 units of procaine penicillin in oil with 2 percent aluminum monostearate (PAM) given in four sites in the buttocks during a single clinic visit; for gonorrhea, the treatment was 600,000 units of PAM.

Discovery Rate Decreasing

When summary data for 1954 are compared with summary data for 1953, there appears to be a decreasing discovery rate of venereal disease among agricultural migrants. Of the 3,288 farm migrants examined in 1954, 22.8 percent were reactive for syphilis (table 1). The proportion was 25.2 in 1953.

The number of diagnoses of infectious venereal disease also showed a decrease last year over the year before. A total of 198 patients with clinical gonorrhea was treated in 1953 and only 118 in 1954 (table 2). Similarly, 19 cases of primary and secondary syphilis were found during 1953, whereas only 9 such cases were seen last year.

The number of persons brought or returned to treatment for syphilis dropped from 406 in

1953 to 232 in 1954. Several factors might account for this decrease. Although in 1954, followup of persons with positive and doubtful blood tests was better than average for survey work—85.1 percent of the 758 suspects were brought to examination—the proportion was less than the 95.6 percent brought to examination in 1953 (table 3). In addition, many individuals were not treated because they were judged either to have had adequate treatment previously or not to be infected with syphilis. Records of previous blood tests and previous therapy for many individuals who return to New Jersey year after year are now accumulating to assist physicians in ruling out the need for treatment. Also, when patients with positive STS results give a fairly reliable history of previous treatment elsewhere, they are not required to return for re-treatment.

Epidemiological Study

With existing facilities, there is apparently no easy solution to the problem of thorough contact interviewing and investigation in the migrant labor group. In the migrant health clinics, thorough epidemiological study was very difficult for several reasons:

1. Space was inadequate for proper contact interviewing.
2. Lack of privacy reduced the effectiveness of interviewing.
3. In crowded clinic situations, physicians often failed to refer patients for interview.
4. Interviewers were often pressed into serv-

Table 1. Results of serologic tests for syphilis in migrant agricultural workers, by age group and sex, New Jersey, 1954

ice as clerks or technicians in order to process large numbers of patients during short clinic sessions.

To the extent permitted within these limitations, patients with infectious venereal disease were interviewed and their contacts were investigated (table 4). In the interview, particular emphasis was placed on eliciting the names of those contacts who were known to be in the migrant labor force in New Jersey.

Race Track Workers

In addition to those employed in agriculture, there is another group of migrants, the race

track workers, in which the State department of health has been interested for many years. The three large tracks devoted to horse racing operate for several weeks each year in an intermittent season running from May to October. Grooms, stable boys, exercise boys, jockeys, and concession employees follow the racing business in much the same manner as the migrant farm workers follow the harvest seasons. The Migrant Labor Law (4) makes it mandatory that these migrants be examined for venereal disease just as it requires that agricultural migrants be examined.

A total of 1,172 race track workers had sero-

logic tests for syphilis during 1954. Since many of the same workers were employed at each of the three race tracks during the course of the racing season, cards indicating that blood tests had been taken were given to them so that not more than one blood test would be required of each individual. Of the 1,172 workers tested, 180, or 15.4 percent, were reactive for syphilis (table 5). Of the reactors, 59, or 32.8 percent, were brought or returned to treatment. As in the agricultural migrant group, more than half of the suspects diagnosed as infected with venereal disease were declared previously adequately treated or as not infected with syphilis.

Sixteen cases of gonorrhea were found and treated.

Itinerant Seafood Industry Workers

Besides agricultural and race track migrants, approximately 1,000 seasonal employees of seafood industries were tested during recent months. A group of plants in South Jersey employ a physician to examine and treat their employees for venereal disease. Complete data are not available at this time concerning the outcome on approximately 750 persons thus examined.

However, the State department of health arranged for the testing of 243 individuals who were directly or indirectly associated with the seafood industry; 77 reactors were found, or 1 of 3 tested. Of these, 35 patients were treated for syphilis, including 2 children with congenital syphilis. Again, about half of the reactors had received adequate treatment for their infections prior to this survey. In addition, 3 males with gonorrhea applied for and received treatment.

Other Migrant Workers

Many thousands of migrants other than the groups reported are tested each year in New Jersey. The State department of health has urged hotels, manufacturing industries, and others who employ migrants to perform the required health examinations. The result of this emphasis has been that a major share of the responsibility for examining migrant workers has been assumed by employers.

Summary and Conclusions

In summary, the total number of migrants examined by the State department of health last year was 4,703, of which 1,006, or 21.4 percent, were reactive for syphilis. Of these sero-

positive and doubtful, 513 presented evidence of previous adequate treatment or were judged not to be infected with syphilis. Of those remaining, 326, including 11 cases with lesions, were given treatment, and 167 were lost to followup. In other words, approximately 1 in 5 migrants examined had a positive or doubtful test for syphilis and 1 in 14 received treatment. In addition, 137 patients with gonorrhea and 1 patient with chancroid were treated.

Results obtained in the survey of migrant laborers indicate that a very high incidence and prevalence of venereal disease still exists in the three groups examined—migrant agricultural, race track, and seafood industry workers—and that there can be no doubt of the necessity for continuing survey and treatment operations.

Sewage Treatment Plant Construction

Construction contracts for 169 projects to aid in stream pollution abatement were awarded by American cities in the first quarter of 1955. The contracts totaled \$59 million and covered 72 new plants and 97 additions, enlargements, or improvements for existing plants which provide treatment of sewage from municipalities, institutions, and other significant population centers.

Chiropteran Rabies in Montana

By J. FREDERICK BELL, M.D., W. J. HADLOW, D.V.M.,
and WILLIAM L. JELLISON, Ph.D.

A BAT was brought to the Rocky Mountain Laboratory of the Public Health Service by one of its employees on August 20, 1954. The bat, found in a flowerbed at the employee's home, revealed its presence by squeaking at approaching children. Suspecting a snake, the children called their father, who captured the bat without difficulty since it made no attempt to fly.

Upon cursory examination in the laboratory, it was apparent that the animal was weak. Since the bat vociferated when the children approached, it was probably irritable. After euthanasia with ether, the brain was removed and a suspension of approximately 10-percent concentration in serum-saline was prepared from one-half of the brain. Four mice were inoculated intracerebrally with 0.03-ml. portions of the suspension, and the remainder was frozen in sealed ampules. The other half of the brain was fixed in Zenker's fluid. After necropsy, the thoracic and abdominal viscera as well as the carcass were placed in 10-percent formalin.

On the 16th day after injection of brain suspension, 2 of the mice were found dead. The brains were removed, pooled, triturated in serum-saline, and dilutions of the suspension were used to inoculate other mice. The earli-

est signs of illness in the mice of this second passage were seen on the 11th day, and 6 mice injected with the 10^1 dilution were dead by the 14th day. A similar incubation period was observed in third-passage mice injected intracerebrally. A fourth passage by the intracerebral route resulted in a shorter incubation period in those mice injected with 10-percent supernate, inasmuch as the first signs of illness appeared on the 7th day and all 6 mice were dead by the 11th day. Typical Negri bodies were found in the brains of the mice from the first and second passages.

Virus in the bat brain was not titrated immediately, but at a later date some of the original frozen suspension was found to contain $10^3 LD_{50}/0.03$ ml. The incubation period ranged from 14 to 19 days.

Microscopic Findings

Histological sections of the bat brain stained by Lillie's buffered azure eosinate method revealed widespread regressive changes in the neurons as evidenced by their shrunken, distorted, and hyperchromatic appearance. The neuronal damage was most conspicuous in the thalamus and hypothalamus and in some areas of the cerebral cortex but was evident also in the hippocampal formation and in the Purkinje cells of the cerebellum. Inflammatory changes were not observed with the exception of a scanty lymphocytic accumulation around several meningeal vessels. There was moderate hyperemia of the meningeal and parenchymal vessels.

Dr. Bell is senior surgeon, Dr. Hadlow, a pathologist, and Dr. Jellison, a parasitologist, on the staff of the Rocky Mountain Laboratory, Public Health Service, Hamilton, Mont.

Typical round and oval Negri bodies were found in the pyramidal cells of the hippocampus and the cerebral cortex (see fig.), in the Purkinje cells of the cerebellum, and occasionally in the nerve cells elsewhere in the brain. The inclusion bodies, however, were largest and most numerous in the hippocampus. The largest measured 3.5–4.0 microns in diameter and contained distinct basophilic granules usually situated centrally in the inclusion and often surrounded by a prominent hypochromatic ring or halo. Individual neurons frequently contained several smaller, cytoplasmic inclusion bodies, measuring 1–2 microns. Some of these small inclusions appeared to be uniformly eosinophilic. The Negri bodies were found in apparently unaltered cells as well as in those showing marked regressive changes.

Microscopic sections of heart, lung, liver, spleen, kidney, and small intestine showed no noteworthy changes.

Identification of the Virus

In view of present widespread reports of rabies in Chiroptera (1), rabies was suspected when the first-passage mice became ill. The appearance of the sick mice and the finding of typical Negri bodies in mice and in the bat brain were evidence that the disease was rabies or a hitherto unknown lyssoid infection. Therefore, neutralization and protection tests, with known rabies serum, and cross-protection tests, using vaccines prepared from fixed rabies and from the putative virus, were done.

Neutralization and Protection Tests

Antirabies serum was obtained from Dr. Karl Habel of the National Institutes of Health, Bethesda, Md. A serum used as a control was obtained from the blood of stock rabbits. These two serums were used in neutralization tests versus a laboratory strain of fixed rabies virus, the bat virus, and, in addition, a laboratory strain of western equine encephalitis virus which was included to establish the absence of nonspecific virucidal effects. At the time of the neutralization tests, only virus lots of low titer were available, and, therefore, the serums were tested against small doses of virus. However,

Large Negri body in a neuron of the hippocampus in the original bat brain, stained by azure eosinate ($\times 2700$).

the results were clear-cut: The known antirabies serum in a 1:10 dilution gave complete protection against 50 LD₅₀ of the bat virus and 15 LD₅₀ of known rabies virus (the largest doses tested) but failed to protect against even 1 LD₅₀ of western equine encephalitis virus. The normal rabbit serum afforded no protection against any of the viruses. Refined and concentrated antirabies serum (Lederle) injected intraperitoneally in mice also protected the animals against both the bat virus and fixed rabies virus.

Vaccine Protection Tests

Vaccines were prepared by the method of Habel, Bell, and Wright (2) from the brains of mice injected with the bat virus and infected with fixed rabies virus. Sufficient numbers of mice were injected with each vaccine (3) to permit cross-immunization tests with groups of 12 mice per dilution. Normal mice of the same age were challenged as controls. Unfortunately, the fixed rabies challenge and control titrations were done with dilutions of suspensions of brain tissue rather than with dilutions of supernate. However, the results clearly indicate that both vaccines afforded significant protection against homologous and heterologous challenge (see table).

A few vaccinated mice were challenged via the intraperitoneal route with 0.1 ml. of a 10^1 dilution of fixed rabies virus suspension. The results follow:

1. Normal mice (controls): 6 of 6 injected dead within 10 days.
2. Mice vaccinated with fixed rabies virus vaccine: 1 of 5 injected dead on the 2d day, and therefore apparently was not specific.
3. Mice vaccinated with bat virus vaccine: 1 of 6 injected dead on 10th day.

Characteristics

In our limited experience with isolation of street virus, the long incubation period of this strain is unusual. Ernest Tierkel of the Communicable Disease Center, Atlanta, stated in a personal communication that a long incubation period is common in isolations from Florida bats but not in isolations from free-tailed bats (*Tadarida*) of the southwestern United States. The incubation periods in 3 rabbits injected intrathecally (cisternal puncture) with 0.2 ml. of a 10^2 dilution of the second mouse passage were 14, 15, and 24 days, respectively. Mice inoculated intracerebrally with 0.03 ml. of the same dilution became ill on the 10th day and all succumbed by the 15th day. A pool of brain tissue of the above rabbits was tested for virus content by titration in mice ($10^2/0.03$ ml.) and 0.2 ml. was injected intrathecally into 4 rabbits. One rabbit died suddenly on the 15th day. One developed paralysis on the 30th day. The latter animal had much virus in the brain whereas another 1 of the 4, sacrificed the same day and apparently normal, had none. The 4th rabbit was alive 60 days after injection. None of the affected rabbits showed evidence of a furious

syndrome but developed rather sudden paralysis.

Mice that succumbed to infection usually developed paralysis in the hind quarters from one to several days before death. Seven mice injected with the virus developed the same parietic signs as many others injected at the same time but have not yet succumbed to the infection (45 days after injection) and appear to be in good health except for the paralytic sequelae which limit their movements. These animals are being studied further to establish, if possible, that they have survived active rabies infection.

Identification of the Bat

The formalin-fixed bat specimen was transferred to 70 percent alcohol and sent to the Division of Mammals, United States National Museum, Washington, D. C. There it was identified as *Eptesicus fuscus pallidus* Young by Dr. David H. Johnson and accessioned as No. 298459 in the mammal collection. While the skull had been damaged by removal of the brain, the dentition and other characters permitted specific identification. The range of this sub-species extends from the Great Plains westward nearly to the Pacific Coast and from Canada to Mexico. Upon our inquiry and reexamination of the specimen, Dr. Johnson replied that there was "no reason to doubt that it is a native of your vicinity." The question arose because of the recent prior arrival from Ohio of a canvas-covered trailer which was parked in the neighborhood where the bat was captured.

E. f. pallidus is a large insectivorous bat which is not known to migrate but hibernates in caves in the northern States (4, 5). The known range of movement is from 33 to 61 miles in summer and winter, respectively. Engler (6) states that they are cannibalistic in captivity.

Infection of Bats by Various Strains

Unfortunately, the identification of rabies in a bat came at a time when very few of the animals could be found in this area. Several reports of concentrations of bats were investigated, but in most cases only guano was present as evidence of previous habitation. A few ani-

Results of vaccine protection tests

Experiment No.	Vaccine	Challenge	Titer log LD ₅₀	Protection log LD ₅₀
196				
A	Fixed rabies	Bat virus	<2.0	>2.75

C	do	do	4.75	
D	Fixed rabies	Fixed rabies	<2.00	>4.00
E	Bat virus	do	3.87	>2.13
F	do	do	>6.00	

imals, however, were recovered. Four specimens brought to the laboratory dead or which died soon afterwards were tested for rabies, but the virus was not demonstrated. Several other bats in good condition were maintained in the laboratory by feeding them on condensed milk and homogenized liver. Several of these (*E. f. pallidus*) were injected.

Bat 9194, injected intracerebrally with fixed virus, showed only mild irritability 25 days later. It was sacrificed that day and virus was detected by passage of brain tissue triturate to mice. It was notable that the incubation period of the disease in mice was several days longer than was usual for this strain. (It is possible, of course, that the bat was infected in nature before we collected it.) In the bat brain a few Negri bodies were seen in the pyramidal cells of the hippocampus but none in the Purkinje cells of the cerebellum.

Bat 9195, injected intracerebrally with bat virus (second mouse passage), showed tremors beginning on the 14th day. Weak, tremulous, ineffectual movements characterized the illness of this bat until it was sacrificed on the 25th day. Many small Negri bodies were noted in the hippocampus and multiple small Negri bodies in the Purkinje cells of the cerebellum. Inflammatory changes had occurred in the cerebral cortex and overlying meninges. The incubation period in mice injected with a suspension of brain from this bat was markedly shorter than in the case of bat 9194.

Discussion and Summary

A virus isolated from a sick bat in western Montana has been identified as rabies virus. The virus was subjected to neutralization and protection tests with known antirabies serums, and to cross-protection tests with vaccines prepared from the bat virus and from fixed rabies virus. The results of those tests clearly indicated an antigenic relationship between the viruses. Because of small quantitative differences in cross-immunity tests, it appears that

the bat virus antigen may not be fully immunizing versus fixed rabies infection. This is the converse of the conclusions of Kubes and Gallia (7) in regard to chiropteran and Pasteur strains.

The incubation period of the disease in mice was prolonged in first passage but became shorter in serial passages. A titer of 10^3 LD₅₀/0.03 ml. was found in the original brain suspension.

Typical Negri bodies were seen in the brain of the original bat and also in two bats injected intracerebrally, one with fixed virus and the other with bat virus.

The bat from which the virus was isolated has been identified as *Eptesicus fuscus pallidus*, an insectivorous species indigenous to western United States. This is the first reported isolation from the species, and the northernmost isolation from a bat. The source of infection in the bat is conjectural. Rabies has not been reported in Montana since 1952 according to H. F. Wilkins, Montana State veterinary surgeon. Bats of the species *Eptesicus fuscus* are known to hibernate, but whether they may also migrate is not established.

Observations in the vicinity of a central Texas cave inhabited by millions of Mexican free-tailed bats establish the presence of rabies in the bat population and suggest a hypothetical route of transmission to raccoons and other carnivores.

Wildlife Rabies in Texas

—A Preliminary Report—

By R. B. EADS, Ph.D., J. S. WISEMAN, M.S., J. E. GRIMES, B.A.,
and G. C. MENZIES, M.S.

RABIES is prevalent among Texas wild carnivore populations. In recent years the disease has been shown to occur in epizootic proportions in the gray fox, *Urocyon cinereoargenteus*, and skunks, chiefly *Mephitis mephitis* and *Spilogale* spp. (1).

In 1953 the Texas State Department of Health Laboratory confirmed positive findings of rabies in 150 foxes and 49 skunks taken from 44 and 20 counties, respectively. In 1954 it found rabies in 100 foxes and 71 skunks, from 33 and 29 counties, respectively. Occasionally,

Dr. Eads is in charge of the entomology division, bureau of laboratories, Texas State Department of Health, which he joined in 1940. Mr. Wiseman and Mr. Grimes have been with the department since early 1953, Mr. Wiseman as an entomologist in the entomology division and Mr. Grimes as a virologist in the virus division, bureau of laboratories. Mr. Menzies is also a member of the entomology division. Their investigations on bat rabies in Texas have been supported in part by a research grant from the Division of Research Grants and Fellowships, National Institute of Mental Health, Public Health Service.

the laboratory has received wolves, coyotes, raccoons, and bobcats which laboratory tests proved to be positive for rabies.

Since animals are seldom submitted for laboratory examination unless they have invaded premises, usually diurnally, and have attacked domestic animals or human beings, it would seem obvious that the actual level of rabies infection among wild carnivores is much higher than our data indicate.

The recovery of rabies virus from insectivorous bats in Florida by Venters and his associates (2) and again in several other States by other investigators led to consideration of the role of bats in the maintenance and spread of the disease in nature.

In Texas, interest has centered around the Mexican free-tailed bat, *Tadarida mexicana*, as a transmitter of rabies to men and domestic and wild animals because this species is the most abundant and widespread in the State and virologists in the State health department have repeatedly recovered the virus in its brain and salivary gland material. These bats are commonly observed in natural retreats and buildings, and in the central part of Texas they are especially prevalent in certain limestone caves during all but the coldest winter months.

The teeth of *T. mexicana*, although sharp, are short and delicate. Hence, the means whereby the rabies virus could be transmitted to a furred and thick-skinned carnivore, such as the fox, skunk, or raccoon, appear limited. Two natural methods of infection transmission appear feasible:

Live, infected bats which become moribund and fall to the floor of the bat retreat may be able to inflict bites around or inside the mouths of animals attempting to devour them.

The rabies virus from an infected bat, if eaten, may penetrate the mucous membrane of the oral cavity, throat, or esophagus through an abrasion already present or possibly through an abrasion caused by a sharp bone.

Review of the Literature

Pursuant to the question of whether carnivores feed on bats, Allen (3) in his excellent book entitled "Bats," states, "Bats have few enemies." However, a search of the literature reveals an impressive list of mammals, as well as birds and reptiles, which feed on bats.

Campbell (4) tells of killing a "chicken snake" which had swallowed 14 bats from a colony in an old barn.

Davis (5) reports the recovery of a bat, *Molossus nigricans*, in good condition, which had been eaten by a rat snake, *Elaphe laeta*. We observed a colubrid snake consuming a free-tailed bat at the entrance of Ney Cave, near Bandera, Tex., in May 1954, but we do not know how the snake caught the bat. On another occasion, we saw a snake of comparable size and appearance at the same place, but it escaped into a rocky crevice before it could be collected.

Beer (6), Constantine (7), and Bailey (8) have recorded that predatory birds, such as hawks and owls, feed on bats, and on the Mexican free-tailed bat especially.

Sperry (9) recovered fragments of two silver-haired bats (*Lasionycteris noctivagans*) from the stomach contents of a skunk killed in January 1930, in Pisgah National Forest, North Carolina. At the same time and place, he also found a red bat, *Lasiurus borealis*, in the stomach of an opossum.

Taylor (10) in 1954 found that in Texas the red bat is a regular, although negligible, item

of the diet of the ringtailed cat, *Bassariscus astutus*, during the summer months. This nocturnal animal is arboreal and would probably take a greater number of solitary bats from the trees in which the bats spend the day if the bats were not also nocturnal.

Goodpaster and Hoffmeister (11) captured three minks having the remains of *Myotis* bats in their stomach contents. They took the minks in Carter County, Ky., at Carter Cave, which is inhabited by bats only during the winter months. These authors stated that the bats were hanging near enough to the cave floor for the minks to have reached them by jumping.

Bat Rabies Investigations

As part of our overall bat rabies investigations in the Texas State Department of Health, we have made regular observations of one of the largest bat colonies in the United States, in Bracken Cave near San Antonio. Only about 1,000 feet long, from 40 to 100 feet wide, and from 30 to 75 feet high, the cave harbors a multimillion population of *T. mexicana* and an appreciable number of *Myotis velifer* except for certain of the winter months.

During December through January there were no bats at all in the cave. Presumably, the free-tailed bats migrate south, possibly into Mexico, during the winter season and thus come within the range of the vampire bat. Just how far southward *T. mexicana* travels has yet to be determined.

In an effort to learn more about the ecology of this species, 3 of us banded approximately 5,000 individuals during 5 trips to the study cave in September and October 1954. During March-May 1955, approximately 10,000 more bats, chiefly *T. mexicana*, have been banded in this and other central Texas bat caves.

We used insect nets with extension handles for raking the bats off the walls and ceilings of the cave and placed the captured bats in an apple box, the top and bottom of which we covered with screen wire, adding a sliding panel door to the top. When a box contained a few hundred bats, it was taken to the cave entrance for banding.

Using the banding method described by Trapido and Crowe (12), we placed zero-sized

Entrance to one of the bat caves in central Texas where the State health department is conducting rabies transmission and migration studies.

aluminum bird bands on the distal portion of the forearm and adjusted the bands to permit free sliding along the bone without pinching the wing membrane. The United States Fish and Wildlife Service supplied the bird bands.

We found that one person could fasten the bands, pinching them together, as rapidly as two others, wearing leather gloves, could remove the bats from the box and hold out the forearm for banding.

Working during the summer months in these caves is very unpleasant because the guano is more than a foot deep in spots, ammonia fumes are strong, ectoparasites are abundant, and the heat is intense.

Regular monthly collections of bats have been made from the study cave for laboratory examinations.

The table illustrates the frequency with which

the virus of rabies was isolated from brains and salivary glands of *T. mexicanus*. Our laboratory has processed 329 bats of this species from Bracken Cave, collected from May 1954 through April 1955 in 98 pools. Twelve of the pools contained the rabies virus.

The specimens used for the pools were bats which were taken with the aid of insect nets from the cave walls or in flight or they were found moribund on the floor of the cave.

Our studies demonstrated that there may have been a high level of rabies infection in the free-tailed bats during May 1954–April 1955. That the colony had an extremely high mortality rate was evidenced by the fact that the cave floor was covered with dermestid beetle larvae and adults which devoured fallen bats. The maintenance of such an enormous dermestid population would require an appreciable supply

¹ During December 1954 and January 1955 there were no bats in the cave.

of dead bats. Skeletal remains of bats in the guano were abundant throughout the cave.

Our earliest observations during the spring of 1954 confirmed Constantine's report for the National Speleological Society (7) that the bat caves in central Texas attract large numbers of predatory mammals and birds. We found that raccoons, in particular, were far more abundant around the study cave than the food supply appeared to justify, unless they were feeding on bats. Large accumulations of raccoon feces were in evidence at the mouth of the cave throughout the summer, but raccoon tracks or droppings were not found within the cave. The droppings found at the entrance to the cave did not contain any bat skin or bones.

It was not until November 18, 1954, after most of the bats had departed from the cave, that we had definite evidence of raccoons eating bats in numbers. When we noticed that raccoon tracks were abundant throughout the cave, we searched for concentration of scats (feces). Several recently deposited accumulations of fecal material contained bat fur and bones; some of the scats contained nothing but the remains of 5 to 10 bats, but others also con-

tained insect fragments and seeds of the black persimmon, a major item of the raccoon diet during the summer.

We were surprised to find in one of the scats an aluminum band still attached to a portion of bat fur and forearm. We identified the band as having come from a free-tailed bat banded in the study cave on September 29, 1954.

Migration had reduced the colony by November 1954 to a few thousand bats, hanging night and day from the highest ceiling area at the rear of the cave. With the advent of cold weather, the bats appeared to have discontinued their evening feeding flights, thus giving a raccoon or other carnivore little chance of reaching a bat unless it fell to the floor.

Early in December 1954 we baited 6 live traps with sardines and raw hamburger and set them in the study cave in order to collect raccoons for our bat-to-carnivore rabies transmission experiments. The first night of trapping produced 1 raccoon (*Procyon lotor*) and 2 damaged traps from which the raccoons had escaped. The second night we took 2 more raccoons from 4 traps within the cave. On the third night we baited 2 traps and took another raccoon. These animals freely fed on bats in the laboratory.

On April 28, 1955, large quantities of rac-

Banding Mexican free-tailed bats at a cave entrance.

Guano-encrusted rocks on the floor of a bat cave.

Right: Closeup of bats on the wall.

coon feces were again noted at the entrance of Bracken Cave. These were composed largely of bat skin and skeletal material.

A Hypothetical Explanation

The abundance of the raccoons and other carnivores in the vicinity of the large bat caves of central Texas strongly indicate that these animals occasionally feed on bats which fall near the cave entrances during the spring and late summer months.

Our observations show that in the autumn and spring, when other foods, and particularly the black persimmon, become less abundant or absent, raccoons enter the caves and actively search for fallen bats. For a limited period of time bats are an important dietary item of the raccoon in these restricted areas. Thus the possibility of the transmission of rabies from bats to these carnivores exists, but the exact mode of this potential interspecies transmission remains to be demonstrated.

Our investigations have established the isolation of the rabies virus from 12 out of 98 pools containing 329 bats during the period from May 6, 1954, to April 27, 1955, but the virus was not found in 64 pools containing 126 bats collected from October 1954 through March 1955. It seems probable that the presence of the disease might help to account for the number of bats that fall to the floor of the cave and serve as food for the raccoons.

This relationship provides a hypothetical explanation of the way in which rabies might pass from bats to raccoons. Evidence from the literature indicates the possibility of similar transfer to ringtailed cats, skunks, opossums, and other animals. However, the mechanism of transfer has not been found.

Summary

Investigators in the Texas State Department of Health report observations of a close association between Mexican free-tailed bats (*Tadarida mexicana*) and certain carnivores, especially the raccoon. During November 1954 and April 1955 they examined a number of raccoon droppings found within a central Texas cave inhabited by a colony of the free-tailed bats. The droppings were composed largely of bat fur and bone. The State health department laboratory has demonstrated a high level of rabies infection in the bat population within the study cave. Transmission of the rabies virus to raccoons and other carnivorous animals through the agency of infected bats is being investigated.

Memorial to Dr. T. Duckett Jones

Support of young investigators and long-range medical research is promised by a fund recently established in honor of Dr. T. Duckett Jones, who died in 1954.

Jones was medical director of the Helen Hay Whitney Foundation, which is cooperating with the memorial committee. He advocated the creation of long-tenure positions for experienced investigators in universities and research institutions and aid to carefully selected, unrecognized researchers which might permit them to demonstrate their competency. His ideas and suggestions influenced research programs of a number of American institutions, including the National Institutes of Health and the American Heart Association.

The committee feels that research in rheumatic fever, the subject of much of Jones' own research activity, should be given first consideration in the assignment of its resources, but not an exclusive claim.

Mrs. James B. Campbell is chairman of the committee. Other members are Dr. E. Cowles Andrus, Dr. Walter Bauer, Dr. Francis L. Chamberlain, Mrs. Albert D. Lasker, Dr. H. M. Marvin, Dr. Jean Jones Perdue, Dr. David D. Rutstein, Dr. Leonard A. Scheele, Dr. Frederick K. Trask, and Dr. Paul D. White.

The incidence of Trichinella spiralis in the area of Louisville-Jefferson County, Ky., as determined by examining the diaphragms of humans autopsied at the Louisville General Hospital and of swine slaughtered in the Louisville abattoirs.

Trichinella spiralis in the Diaphragms of Humans and Swine

By LETITIA S. KIMSEY, M.D., and STUART L. ADAMS, Ph.D.

INTEREST in the control of trichinosis as a public health measure was awakened by the First National Conference on Trichinosis in 1952, and an amended recommendation of the 1954 Conference on Trichinosis (1) emphasized the continuing importance of data on the prevalence of this disease. The amended recommendation stated:

Dr. Kimsey is assistant professor of microbiology, and Dr. Adams is a research associate in the department of microbiology, University of Louisville School of Medicine, Louisville, Ky. Dr. Adams is also director of research at Joseph E. Seagram & Sons, Inc.

Individual reports of the investigation described have been submitted to the Graduate School of the University of Louisville in partial fulfillment of requirements for the degree of master of science. Dr. Kimsey's report, "The incidence of infestation with Trichinella spiralis as revealed by the examination of 570 diaphragms at the Louisville General Hospital, Louisville, Ky.," was submitted in 1943; Dr. Adams' report, "The incidence of Trichinella spiralis in the diaphragms of swine from the Louisville abattoirs," in 1942.

"Because of the advantages of having up-to-date information concerning the incidence of trichinosis in man, and in view of a decreased incidence of trichinous infection encountered in swine, the United States Public Health Service is requested to repeat the random survey of human trichinosis carried out by that agency between 1936 and 1941."

Even though the study here reported was conducted a decade ago, the data should be useful statistically since there are no published data on the incidence of trichinosis in either the human or porcine population of Kentucky.

Materials and Methods

Using essentially the same methods, one author investigated the incidence of *Trichinella spiralis* in the diaphragms of humans and the other studied the incidence of the parasite in the diaphragms of swine.

Study of Human Diaphragms

The material used in the study of infestation of humans consisted of a series of diaphragms removed at routine autopsy at the Louisville General Hospital, Louisville, Ky. Except for the exclusion of diaphragms of children under

1 year of age, there was no conscious selection of subjects. The investigation was divided into two series and the results were interpreted and reported separately.

Series 1 consisted of 311 diaphragms placed directly in 10 percent formalin when removed from the body and later examined by a modification of the direct microscopic method employed by Nolan and Bozicevich (2). A gram of muscle from which tendinous material had been removed, taken at random from various parts of the diaphragm, was teased into pieces and firmly pressed between two glass plates. The positive findings were recorded in terms of trichinae per gram of diaphragm as revealed by the examination of the pressed preparation, using a wide-field microscope with a 12.5 ocular and a 1.7 objective.

Series 2 consisted of 259 diaphragms which were examined by both the direct microscopic and the digestion techniques. The diaphragms were removed at routine autopsy and kept in jars of fresh water at icebox temperature until time of examination. The specimens were then carefully dissected, and four 1-cm.-wide strips taken from different locations on the circumference of the diaphragm were cut parallel to the direction of the muscle fibers, care being taken to include the tendinous insertions. The strips were placed in 10 percent formalin, and all four were examined later by the direct microscopic method employed in series 1.

The digestion method used was a modification of the digestion-Baermann technique described by Queen (3) in 1931. The portion of the diaphragm that remained after the material for the direct microscopic examination had been removed was finely ground and digested by artificial gastric juice, which consisted of 0.5 percent hydrochloric acid and 0.7 percent commercial pepsin in an aqueous solution. A liter of this digestion material was added to approximately 50 gm. of the ground muscle, and the mixture was simultaneously agitated mechanically and incubated at 37° C. for a period of 12 hours. The mixture was allowed to settle for an equal period of time, and the sediment then was filtered through cheesecloth and later through a No. 3 Coors porcelain desiccator plate placed in a funnel. The sediment from this filtration was centrifuged and the deposit was

poured into a Petri dish for microscopic study with a dissecting microscope with a 20-diameter magnification. There was no quantitative report as to the larvae per gram of digested diaphragm. The detection of larvae in any fraction of the centrifuged sediment constituted a positive finding.

Study of Swine Diaphragms

One thousand swine diaphragms were taken by random selection immediately prior to Government inspection of the viscera of the animals. These diaphragms were collected from 4 abattoirs over a period of 9 months in order to insure representative sampling of the swine slaughtered in the Louisville market.

The method of preservation of the swine diaphragms was the same as that employed for human diaphragms. The diaphragms were examined by both the direct microscopic and the digestion techniques. In the direct microscopic examination, the fascia was removed from the diaphragm, and one-half gram of muscle taken from various parts of the organ was cut into small thin strips and examined in the manner described for the human diaphragms.

The digestion method employed early in the study of the swine diaphragms was the previously described modification of the Baermann technique. All of the diaphragm that remained after the sample for the direct microscopic study had been removed was ground and digested in 3 liters of the artificial gastric juice for 24 hours at 37° C., with constant mechanical agitation. There was no other modification of the technique. However, after 107 diaphragms had been examined, the mass digestion procedure of Hood and Olsen (4) was adopted. The diaphragms were stripped of the tendon and fat and 10-gram portions from each of 10 or 20 diaphragms were digested together. The remainder of each diaphragm was retained so that the specimens might be examined individually if larvae were found in the mass digestion. One liter of artificial gastric juice was used to digest 50 gm. of diaphragm.

Results

Human Diaphragms

Series 1. Of the 311 human diaphragms examined by the direct microscopic method alone, 35 (11.2 percent) were found to contain *Trichinella spiralis*. The more important data concerning the group are shown in table 1.

The density of infestation varied from 1 cyst per gram to 4,500 cysts per gram of diaphragm.

The ages of the patients varied from 1 to 88 years. Of the 311 diaphragms examined, 99 (31.8 percent) were from persons less than 40 years of age at death; 188 (60.5 percent) were from persons dying at between 40 and 80 years of age; and 3 (0.9 percent) were from persons over 80 years of age. The ages of 21 individuals (6.8 percent) were unknown. These persons were dead upon arrival at the hospital—in

most instances, coroner's cases—or they died before a history could be obtained.

The age distribution of the patients with *T. spiralis* infestation is shown in table 2. Of the 23 diaphragms of patients in the first two decades of life, only 1, that of a boy 16 years of age, showed presence of trichinae. Four percent of the group aged 20–29 years and 8.1 percent of the group aged 40–49 years revealed infestation with *T. spiralis*. In each of the other decades (through the seventh), the incidence of infestation was over 13 percent. The highest incidence (18.4 percent) fell in the group aged 70–79 years. The highest percentage (22.8) of the 35 positive cases fell in the group aged 60–69 years.

The incidence of trichinosis by race and sex of the patients is recorded in table 3. Of the 311 diaphragms examined, 184 were from males and 108, from females. The race and sex of 19 patients were not recorded. Twenty-two (11.9 percent) of the 184 males and 12 (11.1 percent) of the 108 females were infested with trichinae. One positive diaphragm was found among the 19 patients of unknown race and sex. Of the 292 persons whose race and sex were recorded, 171 were white, 14 (8.2 percent) being infested with trichinae. Twenty (16.5 percent) of the 121 Negro patients harbored encysted larvae. The highest incidence of in-

festation (18.1 percent) occurred in Negro males; the lowest (7.5 percent), in white females. The white males showed an incidence of 8.4 percent; the Negro females, 14.5 percent.

Series 2. Of the 259 diaphragms examined by both the direct microscopic and digestion methods, 54 (20.8 percent) showed the presence of *T. spiralis*. Of these 54 positive cases, 13 (24.1 percent) were not detected by the digestion method and 7 (12.9 percent) were not revealed by the direct microscopic method. Thirty-four (63.0 percent) were positive by both methods. By the digestion method, 41 (15.8 percent) of the total diaphragms were positive; by the direct microscopic method, 47 (18.1 percent). Of the total positives, 75.9 percent were detected by the digestion method and 87.0 percent by the direct method.

The more important data concerning these positive cases are shown in table 4.

The density of infestation as determined by the direct microscopic method varied from 2 cysts per gram to 73 cysts per gram of diaphragm. Since the modified digestion-Baermann technique was not carried out quantitatively, it was assumed that if the direct microscopic test on a diaphragm failed to reveal any organisms and trichinae were found by the digestion technique, the diaphragm contained less than two cysts per gram.

The ages of the patients in this series varied from 1 to 86 years. Of the diaphragms examined, 70 (27.0 percent) were from persons less than 40 years of age; 174 (67.2 percent) were from persons dying between 40 and 80

¹ Less than 2 cysts per gram. ² Tag lost, diaphragm saved.

years of age; and 6 (2.3 percent) were from persons over 80 years of age. The ages of 9 individuals (3.5 percent of the 259) are unknown. They were dead upon arrival at the hospital or died before a history could be obtained.

The ages of patients in this series are shown by decades in table 5. Only 1 diaphragm of the 25 examined from persons in the first two decades of life contained trichinae. This was a diaphragm of a white male 17 years of age. In the other seven decades of life the lowest percentage of positives was 13.3 percent, in the 20-29-year age group. Fifty percent, 3 of the 6 cases in the 80-89-year age group were positive. Of the 54 positive cases, the highest incidence (25.9 percent) was in the 60-69-year age group.

The incidence of trichinae by sex and race of the patient is recorded in table 6. Of the 259 cases examined, 182 were males and 72, females. The sex and race of 5 patients were not recorded. Of the 182 males examined, 31 (17.0 percent) were infested with trichinae. Twenty-two (30.5 percent) of the 72 females were found to be parasitized. One positive diaphragm occurred among the five patients of unknown sex and race. Of the 254 persons whose sex and race were recorded, 154 were

white, and 31 (20.1 percent) of these were infested with *T. spiralis*.

Twenty-two percent of the 100 Negro patients harbored encysted trichinae. The highest incidence (33.3 percent) occurred in white females; the lowest incidence (15.6 percent), in white males. The Negro males showed an incidence of 19.4 percent and the Negro females, 27.2 percent.

A differential blood count was performed in 24 of the 35 patients whose diaphragms were examined in series 1 (table 1). Of these 24 patients, only 6 showed eosinophils, the greatest number in any patient being 2.0 percent of the total count. Of the 41 patients in series 2 whose diaphragms contained trichinae and upon whom a differential blood count was made, only 13 were found to have eosinophils. The highest incidence was 4.0 percent. There were no eosinophils in 28 of the 41 patients.

Swine Diaphragms

Of the 1,000 swine diaphragms examined, only 2 were found to contain trichinae by the digestion method and 1, by the direct microscopic method. The one specimen found positive by direct examination was also positive by digestion. Thus, the incidence of infestation in the group studied was 0.2 percent.

Discussion

The human diaphragms used in this study were removed at routine autopsy at the Louis-

ville General Hospital, Louisville, Ky. Aside from the exclusion of children under 1 year of age, there was no selection of specimens by age, sex, race, occupation, or clinical history of the patients. The presence of the organism was not suspected clinically in any of the 89 individuals who harbored cysts. Several patients gave vague histories of rheumatism or "growing pains" but these symptoms could well be attributed to some condition other than infestation with trichinae. Schwartz (5) explains in his article on the occurrence, significance, and control of trichinosis that the presence of trichinae in the diaphragm at autopsy does not mean that the person necessarily had previously existing clinical trichinosis. Those persons with relatively few trichinae per gram of diaphragm probably experienced little, if any, inconvenience, and their medical histories would not suggest the symptoms characteristic of the clinical entity called trichinosis. Schwartz states that these light infections have only zoological significance, and the surveys demonstrate that trichinae is consumed in pork eaten by the public and that many Americans eat insufficiently cooked or inadequately cured pork.

By the direct microscopic method, 35 (11.2 percent) of the 311 diaphragms of series 1 were found to contain *T. spiralis*, and 47 (18.1 percent) of the 259 diaphragms of series 2 were positive. When subjected to statistical analysis, however, the difference in incidence of trichinae in the two series was insignificant.

There was a marked difference in the incidence of infestation with trichinae in the human diaphragms as determined by the direct microscopic examination in series 1 and that detected by the combination of the direct microscopic and the modified digestion-Baermann methods in series 2. This discrepancy between results of the direct microscopic method and the digestion method is to be expected from the work of Hall and Collins (6), who found that either method alone failed to detect trichinae in a certain number of cases. This fact has been supported by the findings of Nolan and Bozicevich (2), who stated that the microscopic method failed in a number of cases of light infestation. Conversely, the digestion method was reliable in detecting even very light infes-

tations, although it was valueless in detecting dead trichinae.

The 20.8 percent of human infestation with trichinae as determined by the combined direct microscopic and modified digestion-Baermann tests is rather high for this area of the country. The southern States have, according to other investigators, a much lower incidence of trichinosis than that reported in other geographic sections of the United States. Hinman (7) in 1936 reported that 7 (3.5 percent) of 200 diaphragms from human autopsies at the Charity Hospital, New Orleans, La., were positive for trichinae when examined by the digestion method.

Sawitz (8), in a study of 200 autopsies from the Touro Infirmary and Charity Hospital, New Orleans, found that 5.0 percent contained *T. spiralis*. The diaphragms and pectoral muscles were examined by the compression and digestion methods. Two years later, in 1939, Sawitz (9) published an article on the incidence of trichinosis in man, dogs, and cats in the New Orleans area. In addition to the 200 cases just described, his study included material from 200 unselected routine autopsies of patients from the same institutions. Essentially, the same methods of examination were employed. Of the 400 cases, larvae of *T. spiralis* were found in 24, an incidence of 6.0 percent in the human population of the New Orleans area.

Meleney (10), in 1941, reported that among 209 human diaphragms from persons who died at the Vanderbilt University Hospital and the Nashville General Hospital, in Nashville, Tenn., 10 percent were positive for *T. spiralis* when examined by the combined digestion and microscopic press methods. However, in a preliminary report on the incidence of trichinosis in Alabama, Walker and Breckenridge (11) in 1938 reported that they had examined the diaphragm, intercostal, pectoral, and rectus abdominis muscles from 100 patients at autopsy by the digestion and press methods and found an incidence of 33 percent.

In 1943, the results of a very extensive survey of the incidence of *T. spiralis* in the population of the United States were published by Wright, Kerr, and Jacobs (12). Diaphragms were examined from a total of 5,313 individuals coming

to necropsy in 189 hospitals located in 114 cities in 37 States and the District of Columbia. These diaphragms were examined by both the direct microscopic and the digestion-Baermann methods. Of these 5,313 diaphragms, 855 (16.1 percent) were positive for *T. spiralis*. Omitting results of examination in a series of 200 diaphragms from persons of Jewish faith, of which only one was positive, the representative cases totaled 5,113, of which 854 (16.7 percent) were positive. Several papers in the series contained summaries of the finding of trichinae in surveys conducted by other investigators already referred to in this article. Although no statistics were given for Kentucky, the State was included in the East South Central group with Tennessee, Alabama, and Mississippi. Of the total 5,313 diaphragms examined, 85 were from this area and 15 (17.6 percent) of these were positive for trichinae. However, the interpretation was to the effect that, on the basis of this small number of cases, conclusions could not be drawn as to the probable incidence of human infection with trichinae in these areas.

Even though trichinosis has been a reportable disease in Louisville since 1917, an examination of the Louisville and Jefferson County Health Department records for the past 20 years failed to disclose a single case.

The low incidence of trichinosis in the south is explained by the fact that the majority of hogs in that area are peanut or grain fed, whereas many of those in more densely populated sections of the country are garbage fed. Hall (13) stated that the incidence of trichinae in swine is approximately as follows: Pasture-raised swine, mostly in the midwest, are free or practically free from trichinae. The so-called grain-fed swine in the midwest are in reality a mixture of some pasture-raised and some garbage-fed swine, and the mixture has an average infestation of about 1.5 percent. Southern swine have an average infestation of less than 1 percent. Garbage-fed hogs, which are more numerous along the southern part of the Pacific coast and the northern part of the Atlantic coast, have an average incidence of about 5 percent. The last group, which has practically disappeared, is the offal-fed hog, which has the highest incidence of infestation, about 18 percent.

The swine examined in the present study would be classified by Hall and others as grain fed, for, although the exact feeding could not be determined precisely, these swine were raised in a section of the country in which grain feeding predominates and were purchased for slaughter in the belief that they had been grain fed. It is estimated that approximately 50 percent of the swine were raised within a 100-mile radius of Louisville and that the remaining 50 percent were predominantly from north central Indiana and Illinois. The 0.2 percent infestation found in these swine is lower than the average given by Hall. However, similarly low incidences have been found in some other surveys. For example, Kerr (14) found 3 cases of infestation in a group of 566 grain-fed swine examined, and Cameron (15) in 1940 reported 2 positives in a group of 995 swine examined in Canada. It is evident that with such a small number of positives a difference of several tenths of 1 percent is not significant.

In 1953, Schwartz (5) reported a survey conducted over a 3-year period in which the diaphragms of 3,031 hogs from the midwest (Corn Belt hogs) were examined by the digestion method and 19 (0.63 percent) were found to harbor trichinae. The direct microscopic examination of small samples from a fairly large proportion of these diaphragms gave consistently negative results. The maximum number of parasites recovered from any diaphragm was between 7 and 8 per gram, most containing only 5 trichinae per 1,000 grams to 2 trichinae per gram. A parallel study of garbage-fed hogs carried out during the same period on 1,328 diaphragms revealed 149 (11.21 percent) infected with trichinae when the digestion method was used. Sixty-four (4.81 percent) of the diaphragms were found to be infected when examined by the direct microscopic method alone, and counts by the artificial digestion method were 100 or more parasites per gram of tissue. In 1 case there were 2,741 parasites per gram of tissue.

The greater part of the pork consumed by the people of Louisville is from hogs that have been slaughtered in the local abattoirs. Louisville maintains meat inspection and slaughterhouse ordinances, and no meat is placed on the local market until it has been inspected and

passed by a duly authorized inspector of the United States Government or by an authorized inspector of the Louisville and Jefferson County Health Department. However, the routine inspection does not include an examination for trichina larvae.

To be able to draw a comparison between the incidence of trichinosis in humans and in swine in the Louisville area as shown by this study, it becomes necessary to consider those factors which can account for the difference between 0.2 percent infestation in swine and 20.8 percent infestation in humans. First, it is possible that the high incidence of trichinous infestation in patients in the Louisville General Hospital may not be representative of the population as a whole. A large percentage of these patients are charity cases and their economic and social status tends to be low. Pork, particularly sausage, probably was a common item of the diet since it is usually less expensive than other meat. It is possible that some of these patients consumed large quantities of so-called country sausage. Second, records of these patients with respect to period of residency in the city are incomplete, and it is reasonable to suppose that a large portion of the life of at least some of them was spent in other localities. Third, one infected hog can be the source of disease for a large number of persons, and, by the same token, during a lifetime the average individual consumes meat from an extremely large number of hogs.

Peres (16) in 1942 reported the data from surveys conducted by different investigators almost simultaneously engaged in the study of the incidence of *T. spiralis* in the human and porcine population of the New Orleans area. The incidence in both the human and porcine populations was lower than that found in this study, but Peres likewise found a sharp difference between the incidence of trichinae in the two groups. He used the statistics of Hinman (7) and Sawitz (9) for the incidence of trichinae in man. Studying 2 square inches of diaphragm from each of 200 autopsies, Hinman found an incidence of trichinae of 3.5 percent. Sawitz, using larger samples and examining diaphragms obtained from 400 autopsies, found the incidence to be 6 percent. Peres during 1938 and 1939 examined the diaphragms of 516

southern hogs and the loins of 399 midwestern hogs for the presence of *T. spiralis* in the artificially digested material. None was found infected with trichinae. Likewise, none of 50 samples of sausage from local butchers revealed infection. Pork consumed in the New Orleans area comes from hogs that are raised in the south (Louisiana, Mississippi, and Alabama), hogs that are raised on the outskirts of the city, and those that are raised in the midwest. Those hogs from the outskirts are raised mostly on garbage; those from the other parts of the south are allowed to roam the fields and to feed on peanuts; and those from the midwest are raised largely on grain. About four-fifths of the hogs consumed in the New Orleans area are from the midwest. Certainly, the low incidence agrees with the low infection rate in man in the New Orleans area, as contrasted with other areas of the United States.

Summary

The direct microscopic examination of 311 human diaphragms from routine autopsies at the Louisville General Hospital, Louisville, Ky., revealed an 11.2 percent incidence of *Trichinella spiralis*. A second series of examinations, using both the direct microscopic method and a modification of the digestion-Baermann methods, detected an incidence of 20.8 percent in the 259 human diaphragms studied. No selection of material was made, except that the diaphragms of all children under 1 year of age were excluded.

No conclusion could be drawn statistically as to the difference in incidence of infestation with *T. spiralis* by race, sex, or age because of the limited number of patients in each category.

The incidence of human infestation with trichinae in Louisville is somewhat higher than that reported by other investigators in studies of human diaphragms taken at autopsy in various other cities in the southern part of the United States. However, there is no statistically significant difference between the incidence of *T. spiralis* reported in this study and that found by Wright in either the human population of the United States as a whole or in that section designated by him as the East

South Central group of States to which Kentucky belongs.

In the examination of 1,000 diaphragms collected from swine slaughtered in Louisville abattoirs, 2 were found infested with trichinae by a modification of the digestion-Baermann method and one of these was also found infested by the direct microscopic method, an incidence of 0.2 percent. Although the exact type of feed is unknown, these swine may be classified as grain fed in conformity with the method used by Hall and others of classifying swine according to the type of feeding most prevalent in the section of the country in which the swine were raised. The incidence reported here is lower than the estimated average of 1.5 percent for the United States, but many other investigators have reported similarly low degrees of infestation.

ACKNOWLEDGMENTS

The authors wish to express their appreciation for the assistance given them in the preparation of this paper. They are especially grateful to Drs. J. A. Kennedy, A. J. Miller, and Malcolm L. Barnes of the University of Louisville School of Medicine, who directed the investigation, and to Dorothy Hampton Woerner for the statistical treatment of the data.

Neisseria meningitidis Isolated From Case Of Acute Conjunctivitis

By HUGH MILLER, Jr., B.S.

The identification of the etiological agent in conjunctivitis more often confronts hospital or clinic laboratories than a public health laboratory, but it is a matter of public health interest. The principle involved here applies whenever a Neisseria organism of any kind, not only gonococcus, is suspected. The implication is that reliance on simple microscopic procedure and the acceptance of misleading shortcuts can lead to major error.

. . .

A CASE of uncomplicated conjunctivitis occurring in April 1953 was found to be due to *Neisseria meningitidis* as the result of bacteriological studies made by the San Benito County Health Department in California.

Smear preparations alone are frequently employed for recognizing the gonococcus from genitourinary tract secretions. Ordinarily, this procedure would present no problem. It entails, however, the risk of ascribing an incorrect etiological agent to the disease process and of

Mr. Miller, now laboratory director of the Merced County Health Department in California, was a bacteriologist at the San Benito County Health Department, Hollister, Calif., at the time of this report. The clinical information on the case was provided by Roswell L. Hull, M.D. Bacteriological and serologic confirmation of the cultures was made by Jean Johnston of the Oakland (Calif.) Department of Public Health, the division of laboratories of the California State Department of Public Health, and the Communicable Disease Center of the Public Health Service.

incorrect clinical and epidemiological interpretation, particularly in the case of extragenital infections.

Gram-negative intracellular diplococci were demonstrated on smear preparations of the discharge from acute, purulent conjunctivitis of one day's duration of the right eye in a 4-year-old boy. Cultures were requested prior to treatment and were submitted. The patient responded well to the parenteral administration of 900,000 units of penicillin procaine G followed by 300,000 units per day for 6 days. Symptoms were absent at 48 hours.

The discharge was plated on chocolate agar with the addition of Difco's Bacto supplement A as recommended for 24-hour gonococcus cultures (1). These plates were incubated at 37° C. in a candle jar. Within 24 hours, numerous gray, opaque colonies with an entire edge were present. They were oxidase-positive and showed morphology typical of *Neisseria* by Gram stain. By biochemical test the culture was identified as the meningococcus. Serologically, the organism was placed in group 2.

Since this case was at first considered to be gonorrhea, considerable investigation was made of family and other contacts. Investigative work could be more rationally directed if cases of extragenitourinary *Neisserian* infections were first proved bacteriologically. Bacteriological proof of such infections would avoid also the social, medical, and legal implications usually associated with gonococcal infections in children. It should be noted that Thygeson (2) calls attention to the clinical similarity of inflammation of the eye by the gonococcus and the meningococcus and to the resultant need for bacteriological studies to establish an etiological diagnosis.

Health Education for Palestine Arab Refugees

By THERON H. BUTTERWORTH, Ph.D.

THE UNITED NATIONS Relief and Works Agency for Palestine Refugees (UNRWA) in 1951 requested the assistance of the World Health Organization in evaluating its activities and developing future plans for public health education. The World Health Organization met this request by loaning a health educator to the Agency for 2½ months during the summer of 1952.

The WHO health educator worked with the staff of the UNRWA headquarters office in Beirut and with Agency's country headquarters' staff in Lebanon, Syria, Jordan, and the Gaza strip, formerly under the Palestine mandate, now under Egyptian control. He visited representative field health programs of the Agency in all these countries and held discussions on health problems and health education with staff groups and with the Arab refugees from Palestine.

In most of this work the health educator had the valuable assistance of a refugee who was employed by the Agency and who had received some special training in health education from the Egyptian Government. This assistant had been a camp sanitation officer and a camp leader and was well acquainted with the refugees in the camps and with their problems.

Mr. Butterworth is health educator with the World Health Organization, Geneva, Switzerland. Before joining WHO he was assistant chief of the Health Education Division, Public Health Service, Washington, D. C.

Clarification of the meaning of health education was a major objective in the consultant's day-by-day meetings with individuals and with various groups. In his survey he found some health education, recognizable as such, to be a part of the UNRWA program. However, the survey also found educationally significant situations, which were neither recognized nor utilized as health education. If health education were to be accepted as an integral part of the Agency's program, it seemed important to try to develop a broader concept of what health education is and what it can do.

It was felt that a written statement, concisely and simply presenting a broader educational approach to health, would be useful to the UNRWA staff, especially to the health, education, and welfare divisions. Such a statement was prepared during the summer of 1952 as a stimulation to continued thought and discussion, as a record of some of the thinking which had taken place in group discussions throughout the camps, and as a guide for future planning.

Believing that this statement, which was prepared for wide distribution among the UNRWA staff, may also be of some general interest to the public health profession, it is presented below with a few editorial changes which seem appropriate in this new setting.

The Statement on Health Education

Good health education aims to help more people make more free-choice decisions which will result in the maintenance or improvement of their health. The state of health of each

individual is basically the result of his own actions; or, putting it another way, our health is what we make it, to the degree that we are at all able to control our private and social condition. Other than small babies, mental defectives, and those incompetent to assume the normal responsibilities of life, there are few persons who are exceptions to this statement. Each of us inherits certain health strengths and weaknesses, sometimes serious health handicaps. Whether we use our inheritance and the environment in which we find ourselves most effectively for the maintenance and promotion of sound health is largely a matter of personal or group choice.

Society usually provides such health protection services as water purification, sewage disposal, food protection, or quarantine services. And even when these services are provided, their effectiveness is still dependent in large measure on individual and group choice of action. One may choose to drink from the pure water supply or from a supply of questionable potability. Clean safe food provided in a store can become contaminated because of bad health habits in the home. Sewage disposal systems must be used properly to be effective. Quarantine laws protect only to the extent that they are obeyed.

On the other hand, where governments have failed to take the necessary action to protect the health of the citizen, each individual can, through personal choice, and without the aid of government, act to protect his own health and that of his neighbor though his choice of action may be limited by the culture within which he exists. Water can be boiled. Foods can be washed, peeled, cooked, protected by refrigeration, and shielded from dust or insect contamination. Human excreta can be disposed of safely. Ill persons can be avoided and simple isolation practiced. Occasionally, individuals may be forced into situations injurious to their health, but even these situations often represent a group choice, which still leaves opportunities to choose a personal course regarding health.

Health Education Defined

The correct choice of action is most frequently made by those of us whose education regarding health is most complete. By educa-

tion, we mean that aggregate of experience which enables us to live with the highest degree of efficiency, satisfaction, and service in the environment in which we find ourselves. The importance of sound health education is, therefore, obvious.

"Health education is the sum of all experiences which favourably influence habits, attitudes, and knowledge relating to individual, community, and racial health" (1), to quote one definition of health education, and "health," as defined by the Constitution of the World Health Organization, is "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (2).

The health education experiences most frequently referred to are (a) the conscious, formalized type of instruction, whether in the school class, university, or community study group, and (b) the exposure to one or more of the usual types of mass media. These kinds of experiences are related to the imparting of information and may or may not educate for action. Too frequently they do not. Individuals may become quite well informed about the ways to establish and maintain health, but until they freely choose to act in accordance with such information they are not really "educated" about health.

Many basic health attitudes and practices are developed without conscious instruction. Care of one's body, eating habits, patterns of sleep, care of the teeth, home remedy practices, actions in the face of oncoming illness, attitudes toward health and disease, choice and use of professional health and medical services—these and many other actions that daily affect health are much more the result of the experience of living in close contact with certain cultural patterns and social customs than of specific information acquired, no matter from what source.

It is true that present actions are dictated by past experience, notwithstanding the fact that one may possess information which indicates an entirely different choice of action.

The Bedouin mother who had had the experience of losing two children because, as she thought, they had got their heads wet, chose not to bathe her third child. She made this decision in spite of the information given her by the nurse as to the great benefit to the child of regu-

lar bathing and the careful explanation that wetting the head had not killed the other two children. The experience of daily visiting the baby center and seeing other mothers wetting their children's heads without harm finally convinced her that she should try it too. Another experience had been added to her life which helped her to make another free choice, that of washing her baby.

The word "favourably" in the definition of health education (1) is important. Some education in respect to health is unfavorable. Too often the unfavorable education is of the experiential type, and its importance is not recognized. A class may learn from the textbook that good ventilation is necessary for the promotion of sound health. Yet, because of a teacher's choice, this same class may sit daily for several years in a hot, poorly ventilated room. The members of the class may develop a liking for such an unhealthy condition despite the instruction in the book.

Or, a woman is urged to come to a maternity home for delivery. Once there, she is given the best medical and nursing care from a technical standpoint and is delivered of a fine baby. But, at the same time there may be so little human kindness and sympathy associated with the professional services that she "learns" that maternity centers are places to be avoided. The experiences of personal neglect and unhappiness will far outweigh the information concerning the usefulness of maternity centers which she may receive at the next antenatal class, if she attends one.

Experiences continually shape patterns of health habits. These experiences, being frequently repeated and usually touching personal lives closely, tend to outweigh the experiences of didactic teaching and information received from various sources. Those of us in public health have only to consider our own actions regarding health to recognize the truth of this statement.

Most of the experiences which educate positively or negatively for health can be controlled. Those of us who are in public health, in whatever particular professional group, need to train ourselves to recognize these experiences and to attach more importance to planning that the experiences be essentially favorable in effect.

In our planning groups we would do well to include, whenever possible, the persons themselves who are to be educated. For it has been said that people usually act upon plans that they have helped to make.

Action is important. To know that vaccination protects against smallpox is to be informed, but to be vaccinated is to be "health educated" with respect to the control of smallpox. Health education, to be effective, must achieve desirable action.

Health Education in UNRWA

In studying health education in UNRWA, we noticed among the professional staff and the refugees themselves a general confusion between health instruction and health education. The aim of health education was most frequently considered to be informing people about health—specific situations which might be called "health instruction." situations in which people were being told what to do—rather than stimulating people to act wisely in regard to their health. The objective was arrived at through the fallacious reasoning that to know is to act.

Health education found throughout the camps was being carried on by many different people in UNRWA. This is as it should be, for health education is, for the most part, an aspect of a program or service rather than a separate entity in itself. It should be carried on by all members of the staff, with the person designated as health educator having the responsibility of stimulating and facilitating the health education aspects of the work of others, as well as of carrying on some direct education.

The program contained many examples of health education and many more opportunities not yet put to use in the interests of health education. Some of the situations found in UNRWA camps more commonly recognized as involving health instruction are these:

Teachers in elementary schools give some health instruction.

Some sanitary inspectors during their daily work give talks to groups of people, explaining the reasons for sanitary regulations.

Health instruction is a part of the literacy training included in the work of one sewing class.

Positive Education for Health

WHILE as many as 6,000 Palestine Arab refugees are still living under canvas in a refugee camp, most of the camp populations have now been housed in huts of concrete or lumber, which give much better protection against winter storms and hot desert wind. From more than 30,000 tent units in 1950, UNRWA has reduced

the tent housing to approximately 10,000 in 1954. The present number in all UNRWA refugee camps is 340,000. Each camp has a supplementary feeding center, which serves milk and a daily cooked meal to all babies and children recommended by the camp physician. From early pregnancy, mothers are encouraged to attend the antenatal clinics. They learn to make their own baby clothes. They are urged to come to the maternity home for delivery of their child. Once a baby is born, his mother is encouraged to bring him regularly to the infant health clinic. She learns how to bathe her baby. Both mothers and children are having experiences which daily help them to learn the value of good food, carefully prepared and served.

Posters are displayed on the walls of schools, offices, clinics, feeding centers, and similar places.

Some films on health subjects have been shown to school children and to community groups.

Nurses and midwives teach mothers how to wash and dress their babies.

Suggestions for improving health education in UNRWA, made by staff and refugees, included motion picture shows, posters, talks to mothers, additional hours of instruction in schools, use of pamphlets, lectures to young girls, and special classes on health. All of these ways of instructing are important but of little effect if they are not made an integral part of a planned, broad-based education program which includes, in addition, those kinds of personal experiences which influence individuals to action.

The following are a few experiences of those in the camps of UNRWA, which may be having an even deeper effect on the formation of individual health habits but which are not always recognized as having health education significance:

Mothers and children at feeding centers enjoy meals which daily help them to learn the value of good food, carefully prepared and served.

In the feeding centers where young girl volunteers are assisting, good habits are formed with respect to the preparation and care of food.

In some areas it was reported that nurses and midwives were making at least a few visits to their patients' homes, a most effective form of health education.

The experience of being a part of the well-regulated community life of camps and compounds, with available sanitary services, pure water supplies, clinic services, feeding and recreation centers, and reading rooms may be the most important single factor responsible for changing for the better the health habits of the refugees.

The observable good effects of early diagnosis and treatment, of immunization and professional medical care, in reducing or entirely preventing illness, are a potent educational experience.

Hospitalization, when it is a satisfying experience, increases respect for health practices.

In one feeding center, sick mothers and babies, by being placed in isolation, learned to attach importance to the communicability of disease and to the practice of simple isolation.

Profitable and healthy use of leisure time was learned at welfare centers where games are available.

Other examples of health education were found in UNRWA camps, but an extension of the list would serve no useful purpose here. The amount and quality of the health education found were, to a large degree, proportionate to the interest and conviction and capacity of the professional worker responsible. Although there were some who were notable exceptions, many members of the professional field staff of the health division seemed to hold the opinion that medical service—the treatment of disease—was of first importance and that since caseloads and the scarcity of equipment and supplies made it almost impossible to meet demands in this area, it was useless to attempt health education. Health education they considered to be an extra duty, not seeming to understand that through effective health education a crushing caseload might eventually be lightened.

Another attitude which must be considered in these particular health education activities is the refugee's conviction that under present living conditions he can do nothing to protect or improve his health. To the question, how can we help the refugee improve his health? the answer was repeatedly: Supply him with more and better food, a better house, more clothes, and he will take proper care of his health; he knows how but is prevented from doing so because of his living conditions.

Since even the most highly developed and health-educated people still need further health education because they do not always act for their own best interests, it seems improbable that the refugee would become sufficiently health-educated simply by being given clothes, a better home, and better food. In fact, in this part of the world a look at any group which is not composed of refugees refutes the argument. That these people can learn to change health habits for the better has been demonstrated.

Many refugees in only these few years have

changed lifelong habits. Many a desert dweller who had never before used latrines now uses them.

Many a refugee who never gave a thought to his water supply now chooses to use the safe supply provided for him.

Many a mother is washing and dressing her baby in a more satisfactory manner and is submitting her children to immunization, a procedure to which she objected vigorously a few years ago.

People—all kinds of people—can be helped to learn how to make good choices respecting their health. The first step is to help them want to make the change.

Program Development and Planning

The creation of trained leadership is the first need for the further development of health education on a wider basis among the Palestine refugees. Once there is trained leadership, the priority steps in developing the type of health education defined in the foregoing might take the form of the following suggestions:

1. Assist the UNRWA staff to make use of existing opportunities for health education as these are recognized and help the staff stimulate and create new situations where necessary so that refugees will have more opportunities to acquire positive health habits.

2. Assist in the training of additional leadership in health education of the public.

3. Develop, with the assistance of the Palestine Arab refugees, a broad, planned program of health education which can serve as a foundation for the continuation of health education services wherever the refugees may eventually live.

4. Develop an apprenticeship program whereby the kinds of effective health education now being carried on by some staff members can be learned by others.

5. Assist in obtaining or developing simple health education materials, to be tested for effectiveness before being given wide distribution.

Before a year passed the United Nations Relief and Works Agency for Palestine Refugees had started acting on these suggestions for future planning. The Agency entered into negotiations with the World Health Organization

for specific assistance in developing the health education program. The two organizations signed an agreement in August 1953 whereby, under the United Nations expanded program of technical assistance, the World Health Organization would assign a qualified public health educator to the Agency, would underwrite training fellowships in health education for 10 persons, and would provide a modest sum for teaching equipment and materials.

In November 1953 the World Health Organization assigned a public health educator to UNRWA on a 2-year contract. Through his coordination with members of the UNRWA staff and the staffs of other agencies, a course of instruction in health education was established at the Agency headquarters office in Beirut. The course consists of 6 months of academic work, which is integrated with some field work, and 6 months of full-time supervised field training. Ten Palestine refugees, 7 men and 3 women, were recruited for the training from the areas served by UNRWA and reported on February 22, 1954. The 9 members of the class who completed their academic work in August 1954 and their supervised field work in February 1955 have been employed on a full-time basis by the Agency and are working in the 4 countries in which they did field work.

Thus far the training course has been successful. The Agency requested an increase in fellowship funds, which WHO granted, to assist in the support of a second class of 11 persons who commenced their academic work in November 1954. This group is now on supervised field work in Lebanon, Syria, Jordan, and Gaza. They will complete the year's course in October 1955, at which time it is anticipated they will also be employed by the Agency. It is hoped that eventually they will be utilized as health education leaders by governments and voluntary agencies in the eastern Mediterranean area.

• • •

A section (pp. 8-14) in the 1955 annual edition of the publication, Health Educators at Work, has been devoted to program planning in health education for the Palestine Arab refugee. Written by Dr. Louis Findlay and William A. Darity, the article tells what came after Mr. Butterworth's article and describes the actual

training program in health education. Dr. Findlay is the WHO medical officer assigned to UNRWA as chief of the health division, Beirut headquarters office, and Mr. Darity is the WHO health educator on loan to the same office. *Health Educators at Work* is published by the Department of Public Health Education, School of Public Health, University of North Carolina, Chapel Hill, and the Department of

Public Health Education, North Carolina College, Durham.

PHS film

Functioning of Gas Feed Chlorinators

Part 1: Visible Vacuum Chlorinator.

Part 2: Volume Metering Chlorinator.

35 mm. Filmstrips, color graphics, Part 1—12 minutes, 57 frames; Part 2—10 minutes, 42 frames. 1954.

Audience: Sanitary engineers, sanitarians, and others interested in water chlorination.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE, Atlanta 23, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

The primary parts of visible vacuum and volume metering chlorinators and their functions are illustrated in these filmstrips.

Points to be checked at each inspection for assurance of proper operation of the machines are also depicted. For the visible vacuum chlorinator in part 1, the scale inside

the bell jar that indicates the amount of chlorine being fed, the weight of the chlorine cylinder to tell how near it is to being empty, the chlorine gas, water supply, and auxiliary supply pressure gauges are shown as operation check-points.

For the volume metering chlorinator, part 2, the water pressure gauge,

the pulsations-per-minute, the chart for checking the amount of chlorine fed per day, and the weight of the chlorine cylinder are emphasized.

The basic principles and inspection check-points pictured in these filmstrips aid in the understanding of the functioning of the general types of the machines featured.

A cross section of a visible vacuum chlorinator. Its function is to apply chlorine gas to water in an accurate and continuous flow.

Education of Public Health Workers

By EDWARD M. COHART, M.D., WILLIAM R. WILLARD, M.D.,
and FRANCES KORD, M.S.

HOW much formal education have public health workers had? How much training in public health have they had? In what fields have public health workers received major education? What further education do they want?

The Yale Public Health Personnel Research Project sought answers to these questions, in keeping with its mission to study people, rather than operations, in public health. Answers were obtained through interviews with 875 professional and semiprofessional public health workers in the State health departments of Colorado, Connecticut, Florida, Maryland, and Michigan, and in selected local health departments and visiting nurse associations in these States and New York. (An account of the methods used was given in the May issue of this journal, pp. 447-452.) These workers were distributed among the various public health services and classified according to position in the administrative hierarchy as shown in table 1.

The agencies chosen for this study were se-

lected, on the basis of the value judgments of the consultants and advisers to the Yale project, as representative of "better-than-average" health departments. Every public health worker whose activities differed materially from those of any of his co-workers was interviewed. As a result, the proportion of high-echelon personnel interviewed was much larger than the proportion of staff-level personnel. This bias may affect conclusions drawn for the combined group of high-echelon and staff personnel and comparisons between them.

Level of Education

Only 5 percent of the personnel at the higher administrative levels (those of supervisor and higher rank) and 13 percent at staff level had not gone beyond high school (table 2). About 40 percent of the personnel in the statistics service, at both staff and higher administrative levels, as well as 27 percent of the sanitation personnel at staff level and 20 percent of the administration personnel in the high echelons, were in this category.

Thirteen percent of the high-echelon personnel and 32 percent of staff-level personnel had 1 to 4 years of college education but had not received a degree. Whereas 80 percent or more of the high-echelon personnel in most of the services were college graduates, only 40 percent of administration personnel and 47 percent of statistics personnel were in this class. Fifty-five percent of all staff-level personnel were college graduates; the nursing service had the lowest proportion, with 32 percent.

Fifty-three percent of all high-echelon per-

Dr. Cohart, associate professor of public health, Yale University School of Medicine, and Dr. Willard, dean of the College of Medicine at Syracuse, State University of New York, were co-directors of the Yale Public Health Personnel Research Project. Miss Kord, director of health education for the Massachusetts Tuberculosis and Health League since 1953, was a research assistant with the Yale project. The project was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

Table 1. Number of personnel interviewed in official agencies and visiting nurse associations, by administrative level and service

Service	High- echelon ¹	Staff ²	Total
Medical.....	99	13	112
Nursing.....	118	³ 142	260
Sanitation.....	69	117	186

Nutrition.....	12	1	13
Social work.....	8	6	14
Other professional.....	14	25	39
Total.....	425	450	875

¹ Includes persons with titles of supervisor, consultant, administrative assistant, assistant program director, program director, assistant health officer, and health officer.

² Includes persons classified as staff and senior staff.

³ Includes 1 practical nurse who is counted with "other professional" personnel in subsequent tables and analysis.

⁴ Unless otherwise stated, veterinarians are included with sanitation personnel in subsequent tables and analysis.

sonnel held master's or doctor's degrees. Even when the medical service is excluded, the proportion is still slightly higher than 40 percent. Graduate degrees were least common among statistics and administration personnel. Among staff-level personnel, only 22 percent possessed master's or doctor's degrees. Aside from the medical service, the health education service had the highest proportion of personnel with such degrees.

In general, except for the medical service where the doctoral degree is the rule, graduate education was found to be positively associated with position in the administrative hierarchy. Meaningful comparison could be made only in some of the larger services, such as nursing, sanitation, and laboratory.

In the nursing service, 36 percent of the program directors and consultants, as compared with 10 percent of the supervisors and 3 percent of the staff personnel, had graduate degrees. Among sanitation personnel, 53 percent of the program directors, 17 percent of the consultants and supervisors, and 22 percent of the staff workers had graduate degrees. Among the

laboratory personnel, 66 percent of the high-echelon personnel, 41 percent of the senior staff, and 17 percent of the junior staff held graduate degrees. The laboratory service presented a different pattern from the other two services in that the level of education of senior staff personnel differed materially from that of junior staff personnel.

Because of the marked salary differentials among the several services, the relation of salary to level of education was analyzed for each of the larger services separately. In the medical service, no association could be shown between educational level and salary since all members had doctoral degrees, but in the other services analyzed, a positive association was found.

Six percent of the nurses earning less than \$4,000 and 30 percent of those earning \$4,000 or more had graduate degrees; 40 percent of those earning less than \$4,000 and 75 percent of those earning \$4,000 or more were college graduates.

Among sanitation personnel with salaries of \$4,000 or higher, almost half had graduate degrees, whereas only 5 percent of those earning less than \$4,000 a year had achieved this level of education. One-third of the sanitation personnel earning less than \$4,000 and 85 percent of those in the higher salary brackets were college graduates. Half of the engineers and 6 percent of the sanitarians with graduate degrees held positions which paid \$6,000 or more.

More than half of the laboratory personnel in the \$4,000-and-higher salary brackets and only 6 percent of those earning less than \$4,000 held graduate degrees. It was rare for a laboratory worker without at least an undergraduate degree to earn \$4,000 or more. Only 3 percent of the laboratory personnel earning \$4,000 or more were not college graduates. In the salary brackets below \$4,000, 40 percent of the personnel were not college graduates.

Level of Public Health Training

Public health training was classified into formal and informal. Included in formal training were graduate degrees in public health, baccalaureate majors or minors in public health, and certificates in public health nursing. Planned inservice training (but not orientation as part

of supervision), institutes, short courses, field training, and the study of public health in the basic training of nurses were considered informal public health training.

One-quarter of the high-echelon personnel held graduate degrees in public health; one-fifth had had undergraduate training in the nature of a major or minor in public health or a certificate in public health nursing; and one-third had received informal public health training only (table 3). More than half of the high-echelon medical personnel and an even higher proportion of the high-echelon nurses had had formal public health training, but most of the nurses had received their training at the undergraduate level. Undergraduate public health training of personnel other than nurses was negligible.

Only 7 percent of the staff personnel held graduate degrees in public health, and only 14 percent had had formal public health training at the undergraduate level. Among staff per-

sonnel, as among high-echelon personnel, undergraduate training in public health was restricted almost entirely to nurses. A trend toward the more widespread inclusion of instruction in public health in the basic training of nurses is indicated by the fact that 65 percent of the nurses who had received their training since 1930 had had such instruction, as compared to 45 percent prior to that date.

Approximately half of the staff-level personnel in the medical, nursing, and health education services had received formal public health training, as compared with 4 to 12 percent of the personnel in the other professional services.

In view of the high educational level of many members of the laboratory service, but the relative paucity of public health training, the areas of graduate study of laboratory personnel were investigated. This information was available for 36 laboratory personnel: 86 percent had specialized in the natural sciences; 14 percent, in public health; 8 percent, in medicine; 5 percent,

in engineering; and 3 percent, in veterinary medicine.

All the graduates of accredited schools of public health were given the opportunity to discuss the training which they had received, and 80 of them offered comments. It is important to point out some of the characteristics of this group before considering the replies. Approximately half had received their public health degrees since 1945, and only 15 percent, prior to 1935. Professionally, the group was constituted as follows: physicians, 52 percent; health educators, 11 percent; nurses, 9 percent; engineers and laboratory scientists, each 6 percent; dentists, 5 percent; sanitarians, 4 percent; statistics and nutrition personnel, each 2 percent; and administrators, 1 percent.

The most frequent criticism of the public health curriculum was to the effect that not enough instruction was given in the practical

aspects of community organization and public relations. This was closely followed in frequency by statements about the lack of adequate courses in administration. Through many of the comments ran the complaint, either implied or clearly stated, that the graduate curriculum in public health was not practical enough, that it should place much more emphasis on field work, and that perhaps many of the teachers might benefit from current, or at least more recent, practical experience in the field.

Table 3 reveals that one-third of all high-echelon personnel had had only informal public health training. An additional one-third had received such training as well as formal public health training. As can be seen in table 4, informal training was most frequent among nursing personnel and practically nonexistent for administration personnel.

An analysis of the type of informal training

received reveals that, in every service, there was greater participation in short courses or institutes than in any other category of informal public health training. Of all high-echelon personnel, 53 percent had participated in short courses or institutes and 34 percent in field training in other agencies. The extent of participation in field training in other agencies by nurses was at least twice that of any of the other services. Inservice training was the least frequent of the three components of informal public health training.

Two-thirds of the workers at staff level also had received informal public health training, either alone or in combination with formal education in public health. Forty percent had had short courses or institutes; 24 percent had had field training in another agency; and 22 percent had had inservice training.

Staff nurses, like high-echelon nurses, had participated in informal public health training to a greater extent than members of any of the other services. About 90 percent of the nurses

had had some kind of informal training in public health, and 72 percent had participated in short courses or institutes.

Content of Education

The content of major education, that is, "minors" or "majors" at the undergraduate or graduate level, was classified according to nine broad categories as follows: mathematics and the natural sciences, medicine, fields allied to medicine, engineering, public health, social sciences, administration, the humanities, and others. The distribution of public health workers according to this system of classification of major education is given in table 5.

The public health workers in this study can be divided into two groups in accordance with the proportions who had had major education in the natural sciences. In one group are the medical, sanitarian, and laboratory scientist personnel, at least two-thirds of whom have had major education in the natural sciences. The

¹ College or professional school graduate.

second group embraces all the remaining categories of personnel, only one-third or less of whom have had such education.

Medical education was limited almost entirely to the medical service. All the nurses and a large percentage of the nutritionists, of course, had had major education in allied medical fields. Except for an occasional person with engineering training in the administration, statistics, and laboratory services, engineers were limited to the sanitation service.

More than half of the medical and nursing personnel had had formal public health training. They ranked highest in this respect, whereas sanitation, laboratory, statistics, and administration personnel were at the bottom of a rank-order listing.

With the exception of 14 percent of the personnel in the health education service and 26 percent of those in the statistics service, less than 10 percent of the personnel had had major education in the social sciences. The social science education of the statistics personnel was primarily in the field of economics.

Less than one-third of the administration personnel had had major education in administration. None of the physicians, nurses, laboratory personnel, or sanitary inspectors and only 2 to 3 percent of the sanitarians and engineers had had major education in general administration.

One-third or less of the several categories of public health personnel had had major education in the humanities; health education personnel had the highest percentage with major education in these fields.

Because of the prevailing interest in the baccalaureate majors of medical personnel who enter upon careers in public health, this subject was investigated. Eighty-two percent of the physicians had majored in the natural sciences, and 9 percent, in the humanities. The remaining 9 percent were spread among several different fields, with only 1 percent in the social sciences. It is evident, therefore, that education in social sciences could not have been a major factor in directing the paths of these individuals into public health.

Another area in which there has been considerable interest is the baccalaureate majors of health education personnel. The findings in this study corroborate the general impression that health education personnel have diverse educational backgrounds. One-third had majored in the humanities; another third, in the natural sciences; and only 11 percent, in the social sciences. In the group of health educators with graduate degrees from accredited schools of public health, almost half had majored in the natural sciences, but none had majored in the social sciences.

Desire for Additional Education

Approximately 70 percent of 608 professional public health workers (in Connecticut, Maryland, Michigan, and New York) desired additional education (table 6). Differences between State and local personnel were not significant, and the desire for further education was not related to position in the administrative hierarchy. Fewer medical than nursing, sanitation, or laboratory personnel wanted additional education.

Sixty-eight percent of the workers desiring further education wanted individual courses not leading to a degree; 1 percent wanted a baccalaureate degree in engineering; and between 6 and 10 percent desired each of the following types of education: inservice training, institutes, a baccalaureate degree in a field other than engineering, a graduate degree in public health, and other graduate degrees. A significantly higher proportion of high-echelon nurses

(20 percent) than of other high-echelon personnel (4 percent) desired a graduate degree from a school other than an accredited school of public health, and a significantly higher percentage of the staff nurses (30 percent) than of other staff personnel (4 percent) desired a baccalaureate degree.

As a further index of the emphasis placed upon education by different categories of public health personnel, the data were analyzed to determine how many of those without degrees desired them. The numbers without college degrees in the higher levels of the administrative hierarchy were too small for meaningful comparison by service. At the staff-level, 31 percent of the nurses, 23 percent of the laboratory personnel, and 10 percent of the sanitation workers not holding degrees desired them. A significantly higher proportion of nurses than of all other personnel combined desired a baccalaureate degree.

¹ In Connecticut, Maryland, Michigan, and New York.

² Includes the social sciences, the science of human behavior, administration, community organization, and the arts and techniques of communication.

³ Total percentages are approximations only, because the staff-level interview sample was not equally representative of all services.

Education desired was divided into four broad categories: public health, mathematics and the natural sciences, social studies, and the humanities. Social studies included the social sciences, the science of human behavior, administration, community organization, and the arts and techniques of communication. The preferences of the members of the several services in accordance with administrative level are to be found in table 6.

Of all the public health personnel interviewed, approximately one-half desired further education in public health; one-fifth, in social studies; one-sixth, in mathematics and the natural sciences; and only a small fraction, in the humanities. A significantly larger proportion of the high-echelon personnel (24 percent) than of the staff personnel (16 percent) desired further education in social studies.

There were a number of significant differences among the services. Fewer laboratory personnel than any other category, except statistics and health education personnel at staff level, desired further education in public health. A much larger percentage of laboratory personnel than of personnel in any other service were interested in further education in the natural sciences, and, correspondingly, a much smaller percentage of laboratory personnel wanted further education in social studies.

A more detailed examination of the desire for further education in public health revealed that the greatest demand among high-echelon personnel was for general public health education. Fifteen percent indicated this preference. Five percent wanted education in environmental sanitation; 5 percent, in medicine; and 3 percent, in engineering. Two percent or less expressed the desire for education in adult health, communicable disease, health education, laboratory science, maternal and child health, medical care, mental health, nursing, or rehabilitation.

Among staff-level personnel, 11 percent desired education in nursing; 9 percent, in environmental sanitation; and 4 percent, in engineering. Seven percent of the staff workers were interested in general public health education. Two percent or less expressed a preference for education dealing with any of the other aspects of public health.

Areas for Evaluation

Although the purpose of the research reported here was simply to determine the facts, it would seem appropriate to point out a few of the areas in which the factual data call for evaluation.

There was a wide range in educational level. Approximately one-tenth of the professional and semiprofessional personnel had not gone beyond high school. Another one-quarter had not received a college degree. Nurses are in an unusual position in this respect, inasmuch as most nurses obtain their training in hospital schools of nursing, which do not grant degrees.

Do these findings indicate that a sizable proportion of the workers have not reached an educational level sufficient to qualify them for their jobs? If the answer to this question is in the affirmative, what are the factors responsible for this state of affairs and how can they be altered?

Or are there forces operating within the domain of public health which place unwarranted emphasis on educational level and therefore lead to the pursuit of academic degrees which do not necessarily contribute to the successful fulfillment of public health job responsibilities? Why, for example, do public health nurses feel a strong need to obtain a baccalaureate degree? Is it because they feel the need for more education in the liberal arts, the social sciences, or the techniques of nursing? Or is it because the possession of a college degree, regardless of area of study, is necessary for advancement?

Undergraduate training in public health was relatively frequent among the nurses and practically nonexistent among the other categories of personnel. Are opportunities for undergraduate education in public health being missed? Or should education in public health be reserved for the graduate level?

Laboratory personnel differ from most other health department personnel in that their interests appear to be restricted to the laboratory and do not encompass the broad field of public health practice. What effect does this have on the "team approach?" For that matter, what is the effect of marked variation in educational level and background upon communication, administration, and a cooperative effort? Does

the common understanding essential for teamwork exist?

A positive correlation was shown to exist between formal education and position in the administrative hierarchy and between education and salary, but exceptions were sufficiently frequent to give one pause. Are these exceptions examples of poor public health practice? Or is formal education perhaps less important than public health workers are in the habit of believing?

It was reported in a previous article that about one-third of the time of health workers was devoted to activities related to administration and community organization. How have public health workers been qualified by education to perform these tasks? Major education in administration was rare indeed, except among personnel in the administration service, and even there it was found among a minority only. Major education in the social sciences, although not as rare as that in administration, was limited to less than 1 in 10 workers. Emphasis was on the natural sciences. Is this adequate preparation for public health practice? Perhaps we have placed too much emphasis on level of education and given insufficient consideration to content.

The importance and value of public health training need reexamination in the light of several of the findings of this study. Between one-fifth and one-third of the public health workers had had neither formal nor informal public health training, and another third had had informal training only. Formal public health training was more frequent among high-echelon than among staff-level personnel and very much more frequent among the physicians, nurses, and health educators than among other personnel. How do these facts influence public health practice? And, conversely, what is the effect of public health practice on public health training?

Only a relatively small proportion of the personnel desired inservice training. An investigation into the reasons for this attitude might be revealing. It is not unlikely that the nature

and caliber of inservice training programs were important determinants of this attitude and that the proper organization of inservice training presents a major opportunity for the education of public health workers. Where does responsibility for such organization rest?

What is the role of the schools of public health in the education of public health workers? It appears that the schools of public health play a major role in the education of medical personnel only. More than 50 percent of the public health physicians and health education personnel had received graduate education in public health, but only about 10 percent of the members of the other services had had such education, many of them in schools other than the accredited schools of public health. Furthermore, informal public health education in the form of short courses and institutes was the greatest single source of public health training for the latter workers and also the type of training desired by the largest number. Schools of public health play a very minor role in sponsoring and giving such courses.

The most frequent criticism of the curriculum of schools of public health was related to the teaching of administration and community organization. A common complaint was that this training was not only insufficient in amount, but also inadequate in scope, because of the failure to include practical applications of principles, in line with the needs of practitioners of public health.

The problem raised by this criticism is part of a broader question which relates to the role of institutions of higher learning generally. Is it the responsibility of such institutions to train investigators and research workers who will enlarge the boundaries of knowledge? Or is it their responsibility to train practitioners to apply present knowledge effectively to the problems of our society? Or is it perhaps both of these? If the responsibility does, in fact, encompass the training of both researcher and practitioner, then it appears that it is not being discharged adequately by our schools of public health.

Morbidity and Mortality in Early Infancy

Infant mortality in the United States, as evidenced by records available since the organization of the birth registration area in 1915, has declined rather steadily. The rates in the Mountain and Southern States are somewhat higher than in the three other broad regions—the Northeast, North Central, and Pacific sections.

Trends of infant mortality of males and females are parallel but the rates for females are considerably lower than those for males. Considering actual rates by age of the infant, the older the infant the more rapid the percentage decline in infant death rates.

Reduction of rates to a comparable annual basis indicates extremely high mortality from all causes at the ages under 1 day and 1–2 days, with an uninterrupted decline with age in the rates for the 12 months of the first year of life.

Among infants of all ages under 1 year, the most frequent causes of illness are respiratory, digestive, communicable, and congenital malformations and diseases of early infancy. In contrast, the most frequent causes of death are immaturity, both with and without various diseases of early infancy, and congenital malformations. Pneumonia also stands high as a cause of infant mortality.

In five broad diagnosis groups for illness and mortality, infant illness rates for females are generally below those for males, and infant mortality rates for females are almost uniformly lower than for males.

Considering an immature infant as one weighing 2,500 gm. or less at birth, and a mature infant as one weighing 2,501 gm. or more at birth, the neonatal infant mortality from all causes and from specific causes among the mature as compared with the immature was extremely small. However, neonatal mortality among infants weighing 4,501 gm. or more at birth was somewhat higher than at the minimum, which occurred among infants weighing 3,501–4,000 gm.

Whooping cough, measles, and chickenpox had relatively high incidence rates during the first year of life, and mumps and german measles, rather low rates in that period. Whooping cough and chickenpox had relatively high secondary attack rates but measles, german measles, and mumps had relatively low such rates.

Public Health

MONOGRAPH

No. 31

The accompanying summary covers the principal findings presented in Public Health Monograph No. 31, published concurrently with this issue of Public Health Reports. The authors are with the Division of Public Health Methods, Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

Cancer Control Activities of the National Cancer Institute

By RAYMOND F. KAISER, M.D.

CANCER CONTROL is concerned with the actual prevention of cancer whenever possible, with the discovery of the disease in its earliest stage, and with the provision of adequate services and facilities for diagnosis and treatment. Ideally, a cancer control program to be effective requires:

1. An alert and trained profession.
2. An informed public.
3. Suitable methods for prevention of the disease.
4. Case finding, screening, or diagnostic procedures which can be applied on a mass basis to sort out individuals with the disease from the remainder of the population.
5. Adequate services and facilities for diagnosis and treatment.

The cancer control program of the National Cancer Institute of the Public Health Service is designed to meet some of the needs which exist in these requirements and to demonstrate appropriate methods for fulfilling some of these conditions. This program, now in its eighth

year, has special implications for practicing physicians.

Cancer diagnosis and treatment frequently call for the services not of a single physician but of a qualified team. However, the cancer patient ordinarily is seen first by a general practitioner, whose diagnostic training and experience often determines the outcome. For this reason, the major emphasis in cancer control is placed on programs designed to aid the physician by improving professional undergraduate, graduate, and postgraduate education and by providing diagnostic and other special services to help the physician be effective.

If the physician is to manage successfully an optimal number of cancer cases, he must bring to his practice an awareness of cancer in all of its diverse manifestations. Obviously, the place to inculcate such an awareness is in the undergraduate school. However, it can be fairly said that until a few years ago most medical school curriculums did not provide an effective and integrated presentation of this important subject.

On the basis of a study of cancer teaching in medical schools made early in 1946, our National Advisory Cancer Council recommended that the National Cancer Institute undertake a program of financial assistance to medical schools to coordinate and improve the teaching of cancer to undergraduates, thereby increasing

Dr. Kaiser is chief of the Field Investigations and Demonstrations Branch of the National Cancer Institute, Public Health Service. He presented this paper before the Maryland Medical and Chirurgical Faculty April 28, 1954.

the students' awareness of cancer. The program, based on these recommendations, has gained universal acceptance during the 7 years of its operation, and today all approved medical schools are participating in the program.

Each of the 4-year medical schools receives a grant up to \$25,000 annually, and each 2-year medical school receives a grant up to \$5,000 a year for the broad purpose of correlating and improving its cancer instruction. Within this general purpose the schools have been permitted maximum latitude to develop the type of program which best meets their particular circumstances. We have always felt that the direction of teaching programs must not come from the outside, but must be intramural and autonomous. Our belief has been justified not only by the widespread acceptance of this program, but by the perceptible improvement in cancer teaching.

A parallel program through which grants up to \$5,000 annually are made to dental schools for instruction of undergraduate students in the recognition of oral cancer has been in existence for approximately the same period of time. This program is based on the fact that a large proportion of oral cancer cases are first seen by dentists, and only a limited percentage of these are recognized as malignant conditions requiring immediate referral to adequate medical attention. This program, too, has enjoyed widespread acceptance, and practically all approved dental schools are participating.

In recent years considerable effort has been devoted to the improvement of cancer instruction in a limited number of schools of nursing in order to determine the most practical methods of providing graduates with a better understanding of cancer and to equip them better for handling cancer nursing activities.

For a number of years similar educational grants have been extended to a small number of schools of public health in order to provide instruction for health department personnel in the public health aspects of the cancer problem.

With the increase in the magnitude of the cancer problem, there has developed a need for physicians with special training in the diagnosis and treatment of cancer. Both voluntary and governmental groups provide support for specialized training of graduate physicians.

The institute's program enables young graduate physicians interested in cancer to undertake clinical training in specialized fields related to its diagnosis and treatment. In recent years there has been a sharp increase in the number of physicians receiving such training in the three major disciplines of surgery, radiology, and pathology. At present, 143 graduate physicians are being supported in such training throughout the country.

For the practicing physicians, a number of attempts have been made to bring recent information about the disease directly to them. One of the most important of these has been the production, jointly by the institute and the American Cancer Society, of a series of films for professional audiences depicting the early diagnosis of cancer. In this series individual films have dealt with the diagnosis of breast, gastrointestinal, uterine, oral cancer, and lung cancer.

These films have been made available to practitioners through medical societies, medical schools, State health departments, and State divisions and county units of the American Cancer Society.

Other attempts at professional education have been handled through support of national cancer conferences, cancer symposiums, professional bulletins, cancer manuals or guidebooks, and refresher courses. These attempts at professional education have met with varying degrees of success; however, it is an essential part of the cancer problem and is considered a field requiring continuous efforts.

An Informed Public

The history of public understanding of the cancer problem in America has been one of gradual gain in the past century, with a marked increase in public interest and awareness of cancer in recent years. It is conceded by most authorities that a large and continuous education program, based on accurate data and using currently available knowledge, will result in considerable control of mortality from many types of cancer. To be successful, a public education program must stimulate the individual's awareness of cancer and motivate him to seek medical attention at the earliest possible moment in the development of cancer.

To develop an informed public, the institute has created educational materials which complement those of voluntary groups. And it has produced, in conjunction with the American Cancer Society, public information materials. Notable among these has been the film entitled "Breast Self-examination" which presents to women basic facts about breast cancer and urges them to seek their physician's advice at an early date. Another recently released film, "The Warning Shadow," was produced under the same sponsorship and is directed toward men over 45 years of age, urging them to seek semi-annual chest X-rays from their physicians.

In addition to assistance in production, the institute has developed arrangements with the American Cancer Society for the use of such information materials in a manner which would stimulate the individual's awareness of cancer and motivate the early seeking of medical care.

In general, the public is better informed about cancer today than at any time in history. However, even with progress in research and therapy, the education problem will continue and, in fact, may increase.

Cancer Prevention

In the field of cancer prevention, knowledge has been meager largely because in the past cancer workers have given little attention to environmental factors which may have a relationship to the causation of human cancer. Much of the knowledge now available has resulted from studies on small groups of people utilizing statistical, genetic, epidemiological, and other techniques to uncover relationships between cancer and environmental factors. For example, the first known etiological agent for scrotal cancer was confined to a small occupational group, the chimney sweeps of London.

Since the inception of the cancer control program, the potentials lying in the field of environmental cancer have been recognized. It was felt that, if relationships could be established between the development of cancer and certain specific materials the individual encounters in his home or industrial environment, it would be possible to eliminate or reduce the exposure to such carcinogenic materials, thereby preventing the development of certain cancers.

Numerous studies and investigations that have an immediate bearing on environmental factors have been undertaken by the National Cancer Institute or have been supported through grants. These studies have shown that most persons, if not all, have some degree of exposure to carcinogenic environmental agents under modern living conditions. They have also shown, however, that there is a latent period before specific cancers appear and that this is related to the degree and duration of exposure to a carcinogenic agent.

While there is much disagreement regarding the exact nature and the role of some of these so-called environmental carcinogenic factors—the current controversy concerning the relationship of cigarette smoking and lung cancer, for one—there has been accumulating in recent years much evidence that cannot be overlooked in respect to cancer control activities.

Among the environmental factors that have been shown to be carcinogenic are (a) certain products and byproducts of the manufacture or processing of aniline dyes, coal tars, and petroleum, (b) arsenicals and some inorganic chemicals, and (c) radioactive substances, X-radiation, and ultraviolet radiation. As more is learned about these and other suspected carcinogenic agents it is feasible to consider the establishment of cancer prevention programs in locations where such hazards exist, incorporating safe production and handling methods for the hazardous materials and instituting periodic examination of the exposed workers.

This is an aspect of the cancer problem which has come under systematic study only recently and in which increased efforts offer unlimited possibilities for making significant contributions to the solution of the cancer problem.

Diagnostic Tests and Case Finding

The key to cancer control today is early diagnosis and treatment, but this statement points up one of our biggest problems—how to find the cancer case early enough. It is recognized that there is no method available today other than general periodic physical examinations which holds promise of discovering early cancer of all types in the population. Periodic examinations do provide the opportunity for discover-

ing a sizable number of early lesions since more than one-half of all cancers occur at sites accessible to direct examination. However, this method is expensive and time consuming; and even if all persons of so-called cancer age could be persuaded to seek periodic examination, there are simply not enough trained hands in the country to do the job. Urgently needed, therefore, is a test which can be applied on a mass basis at reasonable cost and with specificity sufficient enough to identify a high percentage of cancer cases in an early stage.

For a great many years laboratory investigators, as well as practicing physicians, have been looking for differences between persons with early cancer and cancer-free individuals—subtle differences in the blood, sputum, urine, and various body chemicals. The belief that these differences are specific and measurable forms the basis for many reported so-called diagnostic tests. There have been numerous attempts to develop diagnostic and screening tests, and more recently, the entire subject has aroused great public and professional interest. The demand for a diagnostic test has become so great that every new procedure proposed is in danger of premature exploitation before its clinical validity can be determined. Recognizing this situation, the institute, through its Field Investigations and Demonstrations Branch, established a cooperative program with investigators in a number of medical schools. Evaluation of reported cancer tests is carried out under controlled conditions. At the same time, other investigators are encouraged, through grants, to pursue new leads which show promise for the development of a diagnostic or screening test.

Although a general diagnostic test for cancer is not available, some developments in recent years in diagnostic tools may form the basis for a screening test for cancer of specific sites. One of these, the cytological method developed by Papanicolaou and Traut for the discovery of early cervical cancer, has been evaluated and promoted as a diagnostic aid. Its usefulness as a screening procedure for uterine cancer is currently being evaluated by the institute in a study being conducted in Memphis and Shelby County, Tenn., in cooperation with the Univer-

sity of Tennessee Medical School and the county health department. The original cytological technique has been modified for use in the discovery of cancers of other sites, namely, lung, prostate, gastric, and bladder cancer. However, its usefulness and feasibility in these types of cancer have not yet been fully evaluated either as a diagnostic or screening procedure.

A recent promising development in this field is the test for prostatic cancer, developed by Fishman and later modified by Cline. Both of these developments were supported through the institute's control program. Here again further evaluation is necessary and is being carried out by the institute.

Even more recently Penn and Dowdy, with partial support from the control program, have developed a simple blood test which shows some promise of being able to distinguish between people free of cancer and those who may have it. Much more work and evaluation must be carried out on this procedure before it can be declared acceptable.

It might be appropriate at this time to clarify the type of test in which cancer control workers are most interested. Primarily, it is a test which will separate a large group of examinees into two categories—one consisting of those whose reaction to the test is negative, and the other consisting of a relatively smaller number of persons whose reactions are positive and who are, therefore, cancer suspects. It should be a test which would pick up a high percentage of individuals with early localized cancer. It should have a high degree of specificity without a large percentage of either false negative or false positive results. If an acceptable test which meets these general criteria can be developed, it would be a significant forward step in cancer. While such a test would not eliminate the need for further diagnostic procedures to diagnose the case, it would make it possible to concentrate diagnostic efforts on the small group of individuals with positive test results. *Despite the many problems associated with the development of an acceptable mass screening test, results to date have been encouraging.* It seems entirely possible that a test or battery of tests can be developed which will be effective on a mass screening basis in sorting out cancerous and noncancerous individuals.

In this connection, a small beginning has been made to conduct and support statistical epidemiological studies which might reflect geographic, climatic, racial, socioeconomic, and environmental differences in the occurrence of cancer. Preliminary data from some of these studies suggests that it may be possible to sort out the kinds and types of people who would be most likely to develop cancer. If such determinations could be substantiated, case-finding efforts could be directed more appropriately toward groups with the promise of the greatest cancer yield.

Cancer Facilities and Services

One of the most practical activities which has contributed to the control of cancer to date has been the organization and operation of cancer clinics. These clinics, usually operated in a general hospital, provide an environment in which representatives of the various specialty groups concerned with cancer, such as surgery, pathology, and radiology, can work with the patient's physician in arriving at an accurate diagnosis and effective treatment. The number of cancer clinics in the Nation has increased markedly in recent years. However, there are still not enough to meet the need, and the establishment of additional cancer clinics is being promoted and encouraged. This, along with various other types of services for physicians, has been encouraged through the institute's

program of grants to State health agencies for cancer control activities.

Under this program each State receives an annual allotment based on a formula which takes into account cancer mortality, financial need, extent of the problem, and population density. The grants must be matched on a two-for-one basis. These funds may be used for a variety of purposes which aid physicians as well as the cancer patient. Included among these are support for cancer clinics, cytology services, tissue services, cancer registers, statistical research, professional and lay education, nursing services, limited hospitalization for diagnostic purposes, tumor registers, environmental cancer programs, and tissue slide loan registers. All of the official State agencies now have cancer control programs incorporating a few or several of these features.

Conclusion

An extensive, dynamic cancer control program is under way in this country. It has resulted from the combined efforts of many professional groups, private, voluntary, and governmental, as well as from the efforts of medical specialists, clinicians, private practitioners, public health workers, and scientists. There is a continuing need to improve the nature and effectiveness of the program. The latter will improve as cancer research provides more knowledge about the diagnosis, treatment, and prevention of cancer.

X-raying the Heart Cycle

BETHESDA, MD. With the new cardioerontgen actuator, literally a complex trigger for X-ray machines, the taking of X-rays at known times in the heart cycle need no longer be a matter of guesswork.

Superior diagnosis and treatment of heart ailments can often hinge on the cardiologist's sure knowledge that each successive X-ray picture to be compared, sometimes taken years apart, was shot at exactly the same instant in the heart cycle. The ever-changing normal heart volumes and the subtle enlargements of sick hearts are variables that frequently

deserve precise identification and correlation before two X-ray films can be truly compared.

With the new instrument developed by the Public Health Service at the Laboratory of Technical Development, National Heart Institute, the cardiologist can be assured specific mechanical help in this endeavor.

The photograph illustrates the operation of the instrument. The actuator, housed in a special control box (right) operates in conjunction with a conventional electrocardiograph (left) that continuously traces the heart's electrical activity. This activity is correlated with the expansion and contraction of the heart. The electrocardiographic signal triggers the X-ray exposure at any selected time in the heart cycle.

A monitoring photo cell, hanging

below the patient's elbow in the background of the photograph, detects the X-ray exposure and feeds an electrical pulse back into the electrocardiographic curve, marking the exact instant of exposure. A calibrated switch on the actuator permits proper time selection with respect to heart rate so that films can be taken at full expansion, full contraction, or at any intermediate time. In addition, the instrument contains a provision to prevent double exposure.

The actuator is not yet commercially available. A circuit diagram showing the wiring of the instrument and detailed technical information may be obtained from Dr. Bert R. Boone, chief, Laboratory of Technical Development, National Heart Institute, National Institutes of Health, Public Health Service, Bethesda 14, Md.

In preliminary studies, human body lice maintained in the laboratory for many generations on lindane, Lauseto neu, and the pyrethrins developed much less resistance to these insecticides than has been developed to DDT. The lice developed no resistance to a pyrethrum-sulfoxide compound after 30 generations.

Resistance of Human Body Lice to Insecticides

By GAINES W. EDDY, M.S., M. M. COLE, B.S., MAX D. COUCH, B.S.,
and ALLEN SELHIME, B.S.

THAT INSECTS can develop resistance to insecticides has been known for approximately 50 years. However, the subject has been studied extensively in this country only during the last 6 years, following the development of resistance to DDT by houseflies. The literature on the development of insect resistance to insecticides has been reviewed by Babers (1) and Babers and Pratt (2). Several important references are given in the Yearbook of Agriculture for 1952.

The laboratory of the Entomology Research Branch of the United States Department of Agriculture conducted research at Orlando, Fla., from June 1951 to August 1954 on the resistance of the human body louse, *Pediculus humanus humanus* L., to DDT, lindane, Lauseto neu (chloromethyl *p*-chlorophenyl sul-

fone), pyrethrins, and pyrethrins plus sulfoxide (*n*-octyl sulfoxide of isosafrole).

Lindane, Lauseto neu, and pyrethrins were selected for study because of their general effectiveness against both normal and DDT-resistant lice. Lindane is of special interest because it has been adopted by the Armed Forces for the control of body lice in areas where resistance to DDT has developed.

The experimental development of resistance has usually been accomplished under laboratory conditions by selection. A concentration of toxicant that will cause moderate to high mortality is used, and the survivors serve as parents of the next generation. In some of the Orlando studies reported here the lice were exposed to very light deposits of insecticides which caused no apparent mortality or injury. The dosages varied with the insecticides, but most of them were approximately one-tenth those usually required to give a low mortality or moribundity.

Previous Reports on DDT Resistance

A number of workers in the field and in the laboratory have reported on the development of DDT-resistant lice. Bushland and associates in 1945 (3) and Eddy and Bushland in 1948 (4) demonstrated that cloth impregnated

The authors are entomologists with the Entomology Research Branch of the United States Department of Agriculture. Mr. Eddy is entomologist in charge of the Corvallis, Oreg., laboratory of the Insects Affecting Man and Animals Section. Mr. Cole and Mr. Couch, with the same section, are stationed at Orlando, Fla., and Mr. Selhime is with the Fruit Insects Laboratory at Orlando.

with a 0.05-percent DDT solution or treated with a powder containing 0.1 percent of DDT caused complete or nearly complete mortality of body lice in 24 hours. In 1950, King (5) reported that lice surviving single exposures to DDT at a concentration causing high mortality showed no resistance after several generations.

However, Hurlbut and associates in 1952 (6) failed to control lice on Korean military personnel with a powder containing 10 percent DDT and indicated that the failures were due to resistance. In the same year Barnett and Knoblock (7) showed that body lice in Japan were also resistant to DDT. Data on the susceptibility of the lice in Korea and Japan prior to the general use of DDT in those areas apparently were never obtained.

In 1953, Busvine (8) reported that a strain of lice from Egypt were resistant to DDT but susceptible to other insecticides. Hurlbut and associates (9) reported in 1954 that, after being in general use in Egypt since 1947, 10-percent DDT powder did not control lice any longer, and laboratory tests confirmed some degree of resistance to DDT.

Yasutomi (10) presented laboratory data in 1952 showing that body lice in Japan could develop considerable resistance to DDT in three generations and to BHC in two generations. The lice used by Yasutomi were obtained from vagrants in Ueno in Tokyo, Japan, and he assumed that they had had no previous exposure to either DDT or BHC. However, both chemicals had been available and rather widely used in Japan for several years.

The resistance of body lice in Korea to DDT and several other compounds was studied by Eddy in 1952 (11). He showed the lice in Korea to be at least 100 times more resistant to DDT than a laboratory strain of body lice maintained at Orlando, Fla. However, the resistance of the lice to certain other insecticides tested at the same time was not marked.

The resistant Korean lice were collected from prisoners of war who had been dusted with DDT from time to time during 6 to 9 months. In the tests made in Korea 10-percent DDT powder caused 60 percent mortality during a 24-hour exposure, which indicated that many insects in the population were susceptible.

Methods of Current Studies

For the current Orlando studies, two lots of lice highly resistant to DDT were obtained from Korea. The standard, or regular, colony was descended from lice collected in the United States before the advent of DDT.

The methods used for rearing the lice were essentially the same as those described by Culpepper (12, 13). The procedures described by Bushland and associates (14) and Eddy (11) were used to test the insecticides as cloth impregnants and as powders.

After rearing the resistant Korean lice for three generations without exposure to insecticides, a portion of one lot was maintained on cloth that had been impregnated with DDT by dipping it into a 0.01-percent solution in acetone. The remainders of the two lots were then combined and maintained on untreated cloth.

At first all Korean lice were fed twice daily on human subjects, but later they were fed on rabbits once each day. The standard colony had been fed on rabbits for a number of years.

Resistance to DDT

In the tests with the Korean lice maintained on cloth impregnated with 0.01 percent DDT, application of 10 percent DDT caused high but incomplete mortality during the first few generations. However, the resistance gradually increased, and by the 15th generation few or none of the lice were killed in 24 hours.

In another experiment 100 young adult body lice (50 of each sex) from the regular colony, which had had no previous contact with DDT, were placed on cloth impregnated with DDT by dipping it into a 0.001-percent solution. The lice were transferred to freshly impregnated cloth three times weekly. The resistance developed is shown in the table. Most of the data represent averages of 2 tests with 20 lice (10 of each sex) per test and an exposure period of 24 hours. The lice maintained on DDT showed slight resistance by the 5th generation and by the 8th generation were approximately five times as resistant as those of the regular colony. By the 16th generation resistance was very high, but could not be measured accurately as the highest test concentration of DDT (10 percent)

failed to kill all the lice. There was a slight additional increase in resistance by the 25th generation, after which this colony was discontinued.

How much selection, or mortality of susceptible individuals, occurred during the first few generations and whether selection was primarily responsible for the degree of resistance developed were not determined. In subsequent tests to check on these points it was found that adult lice maintained on cloth treated with 0.001 percent DDT did not live quite as long as the controls or lay quite as many eggs. However, the difference did not appear to be sufficient to justify the conclusion that resistance was developed through selection alone.

Other tests indicated that nonresistant lice could be maintained on cloth treated with 0.0001 percent DDT with no more mortality than those maintained on untreated cloth. Accordingly, 2 colonies each with 200 newly hatched nymphs were established on this concentration of DDT and two on untreated cloth. Mortality through seven generations was less for lice exposed to DDT than for the controls. This study is being continued.

Loss of DDT Resistance

A portion of the resistant colony obtained from Korea was reared on untreated cloth to determine the number of generations required for the lice to lose their resistance. Loss of

resistance was evident by the third generation and complete by the eighth.

After 17 generations had been maintained on cloth treated with 0.01 percent DDT, another portion of the resistant Korean colony was removed from DDT and reared on untreated cloth. The colony showed practically no loss of resistance after six generations but a considerable loss by the ninth generation. After 9 generations concentrations of 0.1, 1, and 10 percent of DDT caused 45, 75, and 75 percent knockdown and kill, respectively. Little or no further loss was indicated in tests of the 25th generation. Eventually the lice will probably lose their resistance, but apparently many generations will be required.

Lindane and Lauseto neu

Development of resistance to lindane and Lauseto neu was attempted by the method described above for DDT, that is, by continuously exposing the lice to sublethal concentrations of the insecticides. The concentrations used were 0.00005 percent for lindane and 0.0025 percent for Lauseto neu. The body lice used in these studies were from the Korean colony that had lost its resistance to DDT. In view of this, resistance to both insecticides, especially lindane, was expected to develop.

Lice of the fifth generation exposed to lindane and Lauseto neu showed no more than twice as much resistance as the regular colony. The

Relative susceptibility to DDT of normal body lice and lice maintained on cloth impregnated with 0.001-percent DDT solution for various numbers of generations

Percent concentration	Percent knockdown and mortality after indicated number of generations									
	5		8		12		16		25	
	DDT	Normal	DDT	Normal	DDT	Normal	DDT	Normal	DDT	Normal
10.0					90		95		90	
5.0					100		88		85	
1.0					100		90		70	
0.1	100	100			90		75		55	
0.05			100		95		65	100	75	
0.025	98	98	80	100	65	100	48	98	45	100
0.01	78	98	60	100	70	95	18	95	15	95
0.005	73	98	50	85	35	55	13	83	5	80
0.0025	45	93	40	45	0	45	0	65	0	10
0.001	10	43	10	5	0	5	3	5	0	0
Control (untreated)		13		0		0		0		0

lice have now been reared through 34 generations without any further increase in resistance to either material. The amount of resistance developed thus far is so slight that it seems well within the variation expected with any insecticide.

Pyrethrins and Pyrethrins Plus Sulfoxide

The lice used in studies with pyrethrins were taken from the regular colony, which had had no previous contact with DDT or other insecticides. As in the tests with the other materials, the lice were maintained on cloth treated with sublethal concentrations—0.001 percent of pyrethrins alone and 0.0001 percent of pyrethrins plus 0.001 percent of sulfoxide. No more than twofold resistance to pyrethrins was indicated in tests against different generations of lice up to and including the 17th, at which time the colony was discontinued. The pyrethrum-sulfoxide colony appeared to be no more resistant than the regular colony after 30 generations. Studies with this colony are being continued.

Summary

Studies were conducted on the development and loss of resistance of the body louse (*Pediculus humanus humanus* L.) to DDT, lindane, Lauseto neu (chloromethyl *p*-chlorophenyl sulfone), pyrethrins, and pyrethrins plus sulfoxide. The more important findings are:

1. Highly but not completely DDT-resistant body lice from Korea lost their resistance in 3 to 8 generations when maintained in a DDT-free environment.

2. DDT-resistant lice from Korea developed extreme resistance in 15 generations when maintained on cloth impregnated with a 0.01-percent DDT solution.

3. Extremely resistant lice lost approximately 75 percent of their resistance in 15 generations after being removed from contact with DDT.

4. Body lice from the regular colony, which had never been exposed to DDT, developed a high resistance in 25 generations when maintained on cloth impregnated with 0.001 percent of DDT. There was a very low mortality in the initial exposures, but resistance developed.

5. Body lice maintained for 34 generations

on cloth impregnated with low concentrations of lindane and Lauseto neu and 17 generations on pyrethrins failed to develop more than twofold resistance to these insecticides. Lice maintained on pyrethrins plus sulfoxide failed to develop any resistance in 30 generations.

Sanitary Engineering Degrees Given in 1954

By ARTHUR P. MILLER, C.E.

IN 1954 in the United States, there were 164 graduates from undergraduate sanitary engineering courses. Graduate degrees granted consisted of 120 master's and 9 doctor's.

Mr. Miller is sanitary engineer director in the Division of Sanitary Engineering Services, Public Health Service.

The institutions awarding the degrees are shown in the table. Similar data for undergraduates during the periods 1889-1950, 1951-52, and 1953, and for those awarded master's and doctor's degrees during the 54-year period 1899-1953 have been presented in earlier reports by the author (see list).

Undergraduate Degrees

All but 8 of the 40 colleges and universities reporting the availability of undergraduate courses in sanitary engineering had one or more graduates in 1954. There were 216 graduates in 1953 and an average of 242 per year for the 5-year period 1949-53. The number of graduates per 1,000 engineering graduates was 7.5 in 1954; 9.0 in 1953; and 6.2 in the 5-year period 1949-53.

Number of degrees in sanitary engineering, by level, granted in the United States, 1954

Leaders (.....) indicate no courses offered at this level.

¹ Other institutions offering sanitary engineering courses at the master's (m) or doctor's (d) level are: California Institute of Technology (d); Connecticut, University of (m); Idaho, University of (m); Illinois Institute of Technology (m, d); Iowa State College (m, d); Kentucky, University of (m); North Dakota, University of (m); Northwestern Technological Institute (m, d); South Dakota State College (m); Tennessee, University of (m); and Wyoming, University of (m).

Master's Degrees

Of the 120 master's degrees granted in 1954, 25 were awarded to nationals of foreign countries. Thirty, or 54 percent, of the 56 institutions offering graduate work in sanitary engineering at the master's level had graduates. Eight universities conferred 75 of the 120 degrees and 22 other universities awarded the remaining 45 degrees.

The number of master's degrees granted in 1953 was 102, of which 20 were earned by foreign nationals. The average number of master's degrees granted for the 5-year period 1949-53 and the 10-year period 1944-53 were 129 and 108, respectively.

Doctor's Degrees

The 9 doctor's degrees awarded in 1954 by 5 institutions were all to nationals of the United States. In 1953, 5 doctor's degrees, 3 of which were to foreign nationals, were granted. In the 5-year period, 1949-53, the average number of

degrees conferred per year was 6; in the 10-year period, 1944-53, it was 4.

Twenty-one universities offering work at the doctor's level had no successful candidates in 1954 (see footnote to the table).

PHS Staff Announcements

Dr. Kenneth W. Chapman, a specialist in narcotic addiction programs, has been assigned to the Community Services Branch of the National Institute of Mental Health. Dr. Chapman will provide consultative services to State and community governmental agencies and voluntary organizations on the prevention, treatment, and control of drug addiction. He has been executive secretary of the Public Health Service Committee on Drug Addiction.

Graduated from Yale Medical School in 1938, Dr. Chapman entered the Service the following year. Since 1946, he has worked on medical problems of drug addiction, principally at the Public Health Service Hospital in Lexington, Ky., where he was medical officer in charge from 1952-54. In 1955 he became head of the Neuropsychiatry Branch of the Division of Hospitals of the

Bureau of Medical Services, Public Health Service.

Dr. John W. Knutson, chief dental officer and Assistant Surgeon General of the Public Health Service, has been assigned to the World Health Organization for 6 months in order to organize a dental program. Dr. Knutson took over his duties in Geneva on July 1, 1955. Last year he was chairman of an international group of dental consultants convened in Geneva by the World Health Organization, and currently he is vice president of the Public Dental Health Services Commission of the Federation Dentaire Internationale. Dr. Knutson was a founding member of the American Board of Dental Public Health.

Pennsylvania's Aid To Cities in Financing Sewage Treatment Plants

By CHARLES H. YOUNG

PENNSYLVANIA, under 1953 legislation, is helping municipalities defray the cost of operating sewage treatment plants required by the State for the control of water pollution.

Earlier legislation, enacted in 1937, and known as the clean streams law, required construction of the plants. Both the construction and operation costs were to be borne by the municipalities.

The new act, No. 339, marks a change of thinking on the part of the Pennsylvania Legislature since it begins a program of annual subsidies to be paid to municipalities to assist in meeting the costs of the sewage treatment works.

The intent of the Pennsylvania General Assembly was set forth in the preamble of the 1953 act. The preamble is quoted in part and the main provisions are summarized on the following page.

Rules and Regulations

The Pennsylvania Department of Health prepared rules and regulations for the administration of the act. It also prepared application forms for the use of municipalities and municipality authorities in filing construction costs. The rules and regulations are intended primarily to clarify the eligibility of projects, or parts of projects, or items entering into the cost of construction. They stipulate what is required in a general drawing to accompany the applications to show clearly the project for which payment is requested. They explain proportioning costs of projects or parts of projects

when the total project involves more than is eligible for payment consideration. Under the regulations the costs of acquisition or construction are exclusive of grants or equivalent funds received from the State or Federal Government. The regulations further provide for payments to be made to other than the applicant, since many of the municipal authority projects are operated by the municipality under a lease-back agreement. The regulations also require the documentation of costs and provide for other features.

Allowed in determining the cost of acquisition or construction, or both, of the sewage treatment works, intercepting sewer, and pump station are: cost of the plant or pump station site, or both, and rights of way; engineering costs of the report, plans, specifications, supervision and inspection of construction; contract cost for the allowable treatment facilities and appurtenances, including supplemental contracts; financial costs; legal costs, and interest during construction. All cost data must be documented, and breakdowns of the construction costs and other costs are required where such breakdowns are necessary to establish clearly the cost eligibility of the project.

Experience to Date

A few of the municipalities have experienced difficulties in documenting the costs of their projects, particularly projects constructed in the years shortly after the effective date, September 1, 1937, of the clean streams law. These difficulties, however, have been reduced to date to several cases which are being handled on an individual basis.

A total of 124 applications were filed. For various reasons, the number has been reduced to 103. To date, 92 applications have been processed and the municipalities or municipality authorities have been paid a total of \$798,920.28. These municipalities received 2 percent of the approved costs. The remaining applications are in process.

Even though this legislation was given considerable publicity and form letters were mailed to all municipalities that were believed entitled to payment, a few Pennsylvania municipalities did not take advantage of this legis-

Mr. Young is division engineer of the Pennsylvania Department of Health.

"Whereas, The Commonwealth of Pennsylvania under the Act of Assembly approved the twenty-second day of June, one thousand nine hundred thirty-seven (Pamphlet Laws 1987), has required certain municipalities of this Commonwealth to construct sewage treatment plants to abate the pollution of the waters of the Commonwealth and thereby preserve and improve the purity of such waters in the interest of the public health; and,

"Whereas, these municipalities have in the past and will in the future expend large sums of money to acquire and construct sewage treatment plants in accordance with the Clean Streams Program and the aforesaid Act of Assembly, which sewage treat-

ment facilities benefit not only the local municipality but are a benefit to all of the citizens of the Commonwealth of Pennsylvania; and,

"Whereas, the responsibility to preserve and improve the purity of the waters of the Commonwealth does not rest solely upon municipal government but is also a function and responsibility of State government acting in the interest of the general public health, the Commonwealth of Pennsylvania, in consideration of the benefits resulting from the acquisition and construction, both in the past and in the future, of sewage treatment plants by municipalities . . ."

Main Provisions

1. Commencing July 1, 1954, and annually thereafter, the Commonwealth shall pay toward the cost of operating, maintaining, repairing, replacing, and other expenses relating to sewage treatment plants, an amount not to exceed 2 percent of the costs for the acquisition and construction. The annual payments are to be made to municipalities and municipality authorities which have acquired and constructed sewage treatment works since September 1, 1937. The payments are to be made for the year up to and including December 31 of the year preceding the year in which such payment is made, and as is ascertained by the secretary of health and approved by the Governor.

2. The word "construction" shall include, in addition to the construction of new treatment works,

pumping stations, and intercepting sewers, which are integral parts of the treatment facilities, the altering, improving, or adding to of existing treatment works, pumping stations, and intercepting sewers which are essential to the sewage treatment plant system.

3. The Pennsylvania Department of Health is authorized to promulgate rules and regulations for the administration of the act.

4. The amounts to be paid for the foregoing purposes shall be based upon reports filed with the secretary of health prior to January 31, 1954, and annually thereafter.

5. The sum of \$2 million was appropriated to initiate payments to the municipalities and municipality authorities.

lation by filing applications for payment in 1954.

The reaction to this legislation has been generally favorable. It has been particularly favorable from municipalities which have constructed plants in recent years under high costs and from those municipalities which are preparing to construct plants.

The payments to municipalities to date have ranged from a minimum of \$116.07 to a maximum of \$209,591.72. The latter represents a partial payment; the full payment will amount

to approximately \$250,000. The 2-percent annual payment is estimated to represent approximately 15 to 30 percent of the total annual operating expenses, including debt service, depending on the nature of the project. The payments may be used to reduce annual operating costs of the works, thereby reducing the annual sewer rental costs, or to accelerate debt retirement, or a combination of these. It will be interesting to see whether subsequent legislatures will make appropriations to continue the subsidy payments.

Cardiovascular Disease

Data on mortality, prevalence, and control activities

Public Health Service Publication No. 429. 1955. 68 pages.

Designed particularly for use by workers in the heart disease field, this booklet provides information on the mortality and prevalence of cardiovascular-renal disease and on heart disease control activities.

In general, the data permit comparisons among various population groups, among States, or among geographic regions. Also shown are results of case finding among various population groups and for various screening techniques.

Manual of Serologic Tests for Syphilis

Public Health Service Publication No. 411, revised 1955. 106 pages; illustrated. \$1.00.

The latest technical procedures to be observed in the performance of each of the reliable, evaluated serologic tests for syphilis now commonly employed in the United States have been assembled in this manual by the Venereal Disease Research Laboratory in collaboration with the test manual-serologists.

Included are the APHA, Hinton, Kahn, Kline, Kolmer, Mazzini, Rein-Bossak, and VDRL tests as well as chapters on general information and general equipment. The appendix describes methods of collection and preservation of sheep blood, preparation of hemolysin, preparation and preservation of complement, use of merthiolate as a bacteriostat, and quantitative determination of spinal fluid protein.

Especially designed for use in laboratories, the manual has a plastic-coated cover and plastic comb binding. It is the fifth edition of the Manual of Serologic Tests for

Syphilis published by the Venereal Disease Program, previously issued as supplements 9, 11, and 22 to the Journal of Venereal Disease Information and VD-Graphic \$5.

A Comprehensive Program for Water Pollution Control

Central Columbia River Basin. Public Health Service Publication No. 381. Water Pollution Series No. 69. 1954. 20 pages; illustrated.

Adopted by the Public Health Service from a program developed by the Washington Pollution Control Commission in cooperation with the State Department of Public Health, this program is based on beneficial water uses and related conditions that prevailed on January 1, 1954.

Green Bay Western Shore Drainage Basin. Public Health Service Publication No. 368. Water Pollution Series No. 67. 1955. 42 pages; illustrated.

Developed in cooperation with the State Water Pollution Control Agencies of Michigan and Wisconsin and Federal agencies and adopted by the Public Health Service, this program is based on data available as of January 1, 1954.

Lake Superior Drainage Basin. Public Health Service Publication No. 367. Water Pollution Series No. 66. 1954. 51 pages.

Program prepared in cooperation with the Michigan, Minnesota, and Wisconsin water pollution control agencies on data available as of January 1, 1954.

Mississippi-Iowa-Cedar Rivers Basin. Public Health Service Publication No. 346. Water Pollution Series No. 61. 1955. 41 pages.

Adopted by the Public Health Service from a program developed by the Illinois, Iowa, and Minnesota State

water pollution control agencies, based on beneficial water uses and related conditions that prevailed on July 1, 1953.

Mississippi-Salt Rivers Basin. Public Health Service Publication No. 366. Water Pollution Series No. 65. 1954. 24 pages; illustrated.

Adopted by the Public Health Service from a program developed by the Illinois, Iowa, and Missouri State water pollution control agencies, based on beneficial water uses and related conditions that prevailed on January 1, 1954.

Mississippi-Wapsipinicon and Tributaries Rivers Basin. Public Health Service Publication No. 347. Water Pollution Series No. 62. 1954. 47 pages; illustrated.

Adopted by the Public Health Service from a program developed by the Illinois, Iowa, Minnesota, and Wisconsin State water pollution control agencies, based on the beneficial water uses and related conditions that prevailed on July 1, 1953.

Salaries of Local Public Health Workers, August 1954

Public Health Service Publication No. 425. 1955. 41 pages.

This report contains data from the 5th study of salaries of selected classifications of public health workers in official agencies and from the 15th study of public health nurses employed by local nonofficial health agencies and local boards of education.

Presented are salary data by \$200-intervals, according to population group served and by regions of the Department of Health, Education, and Welfare, for each of the following occupations:

Local health officers (medical), public health physicians (exclusive of health officers), sanitary engineers, sanitarians (including other sanitation personnel), veterinarians, professional laboratory workers, health educators, and public health nurses (supervising, staff, and clinic).

technical publications

Meeting the Challenge of Cancer

Public Health Service Publication No. 419. 1955. 23 pages. 15 cents.

This booklet supplements *The Challenge of Cancer*, a 116-page book by Lester Grant, published in 1950 under the joint sponsorship of the National Cancer Institute of the Public Health Service and the National Cancer Institute of Canada. It presents some of the accomplishments in cancer research since that time.

In the supplement, prepared by the National Cancer Institute, the first section delineates the sources of financial support for cancer research and the programs of leading organizations. It also discusses the post-war shift in emphasis from basic to clinical research. The next two sections deal with advances in diagnostic and therapeutic technique and with promising areas of research in these fields. The chemotherapy of cancer is given special attention in a separate section; a review of recent studies in the epidemiology of cancer and a list of source materials complete the supplement.

Grant and Award Programs of the National Institutes of Health

Public Health Service Publication No. 415. 1955. 22 pages.

Scientists, public health workers, students, and others interested will find in this publication comprehensive information about the grant and award programs authorized by the Public Health Service Act and administered by the National Institutes of Health, - Public Health Service. Details are given for the types, scope, and purposes of the grants and

awards; availability of funds; eligibility requirements for recipients; location of training; and opportunities afforded trainees.

The grants and awards are offered to encourage and support research, investigation, and training in health, medical, dental, and allied fields for which other funds have not been provided or which might not otherwise be conducted. ♦

Evaluation in Mental Health

A review of the problem of evaluating mental health activities

Public Health Service Publication No. 413. 1955. 292 pages. \$2.00.

Problems and processes of evaluative studies are reported from a survey made by a subcommittee of the National Advisory Mental Health Council. The survey, begun in 1951, was designed to assist professional workers in improving the scientific basis for mental health programs and in evaluating the effects of their practical operations.

The report of this survey assembles an annotated bibliography of the evaluative studies and presents observations and suggestions arising from collection and analysis of the materials.

Reported Tuberculosis Morbidity and Other Data Calendar Year 1953

Public Health Service Publication No. 442. 1954. 27 pages. 25 cents.

This second published summary of the data supplied to the Public Health Service on the annual tuber-

culosis report form PHS-1393 tabulates newly reported tuberculosis cases by source of morbidity report, activity status, form and extent of the disease, race, sex, and age. Data on X-ray case-finding activities, mortality, and public health nursing visits are also included.

The data, received from all the States, the District of Columbia, Alaska, Hawaii, and Puerto Rico, are intended primarily for reference use. Summaries giving limitations and uses of the data are prepared for each analytical table.

Meeting Community Health Needs

Public Health Service Publication No. 403. (Revision of You'll Want to Know About Your Hospital Program, PHS Pub. No. 8, May 1951.) Revised 1954. 1-fold leaflet.

Operation of the Hospital and Medical Facilities Survey and Construction (Hill-Burton) Act is explained in this leaflet. It tells what community facilities are eligible to receive Federal assistance under the law as amended in 1954. And it explains the application requirements and procedures for obtaining Federal assistance in building a hospital or related health facility. The agency administering the hospital and medical facilities survey and construction program in each State is listed.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Emergency Handling of Frozen Foods

By JOHN B. HOZIER, M.D., M.P.H., and JAMES A. ANDEREGG, C.E., M.S.

IN HIS REPORT on Hurricane Carol, which swept through New England in September 1954, the Public Health Service regional medical director in that area observed: "An interesting phase of the recent disaster was that the primary public problem arose from the loss of electric service. With the loss of electric power, food freezing and storage equipment

failed and large quantities of perishable food in wholesale lots had to be disposed of in such a manner that it would not be scavenged."

With the great expansion of the frozen food industry during the past decade, the emergency handling of frozen foods has become increasingly important. In this paper, we shall consider two major types of emergencies: those due to possible contamination of the food in the event of enemy attack with radiological, biological, or chemical weapons and those due to failure of the refrigerating mechanism, such as occurred in the wake of Hurricane Carol. Many questions concerning the problems posed by these emergencies remain to be answered, but a few guidelines have been developed for use in planning to meet them.

Dr. Hozier is chief of Health Emergency Planning, Office of the Surgeon General, Public Health Service, and Mr. Anderegg is sanitary engineering consultant with this unit. The paper was presented at the 1955 meeting of the Southern Branch of the American Public Health Association in New Orleans, La.

Protection From Contamination

Much has been written in recent months about the hazards of radioactive fallout following an enemy attack with atomic weapons. As far as is known now, the danger to frozen foods probably can be dismissed with the comment that such foods in unbroken packages should be safe. Frozen food in homes is not only packaged, but it is also kept in well-insulated and closed refrigerators or freezing units. Frozen food in commercial storage has the additional protection of well-constructed, heavily insulated, and tightly sealed buildings.

To verify the assumed safety of packaged food products, the Federal Civil Defense Administration sponsored a series of tests on the ability of such foodstuffs to withstand atomic blasts during the atom bomb testing program in Nevada. The tests were directed by the Food and Drug Administration in cooperation with the Department of Agriculture and private industry. One of the tests, conducted in the spring of 1955 with cooperation from the Association of Frozen Food Manufacturers, concerns frozen foods and frozen food containers, and FCDA is expected to publish the findings in the near future. It will be interesting to see whether packaged frozen foods under actual conditions of an atomic blast come up to the expected standards of safety.

Frozen foods in unbroken packages are also fairly well protected from contamination by biological or chemical agents. In the manual, "Defense Against CBR Attack," the Department of Defense has tabulated the effectiveness of various types of protective packaging (1). Sealed cans, according to the manual, afford complete protection against vapors, liquids, biological organisms, and radioactive dusts. Cellophane and metal foil packaging provide complete protection if all joints are tight and if the cellophane has been kept dry. Ordinary paper containers furnish only poor to good protection against these four types of contamination. These evaluations, however, are pertinent only to situations in which the food is protected by packaging alone, that is, where the food is outside a home freezer or where a contaminating agent has been introduced into a commercial freezer warehouse. As previously noted, the nature of the home freezing unit and

of the commercial warehouse normally assures that known contaminating agents will not penetrate as far as the individual food packages.

Preservation During Power Failure

Failure of electric power, which was the cause of a food handling emergency during Hurricane Carol, has occurred frequently as a result of natural disasters. In planning for an unexpected, prolonged period without electricity, consideration must be given to the preservation or the consumption of large quantities of frozen and refrigerated foods so that spoilage will be held to a minimum.

The first and most obvious question in regard to this type of emergency is: How long can frozen foods be kept either in a home freezer or in a refrigerated warehouse before they begin to spoil? The answer is elusive and variable and is dependent on several factors. Tests by the Department of Agriculture indicate, however, that frozen foods can be stored in a typical small home freezer without power for about 3 days (2). The National Association of Refrigerated Warehouses reports that an informal survey among its members drew responses of anywhere from 1 day to 2 weeks in answer to the question: How long will your warehouse store frozen food without power?

Among the many factors that determine the length of time frozen foods can be kept without spoiling during a power failure in either a home freezer or a commercial warehouse are these:

1. Type, quantity, and condition of the insulation of the freezer or warehouse.
2. Temperature within the freezer or warehouse at the time of power failure. The colder the food, the longer it will stay frozen.
3. Type of products stored. Frozen meats, for example, will absorb heat much more slowly than frozen baked foods.
4. How full the freezer or warehouse is at the time of power failure. Generally, a full freezer will hold frozen foods hours longer than an almost empty one. Thus, once the power has failed, frozen foods serve as a temporary refrigerant in delaying temperature rise. By the same reasoning, a large box will keep foods frozen longer than a small one.

5. Whether or not it becomes necessary to open a freezer or warehouse. This is the most important of all the factors influencing holding time. Once power has stopped, frozen food storage units should not be opened except to transfer the food elsewhere or to add dry ice.

When available, dry ice is the best deterrent to temperature rise, particularly in home freezers. In preparing a community to meet disasters which may entail power failure, officials should locate nearby dry ice manufacturing plants and arrange for large quantities to be delivered, by air if necessary, and distributed during the emergency. Despite the heavy loss of food in New England as a result of Hurricane Carol, considerable quantities of frozen foods which otherwise might have spoiled were preserved with dry ice flown in from communities not affected by the storm.

If dry ice is not available, ordinary ice may be used to prolong the storage life of frozen foods, but it should be used only when the foods show evidence of thawing. Ordinary ice should not be added until foods have begun to soften, since ice temperature usually is just below 32° F., whereas frozen foods normally are stored at about 0° F.

Admittedly, the time may arrive during a period of power failure when it is no longer possible to refrigerate frozen food. Dry ice or ordinary ice, even if available initially, may have been exhausted, and temperatures in home freezers and refrigerated warehouses may have risen so that the foods would spoil if not further preserved. It must be remembered that because of the rupture of cellular structure during freezing, foods that have been frozen deteriorate much more rapidly after thawing than do fresh foods.

Almost any method of preserving fresh food—canning, cooking, salting, smoking—can be used to preserve food that has been frozen. Corned beef may not enjoy as much popularity as a sizzling steak, but most housewives have salt on the pantry shelf and putting a choice cut of meat into a brine solution seems preferable to having to discard it after it has spoiled. Similarly, if heavy spoilage losses are to be avoided, operators of frozen food warehouses must be prepared to cook, or otherwise preserve,

thawing food, or to distribute it quickly to persons who can.

Civil Defense Planning

In communities near freezer warehouses, frozen foods may constitute an excellent emergency resource for use in mass feeding operations during a disaster. As pointed out earlier, frozen foods stored in warehouses which remain intact after an enemy attack probably would be safe from contamination. And, because of the imminent danger of food spoilage under assumed conditions of electric power failure, such foods would have to be consumed within a few days. Although some warehouses do have auxiliary diesel electric powerplants, the percentage of warehouses so equipped is relatively small. A proper activity for civil defense officials might be to convince warehouse operators of the advisability of equipping their refrigerated storage units with auxiliary power. From a dollars-and-cents viewpoint, a standby diesel generating unit would seem to be a matter of good business.

As an approach to eventual solution of the many problems involved in protection of foods in time of emergency, the National Research Council, at the request of the Food and Drug Administration, has appointed a committee of experts in food technology to study the subject. The stated purpose of this committee is: "To consider the present preparedness of the food processing and warehousing industry with respect to its vulnerability to overt or covert special weapons attack. If necessary, to recommend corrective measures, or research to develop corrective measures, which will reduce the vulnerability." The National Research Council has been asked to report on the following specific items:

"1. The points where food and the major food processing industries are most vulnerable to overt or covert attack with special weapons.

"2. Corrective measures, or research needed to develop corrective measures, which will reduce this vulnerability.

"3. The suitability of existing facilities and practices for sanitizing or decontaminating food plants, equipment and products in a civil defense emergency.

"4. Any further facilities or practices needed for sanitizing or decontaminating food plants, equipment and products in a civil defense emergency."

It is understood that the study committee's report, anticipated late this year, will include an evaluation of problems in handling frozen foods.

Guides to Preparedness

Despite the many unanswered questions, certain actions can be taken now by local officials in preparation for preservation and proper use of frozen foods during an emergency period:

1. Locate existing refrigerated warehouses and encourage operators to provide auxiliary power sources if they have not already done so. Such standby power could save not only the frozen food stored in the warehouse, but also individual homeowners' stocks, which could be transferred to the warehouse until power is restored in the area.

2. Encourage decentralization of new warehouses away from centers of likely target cities.

3. Locate dry ice manufacturing plants and plan for prompt distribution of dry ice to owners of home freezer units in event of power failure. This may include planning for importation of dry ice if it is not manufactured locally.

4. Educate the public on procedures to follow in the event of power failure. The individual

home owner should know that dry ice is, or is not, available—and where; that freezer units should be kept closed insofar as possible; and that frozen meats and other frozen foods can be preserved for later use only by cooking or otherwise preserving them as soon as they begin to thaw.

5. Prepare an estimate of the numbers and capacities of mobile freezer units, such as trucks and railway cars, that may be available. Some frozen food, particularly that stored in warehouses, might be saved by transfer to these vehicles.

6. To meet the eventuality that all possible sources of power may be destroyed, a plan should be prepared for rapid distribution of large stocks of frozen foods to minimize waste.

We all hope, of course, that the occasion for the use of emergency measures may never arise in our own communities. However, the annual number of natural disasters alone is ample indication of the immediate need for planning the preservation of the Nation's food supply during an emergency.

Departmental Announcement

Herold C. Hunt, Ed.D., Charles William Eliot professor of education at Harvard University, and former general superintendent of schools in Chicago, was appointed Under Secretary of Health, Education, and Welfare by President Eisenhower on Sept. 2, 1955. For more than 25 years, Dr. Hunt has held responsible

administrative positions in public schools, among them superintendencies at St. Johns, Mich.; Kalamazoo, Mich.; New Rochelle, N. Y.; and Kansas City, Mo. He has also lectured at summer sessions of several universities. He has held important positions on many professional education associations, serving as president of the American Association of School Administrators from 1947 to 1948, and as chairman of the American Council on Education in 1948-49.

Recommendations for the Improvement of Fetal Death Statistics

A report by the United States National Committee on Vital and Health Statistics. The committee was formed by the Surgeon General of the Public Health Service at the request of the Department of State in accordance with the recommendations of the First World Health Assembly, 1948. The major objectives of the committee, of which Dr. Lowell J. Reed, Johns Hopkins University, is chairman, are to promote and secure technical developments in the field of vital and health statistics for national and international use.

• • •

FETAL MORTALITY is a problem of considerable importance in the United States today. Estimates indicate that fetal deaths now represent a medical and social problem of equal or greater magnitude than that of infant mortality at the turn of the century. In view of this, it seems important that health interests throughout the country turn more attention toward this problem.

More reliable and complete data on fetal mortality are needed to identify the problems in a more precise manner. As a step toward obtaining improvement in fetal death registration, and the reporting, classifying, and tabulating of causes of fetal deaths, the United States National Committee on Vital and Health Statistics is proposing certain recommendations. These recommendations and background information on their development are presented in this report.

Early in 1951 the National Committee on Vital and Health Statistics established a Subcommittee on Causes of Fetal Death. Its major

objective was to recommend methods for improving the recording and processing of statistics on fetal deaths so that they would be more suitable for use in studies of medical and social factors related to these fatalities.

A preliminary review and summary (1) sponsored by the national committee indicated the magnitude of the problem and its many ramifications. Most important is the extraordinarily large number of deaths for which the cause is either unknown or is reported in ill-defined terms.

One of the greatest deterrents to adequate progress in the field, it was thought, was the lack of clear-cut and acceptable definitions of terms such as stillbirth, abortion, evidence of life, prematurity, and viability. The adoption by the Third World Health Assembly in 1950 of definitions of live birth and fetal death and a number of accompanying recommendations was an important constructive step in the field (2), making it unnecessary to use "stillbirth," "abortion," and "viability" for vital statistics purposes. However, many important problems remain, particularly with regard to the application of definitions.

Basic problems in the recording and classifying of causes of fetal death stem from the difficulty of relating clinical observations during the life process to pathological findings and are further complicated in that two individuals must be considered, the fetus and the mother. As a result, recorded causes often go no further than describing terminal condition and provide little data on underlying causes.

This lack of knowledge of underlying causes, especially in the group of antepartum deaths,

is probably responsible for the prevailing feeling of apathy on the part of the clinician in his approach to the problem. There is a discouraging lack of useful information on most clinic records of maternity patients. The same feeling of apathy is evident in the field of vital statistics and is reflected in the fact that few, if any, tabulations on causes of fetal deaths are prepared in the local, State, and national offices of vital statistics.

It was recognized, from the beginning, that there are two major tasks requiring attention. One relates to specific problems: definitions, medical certification, classification, and the like. The other, a broader function, is that of acting as a coordinating force for groups concerned with the problem of fetal loss.

It was also recognized that, to do effective work in either of these areas, the subcommittee's activities must be linked to and must benefit from the experience and knowledge of the physicians practicing obstetrics, pediatrics, and of related professional groups. The subcommittee operated on the basic principle that sources of information outside the group were to be utilized to a maximum in arriving at recommendations. This led to conducting a major survey of medical opinion, testing of a form in two hospitals, review of case histories of fetal deaths, and examination of tabulations of data for evidence of relationships under question, and other activities. As a result, the recommendations represent the results of careful study and reflect a broadly based point of view.

In addition, steps were taken in the direction of the broader mission originally projected. Liaison was established with the Committee on Fetus and Newborn, of the American Academy of Pediatrics, and with the Public Health Conference on Records and Statistics. The Academy of Obstetrics and Gynecology was advised of the subcommittee's program; the attention of chiefs of obstetrical service in many of the teaching hospitals and medical schools was sharply focused on questions affecting the development of statistics; and early recommendations of the subcommittee were widely publicized by the National Office of Vital Statistics, Public Health Service.

There is evidence that these actions have contributed to the current increase in interest in fetal mortality. But it is clear that a need still exists for a continuing committee. Such a group, composed of representatives from the disciplines concerned, would provide a forum for the exchange of ideas on scientific, administrative, and reporting issues, and for the promotion of activities designed to reduce reproductive wastage. The investigation of the medical, biological, and environmental factors that affect this loss could thereby achieve the high position of priority it deserves.

It is thought, however, that a committee with a much broader base of sponsorship than that of the Subcommittee on Causes of Fetal Death would be required to perform these functions effectively. The appointment of a continuing committee of this type with representatives from the fields of obstetrics, pediatrics, public health, and vital statistics would be an essential step in achieving real progress in the field.

Other recommendations presented in the sections to follow are limited to specific well-defined actions which relate primarily to the improvements in data on the fetal death certificate. Many of these recommendations have already been used extensively by the national and State offices of vital statistics in revising their official certificates of fetal death. The results of 113 responses to a questionnaire sent to obstetricians in 173 hospitals in May 1952 (3) aided materially in arriving at some of these recommendations. The specific recommendations relate to:

- Medical certification of causes of fetal death on the standard form.
- Checklists for all conditions of pregnancy and labor and for methods of delivery.
- Time of death (antepartum, intrapartum) to be reported on the fetal death certificate.
- Tabulations on fetal deaths by national and State vital statistics offices.
- Suggested appointment of ad hoc committees to solve specific problems.

Medical Certification

The medical certification section on causes of fetal death on the fetal death certificate should be revised to a sequential arrangement paral-

Figure 1. The recommended sequential arrangement of the medical certification section has been adopted in the 1955 revision of the standard certificate of fetal death (Form PHS-797). Here, parts I and II of item 22—the medical certification section—replace items 20a, “fetal causes,” and 20b, “maternal causes,” on the 1949 standard certificate.

¹ Optional heading—Certificate of Fetal Death (stillbirth)

lating the section on the death certificate. The new form should clearly indicate that conditions in both the fetus and the mother should be considered by the physician when entering cause information. Explanatory material should accompany the certificate when introducing the sequential arrangement.

The change to the recommended sequential arrangement was followed in preparing the revised standard certificate of fetal death, placed in effect January 1, 1955. Figure 1 gives the wording of the section (item 22, “Cause of Fetal

Death”) adopted by the National Office of Vital Statistics and approved by the Public Health Conference on Records and Statistics.

At the time this recommendation was under consideration, the 1949 standard certificate of fetal death was in effect. There was considerable dissatisfaction with the format of the medical certification section, which was in the form of a two-part question, one part requesting information on fetal causes, the other, on maternal causes. When entries appeared in both parts, it was uncertain which condition the physician

himself considered to be the underlying cause or how the causes were interrelated.

Another problem in attempting to utilize the fetal death record for studying causal factors was the high proportion of ill-defined causes given on the record, or no causes at all.

The change to a sequential arrangement of the certification section is viewed as an important step in overcoming the problems mentioned. One advantage of the recommended arrangement is its consistency with the certification section on the death certificate. As in the case of general mortality, the form provides a basis for determining the physician's judgment as to the underlying cause. It also increases the possibility of studying causes of fetal death as an integrated pattern, that is, the relationship of maternal to fetal causes.

The sequential arrangement was tested briefly in Johns Hopkins University Hospital and Chicago Lying-In Hospital. The participating physicians were favorably impressed by this arrangement and felt that it was more logical than the two-part form. Furthermore, the nationwide survey of many of the leading obstetricians (3) indicated that a great majority believed the sequential form provided a better basis for interpreting the cause of fetal death information than the present form.

The following guides are proposed for the use of the sequential arrangement:

1. Method of filling out medical certification section—Causes of fetal death should be recorded in part I (of item 22 on the standard form) in a sequence of pathologically or etiologically related conditions in the mother and fetus, with the injury or morbid condition which initiated the sequence of events being stated last. In part II (of item 22) should be entered any condition of the fetus or mother which may have contributed to the fetal death but, insofar as is known, was not related directly to the causes given in part I.

2. Certainty of causal relationships—A physician should enter information in part I according to the best evidence that he has available. In some cases this approach may lead to conflicting judgments, depending on the physician's background. However, at the present stage of knowledge concerning causes of fetal death, there are few positive guides that can be

Subcommittee on Causes of Fetal Death

United States National Committee
on Vital and Health Statistics

J. Yerushalmy, Ph.D., subcommittee chairman, University of California School of Public Health.

Iwao M. Moriyama, Ph.D., subcommittee ex officio member, National Office of Vital Statistics, Public Health Service.

Sam Shapiro, subcommittee secretary, Health Insurance Plan for Greater New York, and formerly with the National Office of Vital Statistics.

given to the physician. In view of this situation, the physician should be given full freedom in making entries rather than restricting him by a series of "don't's" on which there may not be agreement. Obviously incorrect (or impossible) statements of cause sequences that might result could be handled in the coding operation as is now being done in the case of general mortality statistics.

3. Use of certain terms—The terms "asphyxia" and "anoxia" should be acceptable as entries on the fetal death certificate. There is a possibility that their indiscriminate use may result. However, in many instances, antecedent causes standing by themselves would be considered incomplete by the physician since they would not be viewed as the cause of death. For example, it could be argued that placenta praevia would not cause the fetal death, but rather it was in the chain of events which cut off the supply of oxygen to the fetus. Recording asphyxia as the direct cause would seem more logical to the physician than banning the use

of the term. Also, asphyxia and anoxia may at times be highly informative even when they are the only causes given.

4. Entry of "unknown" as cause of fetal death—There are instances when the clinician does not know the causal factors, and "unknown" is the only honest entry that he can make. Despite the dangers inherent in making "unknown" an acceptable term, physicians should be advised that their judgment on the matter will be accepted. An official action of this type would greatly aid in gaining acceptance of the fetal death certificate.

Official agencies are urged to take the following promotional measures to improve the reporting of cause of fetal death data:

1. Development of interest at the local level, particularly among individual physicians, in fetal death statistics—The aid of State and local medical societies and maternal welfare committees should be solicited. There is a growing realization of the importance of fetal death statistics, and the climate is more suitable today for promotional activities than at any other time in the past.

2. Distribution of explanatory materials along with the new certificate—The cover used for binding books of certificates should contain instructions which will remind the physician how to fill out the sequential form.

3. Production and distribution of a film on the need for fetal death statistics on problems in reporting cause information and on methods for filling out the medical certification section—This will require a major effort and should be viewed as part of the long-range approach to dealing with the problem.

New Supplemental Checklists

The present form of reporting "complications of pregnancy and labor" and "operations for delivery" should be replaced by checklists of "conditions present during pregnancy and labor" and "methods of delivery." Effort should be directed at obtaining reports of all conditions, both major and minor. The same checklists, except for inapplicable terms, should be placed on both the live birth and fetal death certificates in those areas that plan to use this type of item.

The checklists shown in figure 2 are suggested as guides for changing the form of the items. Provision should be made for evaluating the completeness and accuracy of information obtained on the checklists and the need for changes in the terms covered.

The change is recommended as a basis for improving the accuracy and completeness of reports on these items. For more than 10 years, medical items on complications of pregnancy and labor and operative procedures (on the 1949 standard certificate of fetal death, they appear as item 21, "State any complications of pregnancy and labor," and item 22, "State all operations for delivery") have been on the records of many States because of their potential value in dealing with modbid conditions present in the mother and child at birth (4). However, gross under-reporting and lack of uniformity in the data have appreciably reduced their usefulness (5).

Prior to the subcommittee's study of the problem, the New York State Health Department had designed a checklist form for reporting the information. Despite the hazard of having physicians omit terms that do not appear on the checklist, this approach seemed to offer a convenient and relatively simple method to help overcome present difficulties.

A great majority of the obstetricians surveyed on the matter favored a checklist form (3). This survey also elicited suggestions for changes on the New York form and established that the term "complications" in the form's heading, "Complications of Pregnancy and Labor," was being interpreted variously. Specific comments were weighed carefully in arriving at the terminology and lists given in figure 2. Decisions on important points and the reasoning behind these decisions follow:

The term "conditions" replaced "complications" to convey the idea that reports were to be made without regard to severity or physician's judgment concerning the condition's effect on the outcome of the pregnancy.

Instead of having two columns, one headed "diseases related to pregnancy" and one, "other diseases," as in the New York form, it was decided to use a single column with the heading, "conditions present during pregnancy." This single heading eliminates a point which the

Figure 2. The supplemental checklists recommended for inclusion on live birth and fetal death certificates.

subcommittee and the obstetricians in the survey had found troublesome, that is, which conditions should be grouped together under each of the columns, "diseases related to pregnancy" and "other diseases."

Qualifications for reporting "german measles"—first trimester—and "anemia"—less than 11 grams hemoglobin—were excluded. It was agreed that, for this type of item, the vital record could not be expected to give all the qualifications. More intensive investigations would have to be based on follow-back studies using the record as the starting point. The decision about anemia was based on the result of correspondence with three outstanding hematologists who indicated that the measurement of hemoglobin level must be supplemented by other

observations in order to determine whether a pregnant woman is anemic. There is apparently no agreement on the normal range of hemoglobin in pregnancy.

The item "high forceps" appearing on the New York form was retained in the recommended checklist although this method of delivery is not considered good obstetrical procedure. A byproduct of the statistics will be to indicate how much progress has actually been made in eliminating this method of delivery.

Items on analgesia and anesthesia and induction of labor were suggested by a number of obstetricians in the survey (3) but were not included because they would have required too much amplification on the form before useful information could be derived. This decision

was consistent with the general policy of keeping the number of terms in the lists to a minimum and giving priority to those terms that could be stated in a simple, clear, and meaningful way. In line with these objectives other items such as anomaly of cord, contracted pelvis, and other dystocia were excluded.

Time of Death

The standard certificate of fetal death, and subsequently State certificates, should include an item to determine whether the fetus died before or during labor. Use should be made of the information particularly when tabulating cause of fetal death data.

Such an item, which now appears as item 20 on the 1955 revised standard certificate (fig. 1), was also a part of the standard certificate until 1949, when the item was dropped because of an apparent lack of interest.

However, there are now definite indications that distinguishing between fetal deaths that occur before labor and during labor or delivery would greatly aid in understanding causal factors. Statistics tabulated by one of the States demonstrated the marked difference between the two groups in the distribution of causes of death. For example, placental and cord conditions were given as causes for a third of the fetal deaths that occurred "before labor" as compared with similar statements for more than half of the "during labor" group. Also, diseases and conditions of pregnancy and childbirth ranked second in groups of causes of fetal death in the antepartum period but were reported for very few of the intrapartum fetal deaths.

More extensive tabulations of this type and those which take into account such characteristics as age of mother, birth order, and period of gestation would be a great aid to medical research and public health programs.

Tabulations on Fetal Deaths

National and State offices of vital statistics should be encouraged to prepare:

1. Comparable tabulations on fetal deaths and live births in order to facilitate computation of

fetal death rates—Attention should be given to comparability in definitions.

A review of published and unpublished data showed that some of the tabulations of fetal deaths did not parallel the detail on live births. This has created problems for the research worker who wishes to compute rates. The tabulation of data on birth order (excluding fetal deaths) for live births and birth order (including fetal deaths) for fetal deaths was cited as a confusing practice. To compute fetal death rates by birth order, data should be available for both live births and fetal deaths on an "including fetal deaths" basis.

2. Experimental tabulations comparing the distribution of cause of death data for early neonatal deaths with cause data for late fetal deaths—For the purpose of this comparison, the term "early neonatal" refers to deaths occurring during the first week after birth, and "late" fetal deaths refer to those of gestations of 28 weeks or more—group III in the international recommendations (2).

For the present, the major purpose of these experimental tabulations is to develop a body of data which will clarify the difficulties in comparing causes being certified for fetal deaths and deaths in early infancy. With time, as the reported data improve and coding problems are resolved, the statistics can be studied for evidence of a continuum of conditions affecting the outcome of the pregnancy.

3. Tabulations of causes of fetal death on a multiple-cause basis—In view of the relatively small volume of records involved, preparing multiple-cause tabulations should not prove to be too heavy a burden. Single-cause tabulations would not be highly productive at this stage when so little is known about the causal relationships.

The function of statistics on causes of fetal death is, broadly, to provide information that will be useful in the prevention of fetal loss. Prevention may take the form of an immediate program which requires data on conditions whose etiology is clearly and uniformly understood, or its beginning may be found in slowly evolving research which utilizes data for causal factors whose preventability or etiology may not be known. Single-cause tabulations would not be highly productive for the latter purpose,

which is the more important of the two today. Instead, attention should be focused on multiple-cause tabulations.

No recommendations have been made on the items to be studied in relation to the causes recorded. But it would be desirable to initiate experimental tabulations which relate causes to other medical information and to biological factors such as birth order and age of mother.

Ad Hoc Committees

A number of problems associated with the classification and reporting of causes of fetal deaths and diseases of early infancy emerged in the course of the subcommittee's deliberations. It is recommended that ad hoc committees be appointed to study these problems. Among the problems which were specifically mentioned are:

1. Changes in the Y-code (causes of fetal death code) of the International Classification of Diseases, Injuries, and Causes of Death—Although the Y-code as it now stands appears to be adequate for most purposes, there is a need for reviewing the code principally to see whether any of the causes given in the "ill-defined" category should be treated separately and whether any combinations of causes, as in the case of Y-37, "birth injury," should be provided.

2. Recording of maternal conditions as causes of early neonatal deaths—Where applicable, maternal conditions should be reflected in the medical certification of causes of death for infants who die shortly after birth. However, the physician who fills out the death certificate usually does not have available to him information concerning maternal conditions that may have caused the death. One of the questions needing consideration is how to deal with this issue, which fundamentally requires bridging the gap between the obstetrician and the pediatrician.

There are other practical sides to the issue. For example, a physician who has all of the information concerning the pregnancy may still have to make a choice between a maternal condition whose etiology is not too well known and a condition found in the infant that has a specific meaning for him. Obstetrical and pedi-

atric case histories would undoubtedly clarify the practical problems that would face a physician in applying the principle that appears to be acceptable at this point.

A related question which needs consideration concerns the reconciling of the Y-code (causes of fetal death code) and the "700" rubrics (deaths in early infancy) of the international statistical classification. At the present time the "700" rubrics do not classify maternal conditions that would appear in the medical certification section if the above program were successful.

3. Development of a list of causes of fetal death for physician use—A number of respondents in the survey (3) of obstetricians suggested that physicians be furnished a list of acceptable terms to use in entering causes of fetal death. Proponents argue that such a list could be brief, containing basically just those terms which are needed for classification purposes. The counter position is that the list is really a nomenclature which would be difficult to reduce to a manageable set of terms. It is also contended that if the nomenclature and classification listings were viewed as interchangeable the result would be to confuse the physician and either force him into a narrow pattern of reporting terms or cause a breakdown in the reporting.

The Eighth World Health Assembly

By CHARLES W. MAYO, M.D., and FREDERICK J. BRADY, M.D.

THE Eighth World Health Assembly met in Mexico from May 10 to May 27, 1955. As in past years, the United States delegation to this annual meeting of the member countries of the World Health Organization included officials of government and voluntary and professional health organizations.

Earlier assemblies have reflected the growing importance of the World Health Organization in cooperative international efforts to improve man's health. These assemblies have authorized activities which already are proving surprisingly beneficial: technical assistance to fight malaria and other communicable diseases and to build national health services; worldwide services, such as epidemiological reporting; and mobilization of expert health knowledge in expert committees and seminars. The Eighth World Health Assembly, the first assembly to be held in the Western Hemisphere, made decisions which highlight the value of the work started by the 1946 International Health Conference in New York City where the WHO constitution was drafted.

Atomic Energy

By its constitution, the World Health Organization is established as the coordinating authority on international health work. The Eighth World Health Assembly prepared the way for active participation of WHO in the development of the uses of atomic energy for the purposes of health. It approved plans resulting from careful work done by the secre-

tariat, by the experts on the WHO Executive Board, and by a special consultant group called by WHO in December 1954. The assembly granted the Director-General's request for funds to employ an expert in radioisotopes and to establish a new Expert Committee on Atomic Energy in Relation to Public Health. WHO is expected to take on major responsibilities in sponsoring exchange of information, in training in health protection of those working with, or in the vicinity of, radioactive materials, and in the diagnostic and therapeutic uses of radioisotopes. This authorization of WHO responsibility in the health aspects of atomic energy, parallel to that already authorized in other health fields, indicates the recognition by member governments of the usefulness and potentialities of WHO.

Malaria Eradication

The Eighth World Health Assembly took action also to help put an eventual end to an ancient problem. Malaria, the single most serious worldwide communicable disease, continues to devitalize some 350 million people each year. The governments represented at the assembly voted to shift emphasis forthwith from malaria control to malaria eradication. In recent years, use of DDT and other new insecticides has proved eradication feasible, usually at a cost far below that exacted by halfway measures, which are not fully effective, permit the disease to persist, and require constantly recurring expenditures. The development of mosquito re-

United States Delegation

Chief delegate: Dr. Charles W. Mayo, chairman, Mayo Association, Mayo Clinic, Rochester, Minn.

Delegate: Dr. Frederick J. Brady, assistant chief, Division of International Health, Public Health Service.

Alternates: Dr. LeRoy E. Burney, deputy chief, Bureau of State Services, Public Health Service; Howard B. Calderwood, Office of International Economic and Social Affairs, Department of State; Dr. Martha Eliot, chief, Children's Bureau, Department of Health, Education, and Welfare.

Congressional advisers: The Honorable William H. Avery and the Honorable Thomas E. Morgan, House of Representatives.

Advisers: Dr. Otto Brandhorst, chairman, American Dental Association, St. Louis, Mo.; Dr. A. W. Dent, president, Dillard University, New Orleans, La.; Dr. Harold S. Diehl, dean, University of Minnesota Medical School, Minneapolis, Minn.; Dr. David French, Office of International Administration, Department of State; Dr. William R. Norton, State health officer, Raleigh, N. C.; Miss Agnes Ohlson, president, American Nurses Association, New York, N. Y.; Dr. Arthur S. Osborne, international health representative, Division of International Health, Public Health Service; Dr. Calvin B. Spencer, chief, Division of Foreign Quarantine, Bureau of Medical Services, Public Health Service; Capt. Robert I. Ware, executive officer, Naval Medical School, National Naval Medical Center, Bethesda, Md.; Dr. Charles L. Williams, Jr., chief, Latin American Branch, Public Health Division, International Cooperation Administration; Mrs. Nell Hodgson Woodruff, Atlanta, Ga.

WHO Executive Board

Representative: Dr. H. van Zile Hyde, chairman, chief of the Division of International Health, Public Health Service.

sistance to DDT in some parts of the world suggests there is no time to be lost in eradicating the parasite while it is still possible to control the vector with chlorinated hydrocarbon insecticides. The assembly therefore authorized WHO to place special emphasis on stimulating national governments to intensify malaria eradication programs. This decision by the countries of the world means that many malarious areas, with encouragement and assistance from international agencies like WHO and UNICEF, and from bilateral agencies like our International Cooperation Administration, may

free themselves of malaria within the next 10 to 15 years.

As do other WHO programs of technical assistance, malaria eradication abroad has far-reaching implications for our country and for the possibilities of world peace, since it improves conditions of life, morale, and economic productivity of men and women in malarious lands. Thus, the WHO and ICA technical assistance programs are complementary and share many common objectives. The existence of an international health agency, in which nearly all countries of the free world cooperate, has made it possible for countries to join in a common decision to eradicate malaria.

Poliomyelitis

Recent events have dramatized the serious aspects of poliomyelitis. The assembly made a special appropriation to permit WHO to expand its program in poliomyelitis control. This work of coordinating laboratory research and training and strain identification in many countries is an instance of how WHO stimulates and guides worldwide health services. The United States delegation reported to the assembly on the latest Salk vaccine developments in the United States. Other countries, including Canada and Denmark, also presented information on their Salk vaccine programs.

International Quarantine

Another worldwide WHO activity, one which has received great attention and wide support from governments, is the administration of the International Sanitary (Quarantine) Regulations. These regulations, which promote uniformity in quarantine procedures to combine maximum protection against disease with minimum interference with trade and travel, were amended along lines proposed by the United States in order to meet more effectively the requirements of member governments.

Second General Program of Work

In addition to acting on specific program activities, the Eighth World Health Assembly also laid down the general objectives, methods,

President Eisenhower welcomes the WHO visitors on the White House lawn. On the President's left is Surgeon General Leonard A. Scheele and on his right is Dr. Chester Keefer.

and categories of WHO programs for forthcoming years through 1960 by endorsing the second general program of work substantially as drawn up by the executive board. This program underlines the aims of strengthening national health services, training personnel, and

of controlling, or eradicating when feasible, major communicable diseases. It places increased emphasis on the planning and development of health as an integral part of economic and social development and on WHO's role of coordination among organizations engaged in

international health work. No basic changes are made in the lines along which WHO is developing, an indication of general satisfaction on the part of governments with WHO activities.

Scale of Assessments

The assembly undertook a drastic revision of the scale by which the contributions of members are assessed, the first such revision since the establishment of WHO in 1948. One aspect of the revision is that the percentage of the United States assessment will, over a 4-year period (1956-59), be reduced to a level where it is no more than one-third of the total assessment against active members only. This decision is important to the United States so long as some countries continue to be assessed but are inactive and make no payments. While the United States delegation urged full reduction in the United States percentage immediately, many members could not support a rapid corresponding increase in the assessments of other nations. Following the assembly, Congress removed the ceiling of \$3 million on the authorization for the annual United States contribution to WHO. The recent announcement by the U.S.S.R. of intentions to resume active membership in WHO may accelerate the adjustment of the scale of assessments.

Budget for 1956

The Director-General had proposed a budget for 1956 which would involve substantially the

same amount of assessments against members as in 1955. The payment to WHO of a large number of contributions for previous years resulted in an unexpected increase in available funds and made it possible to provide a higher expenditure level without a proportionate increase in assessments. The assembly voted a total effective working budget of \$10,203,084, including several additional items (\$42,000 for atomic energy, \$309,500 additional for malaria eradication, and an additional \$240,000 for costs of technical personnel on joint projects with UNICEF). The assessment against the United States for 1956 will be about \$3,410,000, an increase of about \$60,000 over that for 1955.

The Value of WHO

We have long believed that the World Health Organization is rightly taking the lead in the international effort to help man remove a burden of ill health that is no longer inevitable or tolerable. It is an effort that is both humanitarian and imperatively realistic. By the same token, WHO is one of the foremost agencies of the United Nations family which is working to build peaceful conditions of life. WHO was fashioned primarily by leaders in the medical and public health professions. It is a technical agency which receives wide support from the people and the governments of the world. Humanity can be proud that this organization continues to develop along lines which are influential and sound, and fosters both public health and goodwill among nations.

Post-Assembly Technical Sessions

FOLLOWING the Eighth World Health Assembly held in University City, Mexico, a series of seminars for assembly delegates was conducted in the United States under the general title "Post-Assembly Technical Sessions."

The National Citizens Committee for the World Health Organization sponsored these sessions and invited the delegates. In response, some 146 guests, 40 ministers or directors of health (current or emeritus), and other top health officials from 50 countries visited the United States and attended part or all of the discussions held from May 30 through June 4, 1955. Foreign students receiving medical and public health training in the United States were also among the group.

The seminars included roundtable discussions by 80 physicians, scientists, and administrators (including 3 from other countries—India, Yugoslavia, and Denmark). Questions raised by the visitors were subjects of general discussion.

Fifty private organizations and firms assisted in staging and presenting the seminars; in particular, various drug manufacturing firms gave financial assistance.

President Eisenhower welcomed the visitors to Washington. The President referred to WHO as one of the principal arms of the United Nations and praised WHO campaigns to improve the health of the people of the world. The delegates also were greeted by Dr. Fred L. Soper, director of the Pan American Sanitary Bureau (WHO Regional Office for the Americas) and three officials of the Department of Health, Education, and Welfare—Dr. Chester Keefer, at that time special assistant to the Secretary for medical affairs; Surgeon

General Leonard A. Scheele of the Public Health Service; and Dr. Martha Eliot, chief of the Children's Bureau. The National Institutes of Health and the Division of International Health of the Public Health Service assisted the Department and the National Citizens Committee in organizing the Washington seminars.

Moving on to Baltimore, the visitors were welcomed by Dr. Lowell Reed, president of the Johns Hopkins University, and by the faculty of the School of Hygiene and Public Health, and then participated in seminars at the Johns Hopkins University.

The program in New York City included greetings from Dr. Victor Belaunde, then President of the United Nations Security Council; Philippe de Seynes, Under Secretary of the United Nations for Economic and Social Affairs; Dr. Thomas Parran, president of the National Citizens Committee for WHO, and the commissioners of health for New York State and New York City, Dr. Herman Hilleboe (p. 1069) and Dr. Leona Baumgartner.

After the post-assembly technical sessions, some of the visiting health officials attended the scientific assembly of the American Medical Association in Atlantic City.

The following pages contain summaries of some of the seminars. Marked by a cordiality characteristic of the World Health Assembly, the discussions sought to inform health officials of other countries about public health programs and principles in the United States and thus increase their understanding of them and of the importance of United States participation in the World Health Organization.

Design and Construction Of Hospital Facilities

The coordinated and integrated hospital system now developing in this country makes hospital services more accessible and provides better quality care, Dr. Cronin said. Although the hospital bed deficit in 1946 was 900,000, and each year more hospitals become physically or functionally obsolete, notable progress has been made toward providing adequate hospital services in all areas of the country.

Cronin said that there are three kinds of hospitals in this country—governmental, voluntary nonprofit, and proprietary. Exclusive of those operated by Federal agencies, there are approximately 7,000 hospitals in the United States.

A study made in 1942 by the United States Department of Agriculture showed a severe shortage of physicians in rural areas and, further, that 3,100 counties had no hospital services whatsoever.

The Hospital Facilities Survey and Construction Act, passed by Congress in 1946, provided funds to the States for planning and building hospitals and related facilities. Under this law, the Federal Government sets minimum building standards, gives technical assistance, and apportions the available funds to the States on the basis of need. The States are responsible for the use of funds, on a matching basis, by suitable project sponsors in areas with high priority of need. Each State has established a

hospital advisory council, with professional and consumer members. It has developed its own hospital service areas on the basis of population and availability of health services, and since 1948, has apportioned its share of Federal funds.

The basic act provided that Federal funds could not be used to build in excess of statewide ratios of 4.5 general hospital beds per 1,000 population, 5 mental beds per 1,000 population, and 2 chronic disease beds and about 1 tuberculosis bed per 1,000 population. One health center is planned for every 30,000 to 50,000 population, depending upon density of population and certain geographic factors.

Since 1948, \$600 million of Federal funds and \$1,340 million of local and State funds have been committed for 2,500 projects and about 540 health centers which, when completed, will provide 117,000 beds. At this time about 400 health centers and 1,800 hospitals, providing 84,000 beds, are completed and in operation. Of the health centers, 75 were built in conjunction with hospitals, contributing to health maintenance both by preventive and curative types of programs.

Fifty-eight percent of the hospitals have less than 50 beds and are located in towns with less than 5,000 population. They have been built in 700 towns which previously had no acceptable hospital facilities. These hospitals are of infinite value in emergencies. Federal funds have also helped build or improve 30 teaching hospitals at universities and medical schools in 18 States, thus helping to alleviate the shortage of professional personnel in the smaller hospitals.

The program is helping to get physicians and other professional persons to locate in smaller communities. Georgia estimates that 60 physicians have been attracted to the newly opened hospitals. A survey shows that 2 out of 5 registered nurses on duty in the new hospitals came out of retirement to practice in their home areas.

New problems arise, Cronin said, as our life expectancy increases. Although the American population has doubled in the first half of this century, our population over 65 years old has quadrupled, and this trend is expected to con-

Discussion Leader: John W. Cronin, M.D., chief, PHS Division of Hospital and Medical Facilities.

Discussion Panel: Edward T. Thompson, M.D., chief, Operations Branch, PHS Division of Hospital and Medical Facilities; August F. Hoenack, acting chief, Architectural and Engineering Branch, PHS Division of Hospital and Medical Facilities.

Rapporteur: Jean Allen, information specialist, PHS Division of Hospital and Medical Facilities.

tinue. Patients with chronic diseases now occupy about 25 percent of all hospital beds. The cost for care in general hospitals is more than double that in chronic disease hospitals, thus imposing a heavy burden on long-term patients.

With these problems in mind, Congress in 1954 amended the Hospital Facilities and Construction Act and increased the authorization of funds to include the building of nursing homes and rehabilitation, diagnostic, and treatment centers, and to give added emphasis to the building of chronic disease hospitals. This action should result in a worthwhile contribution to facilities for our aging population.

Mr. Hoenack said that at the beginning of this program there was very little knowledge concerning the design and equipment of hospitals. Through the cooperation of the American Hospital Association, the American Institute of Architects, the Public Health Service, and various schools and manufacturers, helpful guide materials have been developed. Programs must be fully developed before hospitals are built, and all guide materials must be adapted for local use after study of local needs. The chief technical problems of the program have centered around the necessity for educating both designers and users of hospitals.

Dr. Thompson said the program has contributed to better patient care because the facilities operate under State licensing laws and because the majority of them have been accredited by the American College of Surgeons. There are no Federal regulations covering the operation of hospitals.

In reply to a question, Cronin stated the Federal Government funds are used to pay part of the cost of building and equipping hospitals, but Federal funds are not available for their operation. The average building cost of a general hospital bed is now \$16,000. A university teaching hospital may cost as much as \$30,000 per bed to build.

It is difficult to state the most economical size for a general hospital. Those with more than 200 beds are very expensive to operate because of the variety of services provided. Those between 50 and 100 beds are more economical but

cannot give the specialized treatments found in larger facilities.

Project sponsors must give assurance that they have access to funds to defray an anticipated 2-year operating deficit. Hospitals built under this program must be operated by an eligible sponsor for a period of 20 years.

The State agencies determine the percentage of Federal funds to be awarded projects within their boundaries as well as the priority status of the projects.

Advances in Virology And Parasitology

Dr. Rowe discussed the recent advances in the studies of viruses in tissue culture. The use of tissue culture techniques, stimulated by the discovery by Enders and his co-workers of the cytopathogenicity of poliomyelitis viruses for tissue cultures of human cells, has revolutionized the field of virology. Noteworthy advances brought about by these techniques have been the isolation of the virus of rubella by Enders, of varicella and herpes zoster by Weller, of the mouse and possibly the human salivary gland viruses by Smith, the virus of an epidemic exanthematous disease by Nera and Enders, and the viruses of canine infectious hepatitis and vesicular exanthema of swine.

The discovery of the adenoidal-pharyngeal-conjunctival (APC) viruses was also made

Discussion Leader: Willard H. Wright, Ph.D., chief, Laboratory of Tropical Diseases, National Microbiological Institute, National Institutes of Health, Public Health Service.

Discussion Panel: Wallace P. Rowe, Ph.D., virologist, NIH Laboratory of Infectious Diseases; Leon Jacobs, Ph.D., parasitologist, NIH Laboratory of Tropical Diseases.

Rapporteur: Paul Weinstein, Sc.D., parasitologist, NIH Laboratory of Tropical Diseases.

possible by tissue culture techniques. Following the original isolation of these viruses from spontaneously degenerating cultures of human adenoids and tonsils, various members of the group have been found in association with acute respiratory infections. Type 3 has been shown to be the cause of a new clinical entity, pharyngoconjunctival fever; type 4 (RI-67 strain of Hilleman and Werner) and type 7 (Gomen strain of Trygve Berge) have been found to be the cause of a number of febrile respiratory infections in military recruit personnel. The types most frequently recovered from adenoids and tonsils, types 1, 2, and 5, have also been isolated from sporadic cases of acute febrile pharyngitis.

Tissue culture techniques have also been of value in the study of influenza viruses. Following the report of Mogabgab that field strains of influenza viruses are cytopathogenic for monkey kidney tissue cultures, workers at the National Institutes of Health have shown that this procedure is much more highly sensitive than use of embryonated eggs for the isolation of the 1955 strain of influenza B.

Dr. Jacobs, speaking on the newer knowledge of parasitic diseases, discussed primarily the manifestations of human toxoplasmosis. He reviewed acute congenital and acquired disease syndromes and considered in some detail chronic toxoplasmosis of the eye. The opinion was presented that ocular toxoplasmosis of adults may be the most significant manifestation of the infection. This was based on the findings by Wilder in 1952 of parasites resembling *Toxoplasma* in some 50 human eyes enucleated because of chorioretinitis. Serologic tests on 22 of these subjects were all positive at low titer. Also, a correlation was found between chorioretinitis and the presence of *Toxoplasma* antibodies even though here again the antibodies were mostly at low titer. The low antibody levels could be explained on the basis of the persistence of parasites in neural tissue remote from the sites of antibody formation. Final demonstration that this persistence could occur was obtained by the isolation of *Toxoplasma* from the eye of a 30-year-old man with a history

of recurrent chorioretinitis of 8.5 years duration and only low antibody levels in the serum.

Knowledge of the epidemiology was given, indicating that the infection is most prevalent in warm, moist areas rather than in cold or hot, dry ones.

The antimalarial drug pyrimethamine was found by Eyles to act synergistically with sulfadiazine against proliferating, but not encysted, forms of *Toxoplasma*. Use of these drugs in presumed cases of adult ocular toxoplasmosis has given encouraging results at the Clinical Center of the National Institutes of Health.

New Developments In Insecticides

Mr. Henderson opened his remarks on the area application of insecticides by stating that the use of chlorinated hydrocarbon insecticides such as DDT has controlled or eradicated arthropod-borne diseases in many areas of the world. Although malaria primarily is a rural disease, control formerly was confined chiefly to urban and suburban communities. Sanitation measures, such as building drains, were relied upon for control of malaria. There was little need for a comprehensive operation team to plan and manage these operations at that time.

Discussion Leader: Justin M. Andrews, Sc.D., associate chief for program, Bureau of State Services, Public Health Service.

Discussion Panel: Winton B. Rankin, M.S., assistant to the commissioner, Food and Drug Administration; Herbert L. Haller, Ph.D., assistant director, Crops Research, Agricultural Research Service, Department of Agriculture; William F. Durham, Ph.D., biochemist, Toxicology Section, PHS Communicable Disease Center; John M. Henderson, M.S., deputy chief, Technical Development Laboratories, PHS Communicable Disease Center.

Rapporteur: Donald R. Johnson, M.S., entomologist, PHS Division of International Health.

Malaria control or eradication now is "big business," and the basic principles of organization and management must be followed in order to attain success. Delegation of authority is one of these basic principles. This applies not only to the delegation of authority from the leader of the program within progressively narrowing bounds down to the individual spray crews, but also to procurement of supplies and obtaining statistical data.

An adequate staff must be chosen to administer the program properly. This staff should consist of medical, entomological, and engineering professional personnel who will work together, using all of their combined skills as a malaria control team. The key person is the team leader, who must fuse the staff functions into a common program as well as obtain the necessary financial support.

Resistance to insecticides now must be considered when developing these programs. The development of mosquito resistance to insecticides is a product of selection pressure, duration of that pressure, and the genetics of the species involved. In regard to *Anopheles* mosquitoes, out of the some 50 significant malaria vectors throughout the world, only 4 or 5 have demonstrated development of resistance. The following are solutions to the resistance problem:

1. The eradication of the disease or the mosquito species.

2. Annual shifting to other insecticides. This is complicated by cross resistance such as occurs in the use of chlorinated hydrocarbon insecticides.

3. Development of new insecticides against which resistance will not develop as rapidly as with the presently used insecticides.

4. Judicious application of insecticides. Larviciding with an insecticide of the same group of material used as an adulticide should be avoided. Adulticiding alone is preferable because larviciding exerts more selective pressure than adulticiding.

It may be desirable to reduce the frequency of insecticidal application and to choose an insecticide with a shorter residual duration. Such material should be applied immediately prior to the malaria season. Baselines should

be established in areas where resistance among anophelines has not become apparent in order that we will be able to recognize resistance when it starts.

Dr. Haller talked on the chemical constitution of the new insecticides, which, he said, are among the most important weapons of public health workers. With the aid of the newer insecticides, large international responsibilities in public health have been undertaken. As a result, the worldwide gains made against typhus, dysentery, yellow fever, and malaria are becoming more pronounced. The newer insecticides that have attracted greatest attention may be divided into four broad classes—chlorinated hydrocarbons, organic phosphorus compounds, chemicals that are especially useful with pyrethrum (the so-called synergists), and synthetic pyrethrin-like esters, almost identical in composition with the insecticidal principles in natural pyrethrum. Pyrethrum and the synthetic esters exert a rapid paralytic action (knockdown) on insects, a factor especially important in controlling disease-carrying insects.

Some of the recent developments in insecticide toxicology were brought out by Dr. Durham. During the last 2 or 3 years organic phosphorus compounds have come into general use as insecticides. Malathion, chlorthion, dip-terex, and diazinon are noteworthy because they are considerably less toxic than some of the other phosphates being used. Demeton ranks rather high in its oral toxicity to rats but has certain insecticidal advantages by virtue of its systemic effect.

The major pharmacological action of the organic phosphate compounds is their ability to inhibit the enzyme cholinesterase, with a resultant increase of unhydrolyzed acetylcholine leading to signs and symptoms referable to overstimulation of the parasympathetic nervous system.

One sequel of organic phosphorus intoxication is peculiar to certain of these compounds. This is a neurotoxic effect resulting in "jake-leg paralysis." The serious and essentially irreversible nature of this paralytic syndrome makes it desirable to screen the various insecticides of this group for their ability to cause such

paralysis. Chickens appear to be the best available index of a possible paralytic effect in man. The test consists of subcutaneous dosing of atropinized chickens. None of the organic phosphorus insecticides now in general use produced delayed effects corresponding to jake-leg paralysis.

A distinct and different syndrome appeared in hens dosed with malathion and EPN. They developed leg weakness immediately after dosing in addition to the more usual cholinergic symptoms. Although this is not to be interpreted as an indication that a similar effect in man will result from exposure to these compounds by the more usual routes, it is reason for exercising appropriate safety precautions.

When comparing the hazard of dermal versus respiratory exposure to these compounds applied as sprays, it has been indicated that the dermal route is much more important than the respiratory route.

The effect of daily oral doses as high as 35 mg. of DDT daily on man has been extensively studied. Over a 1-year period, no adverse effects attributable to DDT intoxication have been noted. Dilan and endrin, respectively, appear to be about one-fourth and six times as toxic to rats as DDT.

Although there have been a few cases of dieldrin toxicity to spraymen, all those affected recovered. No known toxicity to occupants of houses sprayed with the most commonly used chlorinated hydrocarbons (DDT, dieldrin, BHC) has been reported, and the benefits derived from these materials greatly outweigh the toxic hazards.

In discussing tolerances for insecticide residues on food, Mr. Rankin stated that in 1952, the Food Protection Committee, Food and Nutrition Board, National Research Council, published its "Basic Considerations Involved in Evaluating Hazards Encountered in the Use of Pesticides on Foods," which contains guiding principles for judging the safety of insecticides and other pesticides. In 1954, many of these basic principles were incorporated in a new law, the pesticide chemicals amendment to the Federal Food, Drug, and Cosmetic Act (Public Law 518, 83d Cong.). This law pro-

vides a practical method for establishing safe tolerances for residues of pesticide chemicals in certain foods. (Insecticides are one form of pesticide chemicals.) The law prohibits the marketing of food if it bears a residue of a pesticide chemical, unless:

1. The chemical generally is recognized by experts as safe, or
2. Upon consideration of an adequate amount of scientific evidence, the Government has established a safe tolerance for residues of the chemical or has exempted it from the requirement of a tolerance, and
3. If a tolerance has been established, the residues remaining on the food are within the safe tolerance level.

The petitioner who requests the establishment of a tolerance for insecticide or pesticide residues or an exemption from the requirement of a tolerance must submit data to the Government to support his application. Data required in a petition are:

1. The name, chemical identity, and composition of the pesticide chemical.
2. The amount, frequency, and time of application of the pesticide chemical.
3. Full reports of investigations made with respect to the safety of the pesticide chemical.
4. The results of tests on the amount of residue remaining, including a description of the analytical methods used.
5. Practicable methods for removing residue which exceeds any proposed tolerance.
6. Proposed tolerances for the pesticide chemical if tolerances are proposed.
7. Reasonable grounds in support of the petition.

The establishment of tolerances under this new law is only a part of a broader problem, the addition of poisonous or deleterious substances to any food. The Federal Food, Drug, and Cosmetic Act provides a different method for establishing tolerances for poisons which are not pesticide chemicals. Although the method is different, the general principles are the same. The chemical identity of the poisonous substance should be established; the acute and chronic pharmacological properties should be well investigated; there should be trust-

worthy analytical methods for determining the quantities which remain in food; the tolerance should involve an ample margin of safety; and allowance must be made for cumulative effect of the same substances from different sources or of related substances.

Collection and Use Of Statistics

Dr. Dunn, opening the discussion, stressed that statistics help answer the practical questions involved in making program decisions. Health administrators can use statistics to (a) identify and measure the extent of public health problems; (b) plan, conduct, evaluate, and promote public health programs; (c) guide the geographic allocation of health facilities and resources; and (d) provide suggested benchmark information needed in epidemiology and in many types of medical research.

In this country, health programs use seven types of statistics. Four of these are essentially repetitive and routinized. They include census data, vital statistics, notifiable disease reports, and the massive reporting of statistics by institutions, particularly the mental institutions. The generally nonrepetitive types include special surveys, research and laboratory statistics,

and service statistics (a large part of which may be repetitive).

Dr. Moriyama said that, in the United States, vital statistics consist of data derived from the legal records of live birth, fetal death, death, marriage, and divorce. They also include data on notifiable diseases reported by physicians. Legal authority and responsibility for registration and permanent filing of the records rest in the individual States. Uniformity of basic items and coordination of registration and statistical activities are achieved through joint planning with the National Office of Vital Statistics of the Public Health Service.

In addition to supplying routine vital statistics, he said, the death certificate is used as a starting point in following back to the attending physician or informant for other data, thus serving as the basis for special studies of specific diseases. Vital statistics data have been used for special analytical studies of tuberculosis, cancer, cardiovascular-renal diseases, multiple sclerosis, and motor-vehicle and home accidents.

Statistics of live births and fetal deaths are also widely used for public health purposes. Certificates now contain information on birth weight, which is useful in coping with premature birth problems. Data are also available on complications of pregnancy and labor and on congenital malformations of the live-born child. Moriyama stated that this information is used for followup by local health departments.

Dr. Dauer stated that on the basis of reports from physicians and institutional authorities the State health departments send weekly telegraphic summaries to the Public Health Service. These data, which show the number of reported cases of each of 20 diseases, are published and distributed to international, Federal, State, and local health agencies, and to the press. The data dissemination is rapid, he said, so they may be used effectively. Telegraphic reports are made at once when any of the 6 quarantinable diseases occur. The States also furnish annual figures for 40 diseases.

Dauer explained that for disease control, and other purposes, a system of reporting epidemics or unusual occurrences of diseases has been de-

Discussion Leader: Halbert L. Dunn, M.D., chief, National Office of Vital Statistics, Public Health Service.

Discussion Panel: Iwao M. Moriyama, Ph.D., chief, Mortality Analysis, PHS National Office of Vital Statistics; Carl C. Dauer, M.D., medical adviser, PHS National Office of Vital Statistics; C. A. Smith, M.D., chief, Venereal Disease Program, PHS Bureau of State Services; Theodore D. Woolsey, biostatistician, PHS Division of Public Health Methods.

Rapporteur: Mort Gilbert, publications officer, PHS National Office of Vital Statistics.

veloped. State health officers are requested to report epidemiological investigations when a disease occurs in unusual circumstances.

Dr. Smith, discussing the national venereal disease control program, stated all sources of data so far discussed in this meeting have been drawn upon. In addition, specialized morbidity reporting and service statistics have been developed. The reports provided the knowledge upon which the control program was based.

Smith said experience showed that it was no longer profitable to direct case-finding surveys to large, unselected segments of the population. By refined survey activities, significant correlations were found between rates of infection and the usual measures of low social status—poor housing, overcrowding, incomplete education, and low income. Files of reported cases and spot maps pinpoint the problem locally and guide the case-finding team to communities and population segments most likely to be productive.

Blood testing, he said, is an excellent means of finding cases of latent syphilis, but to break the chains of infections the most satisfactory mechanism is interviewing and followup of contacts.

Therapy evaluation is also an integral part of the program, Smith emphasized. Knowledge of the effectiveness of intensive arsenotherapy schedules was the basis for the rapid treatment center program of World War II. These statistical techniques were adapted to the evaluation of penicillin, so that the time-dosage relationship and optimum amounts of penicillin therapy were quickly established. The proved efficacy of the long-acting types, he said, made it possible to return the treatment of syphilis to the outpatient clinic and the private physician.

Thus, statistics are more than a tool or service in a communicable disease program. They are an integral part of program planning, operations, and evaluation.

Mr. Woolsey defined a population survey in health statistics as any technique by which health information is collected from a sample of the population.

Sample surveys, he stated, are suitable for collecting various types of health statistics, such as incidence and prevalence of current illness, particularly chronic diseases; days lost from work; prevalence of impairments, such as blindness and deafness; availability of medical care; coverage of medical care insurance; attitudes; and sanitation, housing, and other environmental aspects.

Such statistics serve many uses in the administration and evaluation of public health programs, for example, in ranking health problems, estimating scope and cost of new programs, and in following cohorts of individuals to evaluate disease prevention and therapy. They are used to estimate needs for medical facilities, for rehabilitation services, and for drug preparations and appliances. Frequently, they suggest hypotheses to be tested by medical research.

Woolsey said the household survey approach has many advantages. Social, economic, and environmental data can be obtained; one can work outward from the interview to the patient's medical records; greater flexibility permits questions to be adapted to current needs.

On the other hand, he noted, household surveys are expensive and require technical skills that are uneconomical for small health departments to maintain on a staff basis.

Blueprints for a continuing national survey to obtain current health information are being prepared by the Public Health Service in the event that such a program is assigned to it.

What WHO Means To Us

By HERMAN E. HILLEBOE, M.D.

THOSE familiar with some of the inner workings of the specialized agencies of the United Nations have come to recognize that the international approach to such problems as health offers the best mechanism for assisting people of all nations to help themselves to a better way of life.

The majority of the member states that have ratified the constitution of the World Health Organization have proclaimed their determination to end isolation in the field of health. No nation has a monopoly on discoveries in the prevention, diagnosis, and treatment of disease. Roentgen of Germany gave us the priceless diagnostic tool, the X-ray, and Einthoven of the Netherlands placed in our hands the electrocardiograph. To the scientists in Britain, we owe the discovery of penicillin; to those in Canada, the discovery of insulin; and to our colleagues in Switzerland, the great weapon against malaria—DDT. In public health, as in no other field of worldwide enterprise, we have true interdependence in the discovery and sharing of knowledge of prevention, diagnosis, and treatment of disease.

Through the years, there have been several international organizations that have contributed to international health, but it was not until the birth of the World Health Organization in

1948 that the pattern was so clearly cut as to what should be done and how to do it.

Role of the United States

Some may not be familiar with the details of the United States participation in world health programs. The Public Health Service supplies services to the Public Health Division of the International Cooperation Administration for the recruitment and staffing of overseas missions as well as technical program reviews and professional consultations. The Division of International Health of the Public Health Service is also the center point around which turn the efforts of both multilateral and bilateral health assistance.

The International Cooperation Administration is our official arm for technical assistance. Its programs are under the policy guidance of the Department of State and are now operating in more than 40 countries. As a result of joint conferences on the regional basis between the World Health Organization and the International Cooperation Administration, as well as intracountry planning, many of the programs are being supported by joint effort on the part of WHO and ICA missions. This type of effort has resulted in a sound approach to health problems where the two organizations may supplement each other in their assistance programs.

In 1949 the United States embarked on a program to make the benefits of its scientific advances and industrial progress available for the improvement and growth of less developed

Dr. Hilleboe is commissioner of the New York State Department of Health and president of the American Public Health Association.

areas. The enterprise—known as point 4—was to be a cooperative one in which nations would work with the United States to improve the human economy. The aim of the program was to help the people of the world, through their own efforts, to produce more food, more clothing, more materials for housing, and more mechanical power to lighten their burdens. Technical assistance, which for decades has been given in a limited manner by American missionaries and private business concerns, was broadened so that a whole nation as a fundamental part of its foreign policy committed itself and its resources to the idea of helping all people to help themselves.

Expanded technical assistance programs have appeared all over the world in specialized agencies such as the newly created United Nations Technical Assistance Administration, the Colombo plan initiated by the British Commonwealth nations, and programs of technical assistance started by France, Switzerland, and Norway. These technical assistance programs have and must include health projects. Health is now recognized as closely associated with any economic and social progress. These programs represent a spirit of international cooperation, a refreshing development in the foreign affairs of benevolent nations. The regionalization project in Puerto Rico is an interesting example of a program with multiple sources of support.

Jonathan B. Bingham, former acting director of the point 4 program, in his recent book, "Shirtsleeve Diplomacy," says: "There are many things that diplomats and money can do but nothing compares to the permanent benefits of sitting down with people and actually doing things that show them beyond the question of a doubt that their health is being improved."

The Voluntary Organizations

In discussing international health we cannot forget the pioneer work of the great foundations in developing health programs. The three United States voluntary organizations most actively operating in the international health field are the Rockefeller, Ford, and Kellogg Foundations. The International Health Commission established by the Rockefeller Foundation in 1913 has carried on its activities

successfully in the development of health programs on a cooperative basis. The Kellogg Foundation has done similar work in recent years in the South American Republics, especially in the field of nutrition. These are examples of foundations that have been instrumental in bringing about a modern concept of cooperation in building up within each nation sound and effective programs of disease control and health promotion.

The professional health workers and representatives of the great industries and other leading citizens represented here understand better than most groups the potentialities of the World Health Organization in contributing to world peace. It is the task of the National Citizens Committee for the World Health Organization to bring to the public information on the great potentialities of organizing for world health.

This committee in the United States makes known to our people the importance of good health to the well-being of the Nation. During the last two annual meetings of the American Public Health Association, public sessions were held by the National Citizens Committee for the World Health Organization. Purposeful activities are quickly understood by key citizen groups. With understanding comes acceptance, and with acceptance comes support. This citizens' movement could profitably spread to every nation participating in the activities of the World Health Organization, particularly those nations that have substance to share with less fortunate countries.

Health of One Is Concern of All

There are many of you from other countries who are completely familiar with the important advisory, technical, and research services being performed under the leadership of the World Health Organization. It is significant that the World Health Organization has insisted upon qualified personnel to carry on its activities and that there be a balance of service, training, and research, for it is known that to provide service alone is not sufficient to obtain best results. It is necessary, from the beginning, particularly in less developed countries, to train local people to carry on the new techniques that are being demonstrated. It is equally important to give

the newly trained people an opportunity for exchange of ideas so that they can give the benefit of their experience to their colleagues.

The question has often come up in the United States, sometimes even among health workers, "Why should we support the World Health Organization?" This specific question deserves a specific answer.

As one who first worked with the Expert Committee on Tuberculosis of the Interim Commission of the World Health Organization from 1946-48, I visited many countries of the world, associated with the health leaders of many lands, and participated in some of the field services carried on by Scandinavian teams in their early BCG programs. In recent years, I have observed the work of the World Health Organization in the Far East and in South America. The quality of health leadership provided by the World Health Organization and the importance of demonstration and training when they are used as spearheads to help less developed nations to help themselves continually impress me.

No nation is compelled to support the World Health Organization against its will. No powerful nations are attempting to use influence to force other nations to give financial aid. Everything that is done for WHO is on a voluntary basis. We would not have it any other way.

The world will be strong only in proportion to the strength or weakness of its individual nations. Transportation and communication have changed so much in recent years that no one is now very far away in time from anyone else in the world. Disease can be transported over thousands of miles in a matter of hours. Animal and plant diseases can be carried with ease from one continent to another unless adequate safeguards are set up. Therefore, in the field of health the concern of one nation has now become the concern of all nations. There is nothing controversial about the need for health programs. It is a question of bringing to people the skills and knowledge to carry on preventive services under the leadership of local people.

We must assist WHO with everything that we can spare. We must concentrate attention on major health problems—this will not be diffi-

cult because the leaders of WHO have defined them and also have pointed out public health activities that will achieve global results.

The World Health Organization deserves our support because Americans believe in good health for everyone and not for just a chosen few. Good health contributes to a productive life in the community, which in turn gives the individual satisfactions that help him to live in harmony with his fellow man. Health helps to create in man the leadership qualities that are so urgently needed in so many communities today. The physical improvements that come from improved world health are only part of the story. Added improvements, in the form of emotional and mental stability, come with sound physical health.

The program of WHO should be supported because its failure would have a blighting effect upon so many nations. Already the results of joint programs under WHO are measurable in many countries in spite of the modest budget available for a worldwide enterprise. We need to support WHO so that it may keep pace with the other specialized United Nations programs directed toward the improvement of the welfare of people throughout the world. There cannot be social and economic improvement without improvement in health.

Funds spent for WHO are very modest in comparison to funds spent for other United Nations activities, and, in many cases, small in comparison to funds spent for public health in individual countries, and even in some of our States. New York State, for example, in 1955 has a public health budget of \$64 million for 16 million people. The World Health Organization budget for 1955 is approximately \$9,500,000 for the whole world.

Interchange of Ideas

There are many direct benefits to member nations from WHO programs throughout the six regions of the world. Dr. Boudreau of the Milbank Foundation once said that "better health throughout the world is well worth working for but the experience gained by working together may prove, in the long run, to be of far greater value." This kind of interchange of ideas and this interchange of health

leaders throughout the world is a significant part of the World Health Organization.

In our New York State Health Department, for instance, more than 300 foreign visitors come each year to work with us, to observe, or to exchange greetings. From them we learn as much as we impart.

The professional interchange of ideas is of inestimable value. These scientific workers enter our professional lives and our social lives as well. They observe our culture and our customs; they listen to our music; they enjoy our art and read our contemporary literature. They have a chance to be guests in our homes and see how our families live. These are some of the indirect benefits from training programs on a worldwide basis. On the other hand, we send many American public health workers to foreign countries each year to improve their knowledge in special fields and, in some instances, to impart their special skills to other people who have requested their services. It is clearly evident that one of the great benefits of the World Health Organization, in its 8 years of activity, has been this exchange of scholars and scientists in medicine and public health, to the mutual advantage of all concerned.

In geriatrics and rehabilitation, for example, Scandinavian countries have programs far in advance of anything we are doing on a large scale in America. Physicians in their geriatrics hospitals have answers to many vexing problems confronting us in New York State and in other parts of America. Much more was gleaned from my Scandinavian colleagues on my visit to these countries than they could possibly have learned from me, yet we had the most delightful exchange of ideas and information. Since that visit we have continued to exchange publications and studies of mutual interest. These are the hidden assets of WHO which are of immeasurable benefit and are of a continuing nature.

This spring we had another demonstration of the universality of public health. Shortly after it was announced that the poliomyelitis vaccine trials of 1954 were a success, a mass vaccination program got under way. It started not only in the United States, but also in Canada and Denmark. We hope to learn the answers to many of the epidemiological ques-

tions concerning poliomyelitis from our colleagues in those countries.

In 1951, in preparing for civil defense responsibilities, I studied the use of whole blood under conditions of war in Korea. This afforded an opportunity to study the best way to use blood in field hospitals for relatively large numbers of serious injuries—practical knowledge which could be important in times of disaster. Teams of medical workers from many nations were caring for the wounded and teaching each other their native skills as they went about their routine duties. Here was international health in action.

Need BCG Evaluation

On returning from Korea, I stopped at Taipei, Taiwan, and met a Taiwanese who had worked with me in the Public Health Service during the last war. His tuberculosis control activities in Taiwan, including BCG vaccination and mass X-ray examination, under difficult conditions of limited personnel, supplies, and facilities, obtained measurably good results because of the high quality of his work and his zeal. Again, I learned new methods in handling tuberculosis cases and found out many ways in which this disease affects people differently in different parts of the world.

In the Philippines, on that same trip, we discussed the need for the Tuberculosis Research Office of World Health Organization to collate data on BCG programs and to evaluate their usefulness as public health activities. It was not known how much the tuberculosis mortality and morbidity rates were reduced in whole communities or states by mass BCG vaccination. The lasting effects of BCG vaccine were not known. Since that discussion tens of millions of children have been tuberculin-tested and millions of nonreactors have been vaccinated by World Health Organization teams with the aid of UNICEF funds and supplies. There are some signs that BCG, under certain circumstances, can be useful in tuberculosis control. But we simply have no knowledge or measure of its effectiveness as a means of controlling the disease in a whole community. There remains, then, a great opportunity for WHO to determine, through demographic studies, the relative

value of BCG in the total array of tuberculosis control measures.

Chronic Disease and Disability

There is needed also the same type of definitive studies on the role of new drugs and antibiotics in the prevention and treatment of tuberculosis. Such studies would be most welcome to public health workers all over the world, particularly in those countries where tuberculosis is still rampant.

On a global basis, cardiovascular disease provides a fertile field for epidemiological research that has scarcely been tilled. This research includes the study of the relationship of total fat content of the diet, fat and protein concentration in the blood, the development of atherosclerosis, and the morbidity and mortality from degenerative heart disease. Dr. Ancel Keys has worked with colleagues in England, Scandinavia, Italy, Spain, and Portugal, and, the past winter, among the Bantu in Africa. His intercontinental studies show promise of practical application in preventive medicine. As communicable diseases come under control in many countries and as the proportion of older persons increases with improved public health, the attention of WHO inevitably will be drawn to chronic disease and disability, to which heart disease is a principal contributor.

A survey of patients in the medical wards of several countries is bringing forth some meaningful data, with prevention possibilities, on the cause-and-effect relation of high-fat diets, cholesterol in the blood, and coronary artery disease. The native Bantu gets only 10 percent of his calories from fats and has very little atherosclerosis. The native American gets more than 40 percent of his calories from fats and is greatly affected by atherosclerosis. There are many variables still to be sorted out in this complex relationship, to be sure, but this type of international study in the epidemiology of cardiovascular disease offers hope for new knowledge in the control of a worldwide killer and disabler.

Whether we talk about the control of malaria in India, onchocerciasis in Africa, yaws in Haiti, schistosomiasis in Egypt, yellow fever in the Americas, or heart disease in Britain, we

are aiming at the improvement of the health of individuals, improvement of the status of the family, and an improved economic situation for the community.

If manpower is fundamental to all wealth, then this principal can be preserved and augmented by improving the quality of man's health. It is not easy to measure the benefits of public health in money alone nor is it possible for most people to comprehend astronomical monetary figures. Talking about the billions of dollars saved by wiping out malaria among 200 million people baffles the imagination. But when you go into the villages and see the happy families, productive workers, healthy mothers, and clean living quarters, you see values that leave a lasting imprint on your mind.

People need an inner drive to obtain good health for themselves. The leaders in WHO can help to foster that drive among their own people, and they in turn can pass it on to others. This is the kind of contagion that we are in favor of in WHO. This is the kind of service that builds physical and mental and spiritual health; it builds a sense of sharing and of co-operation in common desires that recognize no geographic boundaries. World Health Organization activities admit no barriers of race, creed, color, religion, or economic status. It is a partnership which is expanding and extending throughout the free world. It is a living demonstration to the underprivileged that many of them may improve their standard of life through the channel of better health.

Dr. M. G. Candau, the Director-General of the World Health Organization, last year cited the need for more trained personnel and the importance of environmental sanitation. Significantly, approximately 40 percent of the year's projects in all regions were mainly concerned with education and training. Member nations also were urged to assign high priority to environmental sanitation in all health programs and to make improvement of sanitary conditions a part of most projects, whether for the control of communicable disease or for the improvement of the health of particular population groups, such as mothers and children.

A combination of these vital factors was emphasized at last month's assembly in Mexico

City when the organization agreed in principle to act as a clearinghouse for the international exchange of information on the medical uses of radioactive substances. The WHO long-term program to train adequate technical personnel through fellowship consultants, study teams, and advanced courses in this important new field is reassuring.

The work of WHO reflects an increasing recognition of its real function—that of technical adviser in the development of national health services and of international coordinator of health activities, rather than a source of supplies and equipment and an aid for the temporary alleviation of certain problems.

In these days of speedy transport, we are almost living in each other's backyard. In learning to live so near one another, we have the opportunity and obligation to help improve

the health and well-being of our less fortunate neighbors.

We need to endorse healthful living by demonstrating that prevention of disease and disability is a wise investment of national resources. Health is incredibly precious, especially to those who have lost it and then repossess it.

Public health can play a leading role in united efforts to gain worldwide stability; it can do this through the World Health Organization by combating disease, poverty, and ignorance. This is, indeed, a cooperative international enterprise which must succeed. We are determined that it shall succeed, if only for the warmth of satisfaction that it brings to our hearts and for the peace and comfort that it brings to the minds and spirits of men and women in less developed countries of the world.

New York Seminars

Poliomyelitis

Dramatizing the importance of careful control and checking of diagnostic procedures, Dr. Salk, developer of the poliomyelitis vaccine, said he expected more "polio" in the summer of 1955 than ever before, with many ailments erroneously diagnosed as poliomyelitis because of the publicity surrounding the disease.

Dr. Frandsen, in his description of mass vac-

inations in Denmark with vaccine prepared in the Danish State Serum Institute according to Salk methods, reported there have been no complications and no cases of poliomyelitis among children vaccinated since April 12. Almost half a million children between ages 7 and 12 (98 percent of the population of that age group) have been inoculated. The Danes are inoculating in the skin rather than in the muscles. The second round began in June. A third shot is scheduled for next year.

Denmark expected to vaccinate the entire population under 40 years of age by the end of the summer. All inoculations are free. The vaccine is paid for by the state and issued to general practitioners. Frandsen expressed Denmark's gratitude to Dr. Salk and others responsible for the vaccine, after describing the severe 1952 and 1953 poliomyelitis epidemics in Denmark.

Dr. Korn's presentation of the factors involved in the evaluation of the 1954 field trials of the Salk vaccine in the United States stressed the voluntary participation in the study of 150,000 workers in 44 States and 211 local areas. Standardization of all procedures, including

Chairman: Hart E. Van Riper, M.D., medical director of the National Foundation for Infantile Paralysis.

Honorary Chairman: Thomas M. Rivers, M.D., vice president and director, Rockefeller Institute for Medical Research.

Participants: Johannes Frandsen, M.D., director general, National Health Service, Denmark; Robert F. Korn, M.D., deputy director of the Poliomyelitis Vaccine Evaluation Center, Ann Arbor, Mich.; Jonas E. Salk, M.D., research professor of bacteriology, University of Pittsburgh.

diagnosis and physical therapy, was one of the most difficult aspects of this undertaking. To avoid the presence of diagnostic errors in statistical summaries, diagnosis of poliomyelitis was confirmed when possible by isolation of the virus from the infected person.

Among the interesting factors in the 1954 evaluations was the significantly and progressively greater difference in response to the vaccines by older children. That is, vaccinated 6-year-olds had a poliomyelitis incidence of 40 in 100,000; those of the same age who were not vaccinated had an incidence of 55 in 100,000. At 7, 8, and 9 years of age, the differences between poliomyelitis incidence in the vaccinated and unvaccinated were much greater, with older children benefiting much more from the vaccination. The percentages for all ages indicated an effectiveness of 68 percent against type I poliomyelitis and of 90-100 percent against types II and III. These were the figures used for the final summary.

In reviewing the results of the field trials, Korns said that of the study population, 129 children contracted poliomyelitis. But 88 of that group had received no injection—they were among the controls. Seven had received a powerless injection, or placebo, and 10 had a single inoculation. Of the 34 cases that had some injection, 22 were nonparalytic. The 12 paralytic cases showed no localization in the injected arm as might be expected if the vaccination were the cause. The dates of onset of the disease showed no relation to the time of the injection.

Dr. Salk's detailed discussion of the vaccine itself brought out the fact that natural immunity to poliomyelitis is much higher in poor, undeveloped communities than in those with a higher standard of living. The explanation lies in early exposure to disease because of poor sanitation and similar conditions, with the resulting production of antibodies.

Salk's presentation was aimed first at explaining the principles of producing a noninfectious vaccine and, second, at the immunological principles involved in the use of the vaccine. The virus is inactivated by formaldehyde. Predict-

able proportions of viruses are inactivated each day, and thus a total virus population in a theoretical batch of 5 million cubic centimeters would be inactivated in, say, 12 days. Since the actual batch is no more than 50,000 cubic centimeters, there is a safety factor of 100. But tests of the vaccine from two different manufacturing laboratories do show differences. These are explainable as slight variations in time or temperature in preparation of the virus—the tiny factors that cannot be entirely controlled.

He described some of the ways in which antibodies are measured with a culture of monkey tissue cells. If monkey kidney cells are healthy and alive, the color in a test tube is changed from red to yellow in several days. In the presence of virus, the cells are destroyed, and the red color is retained.

After preliminary tests, a standard vaccine "A", used as a reference vaccine, was inoculated into children in cubic centimeter amounts of 2, 1, 0.5, 0.25, and 0.0625. The children's antibody response gradually diminished in direct proportion to the amount of vaccine.

With the more potent doses, all responded. At lower amounts not all the children responded after the first inoculation, but after the second shot, they all did.

The third dose, or more, of vaccine within a short time had no effect, even in producing a slight decline in antibodies. Thus, it was decided to space the third shot some months after the first and second for maximum immunity. The body apparently produces a measurable amount of disease-fighting chemical within a few weeks of the first vaccination: the second "shot" gives a measurable kick to the antibody production, and a third one, after antibody production has leveled off into a plateau some months later, provides a second important jump that levels off at that point.

It was found in the course of the study that children with an earlier slight natural immunity (blood samples were taken and level of antibodies determined) received a tremendous boost in antibody level from the first shot. It was also found that the noninfectious vaccina-

tions produce in toto a higher level of antibodies than is reached by a person convalescing from poliomyelitis. A natural infection produces more antibody than the first injection, but with the second and third, the vaccinations are superior to natural infection as immunizing factors.

Antibody persistence was measured in children vaccinated in 1953. The children were given three inoculations a week apart and a fourth 7 months later. Measurement of antibody activity a year later indicated that it maintained a steady high state.

Dr. M. A. Sanchez Vigil, director of the National Institute of Hygiene, Nicaragua, asked the panel if there was any possibility that a virus peculiar to the rhesus monkey, in whose tissues the vaccine culture is grown, could be transmitted to human beings by the vaccine. The answer was "No." The vaccine is tested for the exclusion of other viruses by direct introduction into the brain and tissues of extremely sensitive monkeys; the raw material is tested for disease-producing organisms and excluded if tests are positive; and other tests have shown that formaldehyde destroys other viruses much more quickly than the extremely resistant poliomyelitis virus.

Dr. J. J. Du Pre Le Roux, secretary for health of the Union of South Africa, asked if vaccination could reduce the incidence of natural immunity. The answer to this was "Not likely." Salk thought the duration of virus carriage will be reduced and that better hygiene will also diminish the incidence of virus carriage. Du Pre Le Roux also brought up the question of whether injection of the vaccine would have any effect of sensitizing girls to the Rh factor which produces problems in pregnancy. (The Rh factor is named for the rhesus monkey.) The answer was that in the vaccine filtering process the rhesus antigen is filtered out. Other pertinent data, as yet unreported officially, are the results of experiments on women who have by pregnancy or transfusion been made Rh sensitive. They were injected with the vaccine and showed no reaction to it.

Pandemic Influenza

Influenza differs from other epidemic diseases in that, although mild cases are to be found at all times, there is from time to time a worldwide flareup of a more serious nature. Diphtheria organisms, for example, are consistently present in a given population group, but the influenza virus disappears into a peculiar form of reservoir. Since man is the only host for the virus, the reservoir must be mankind itself.

The spread of influenza poses special problems. The disease would appear to arise at the same time in all parts of the globe for reasons at present unknown, but it has not been proved that influenza does not spread from particular foci. In 1918 and 1919, the disease seemed to appear suddenly for no known reason in many parts of the United States and the rest of the world. However, we are not sure that the influenza virus of that period is the same as the influenza virus types found at present.

After Dr. Horsfall opened a discussion of the potential medical burden of a present-day epidemic of influenza, the panel agreed that currently the total number of influenza cases was not as important as that of other respiratory diseases. When an epidemic, such as the recent outbreak at Fort Dix, N. J., does occur, there is, however, a tremendous burden on medical facilities. The peak of the epidemic at Fort Dix lasted 10 days. There were no fatalities, but 40 percent of the soldiers were hospitalized.

In discussing mutant influenza viruses, Dr.

Chairman: Frank L. Horsfall, M.D., member, Rockefeller Institute for Medical Research.

Participants: John H. Dingle, M.D., professor of preventive medicine, Western Reserve University School of Medicine; George K. Hirst, M.D., chief, division of infectious diseases, Public Health Research Institute of the City of New York; Thomas P. Magill, M.D., professor of bacteriology, State University College of Medicine at New York; and Harry M. Rose, M.D., professor of clinical medicine, Columbia University.

Magill pointed out that there may have been no sudden appearance of new virulent strains because we may have ignored the gradual changes that might have developed in the past. He believes that gradual mutation of the virus is the explanation for the otherwise inexplicable worldwide appearance of a new strain. All influenza viruses are compelled to mutate in the same direction, if they are to survive, because everyone has become immunized to previous strains, in approximately the same degree in comparative age groups.

Virus mutation appears to be continuous, making it hazardous to rely on a vaccine that has been made for longer than a year. Such a vaccine may not immunize because antigenic composition of the virus changes and also because viruses appear with new antigens. However, variations of antigenic composition do not appear to equate directly in terms of virulence of the virus. Antigenic composition and virulence appear to be independent characteristics.

Horsfall summarized the solution to the problem of future pandemics of influenza as lying in two possible methods of control: (a) immunizing populations against influenza, or (b) eradicating the agent, eradicating the reservoir, eliminating the chain of transmission, changing the host by changing his antibodies.

No presently known chemical substances will eradicate the influenza agent. Eradicating the reservoir is not practical since man is the reservoir. Studies have been made in the chain of transmission. The virus is airborne, and controlled experiments have been made in sterilizing the air by various means, including radiation, but these experiments have yet to show effective results.

Elimination of the chain of transmission means isolation. Altering the resistance of the host seems an attractive solution, but this consideration is still in the theoretical stage. There is no basis for assuming such a solution can be realized in the near future.

The vaccine used for immunological control should include the broadest possible antigenic variation. It is possible to include both A and B prototype strains of influenza virus in an aqueous vaccine, but it is not possible to include

more than 3 or 4 variations of the prototype in one aqueous vaccine. While agglutinant vaccines will accommodate a wide antigenic range, because they have a lanolin or mineral oil base, they require an emulsifying agent, which sometimes sets up a systemic or local reaction.

Teaching Public Health

Of basic importance is the philosophy of training medical students in public health practice throughout their medical training and of avoiding the isolation of preventive medicine teaching as a discrete discipline, Dr. Smillie stated. He emphasized that medical school training in public health in the United States is not designed to prepare students to be public health officers. Graduate training in public health administration is offered by schools of public health, he said.

The initial aspect of public health introduced to first-year medical students deals with the statistical interpretation of medical data. This subject is taught through special departments of biostatistics as a separate course. In the second year of medical training, students are introduced to the general field of public health through a course which acquaints them with sanitation, communicable disease control, health education, and other activities. In addition, through the facilities of the New York City Health Department, students at the Cornell University Medical College gain familiarity with the organization of official public health services by means of field visits, inspections of clinics, and observations of environmental control programs.

It is recognized that, in principle, medical students are interested in public health and the other broad aspects of medicine only in their

Chairman: Wilson G. Smillie, M.D., professor of public health and preventive medicine, Cornell University Medical College.

first 2 years of training, Smillie commented. He pointed out that it would be fruitless to attempt such broad, theoretical training during the clinical practice years. However, he said, ways have been devised to continue the students' indoctrination and experience with preventive medicine and rehabilitation even during the clinical years. Whereas medical practice and training formerly were based upon two fundamental points, diagnosis and treatment, they have recently evolved into a four-point program, including prevention of disease and rehabilitation as well as diagnosis and treatment.

To integrate preventive medicine and clinical practice during the third year of training, all medical students continue their observations of clinical and home visit activities of city district health offices. In addition, each student who so desires, and Smillie emphasized that nearly everyone does, is made a health adviser to a family selected from the clientele of a teaching hospital that does not have a regular family physician. In this position, the student is responsible, under close supervision, for the total health of his assigned family for 1 year. Although this amounts to a spare-time activity, done mostly during evenings and weekends, the student must make regular visits to the family once every 2 weeks and must be available to them in time of emergency. It is felt that this program is extremely important in giving the student an insight into various ways of life and into the role of environment as it affects the health of people.

The third year field work in health offices and the family health adviser program are well coordinated, since all preventive medical teaching staff members have dual appointments in the New York City Health Department, and each of the eight city health officers is appointed to the teaching staff of the medical college.

In the fourth year of training, Smillie explained, all the departments of the medical schools join together to teach the student comprehensive medical care. In this program each student is responsible, under direction, for the complete care of a number of patients who come to the hospital. Thus, the student begins to consider, for his patients, prevention of disease

and rehabilitation following disease, as well as care and treatment during illness.

To explain the rather unique inclusion of rehabilitation in the preventive medical training program, Smillie pointed out that the reestablishment of the crippled child or the patient disabled by an accident to his suitable place in the community was formerly a function of the department of physical medicine. Now felt to be important in the total care of sick people, rehabilitation has been incorporated in all departments of teaching and administratively centered in the department of preventive medicine.

Insectborne Viruses

Man is not an essential host for the maintenance of the insectborne viruses, but it has been shown that antibodies to several viruses are common in the human population, Dr. Theiler asserted. During the years that the Rockefeller Foundation was searching for yellow fever virus in Africa and the Americas, new distinguishable viruses were found, he said. These new viruses were all transmitted by bloodsucking arthropods, and all were maintained in cycles involving the arthropods and the wild animals.

By the systematic use of the hemagglutination inhibition test, two groups of viruses have been distinguished. Group A includes eastern, western, and Venezuelan equine encephalitis,

Chairman: George K. Strode, M.D., director (retired), international health division, Rockefeller Foundation.

Participants: Max Theiler, L.R.C.P., D.T.M. and H., director, Rockefeller Foundation Virus Laboratories in New York City; Fred L. Soper, M.D., director, Pan American Sanitary Bureau (Regional Office WHO for the Americas); Hilary Koprowski, M.D., assistant director, viral and rickettsial research, Lederle Laboratories Division of American Cyanamid Co., and member, WHO Expert Committee on Rabies Control.

Semliki Forest virus, and Sindbis. Immune serum prepared against any one of these will inhibit agglutination to a high titer with homologous antigen and, to a lesser extent, with an antigen prepared from any other virus of this group. Certain members of group A have a wide distribution. For example, protective antibodies to Semliki virus have been found in populations of Central and South Africa, Malaya, Borneo, and the Amazon Valley.

The second group (group B) is composed of Ilheus, Ntaya, West Nile, Uganda S, Zika, St. Louis encephalitis, Japanese B encephalitis, Murray Valley virus, Russian spring-summer encephalitis, yellow fever, and dengue. These viruses have a worldwide distribution. An immune serum containing antibodies to any one of this group will inhibit hemagglutination of red blood cells by an antigen prepared from other members of this group but not by an antigen prepared from viruses belonging to group A. The immunological overlap in group B is far more marked than in group A.

The hemagglutination inhibition test is group specific not strain specific. The immunological overlaps have theoretical as well as practical implications. Theoretically, it is probable that the immunological overlaps point to a common evolutionary ancestor. Practically, it is conceivable that an individual immune to one member is relatively immune to another member of the same group.

Extensive testing in various parts of the world indicates that many virus infections are common in man. Almost 100 percent of Egyptian adults were found to show antibodies of West Nile virus. A rational explanation of these infections throughout the world is, at present, not possible, Theiler commented.

Aedes aegypti is known by experiment to be able to transmit almost all of these viruses, but only yellow fever and dengue are known to be transmitted by this mosquito in nature. *A. aegypti* is present throughout the tropical and subtropical regions of the world, but it has transmitted yellow fever only in Africa, the Americas, and, in ancient times, southern Europe. Epidemics of dengue, in contrast, have been reported in all tropical and subtropi-

cal regions. Recently, in Trinidad, an outbreak of jungle yellow fever among men and monkeys was discovered. Despite *A. aegypti* prevalence throughout the island, no *aegypti*-borne epidemic occurred. Theiler suggested that extensive immunity to dengue prevented the development of an epidemic involving man-*aegypti*-man. The suggestion is based on the immunological relation between yellow fever and dengue. Should this hypothesis be confirmed, it may explain many of the known facts on the distribution of the arthropod-borne virus infections.

Dr. Soper, in discussing the yellow fever threat, asserted that although yellow fever has been virtually eliminated in the United States much of the southern part of the country is considered by the Public Health Service to be receptive to the disease.

Soper illustrated the fluctuations in the incidence of the disease with maps. Brazil had fewer than 10 cases a year from 1946 through 1950, but had 223 cases in 1952 and 39 cases in 1953. Bolivia had 354 cases in 1950, 3 cases in 1951, and 1 case in 1952, but in 1953, there were 18 cases. In many areas of the Americas, there were intervals when yellow fever did not appear at all, he added. In a few areas, yellow fever was known to be present constantly.

A. aegypti is found no longer in Brazil, Paraguay, Bolivia, Peru, and Ecuador. However, northern Argentina, the coasts of Mexico, many Caribbean islands, and areas along the northern shore of South America are still infested.

In the areas where yellow fever is constantly present, the disease is endemic in the monkey population and sporadic in the human population. The disease, from time to time, spreads from its endemic areas in the forest. If the disease spreads to an area infested with *A. aegypti*, an epidemic may follow. The threat of yellow fever is permanent in the Americas so long as there exists an area in which *A. aegypti* is present.

Dr. Koprowski outlined the rabies problem and mentioned the successful efforts in Malaya and Israel to control the disease. In most countries, Koprowski said, the key to the problem is the dog population, although the disease

affects a wide range of animal life. Since the dog lives in close association with man and is especially susceptible to the rabies virus, concerted effort must be directed towards eradicating the disease in the dog population. The newer vaccines can be relied upon for effective control, but the more traditional methods of establishing control of rabies in the dog population should not be neglected.

Mental Health Programs

Team members, introduced by Dr. Levine, demonstrated the team approach to psychiatric orientation in the pediatrics department of New York Hospital-Cornell University Medical College. The team included an occupational therapist, a nursery school supervisor, a child psychiatrist, a person in charge of comprehensive medical care and teaching, a resident in pediatrics, and a child psychologist, among others.

In their discussion of the hospital's teaching program in pediatric rehabilitation, members of the pediatrics department stressed the need for instilling in pediatricians an awareness of the psychological factors in child development. They also emphasized the need for "preventive psychiatry" for the general population. This would necessitate getting to the children early. The hospital's pediatrics division includes opportunities for observing well children in a nursery school, work with sick children and

their parents, parent discussion groups led by psychologically oriented pediatricians, a careful followup program for medical students and residents, and extension of the physician into the community beyond his ordinary medical concerns.

In addition, the pediatrics department itself tries to resolve the emotional and psychological problems of the children who are cared for at the hospital. Recognizing, for instance, that a stay in a hospital and illness are traumatic, it has lengthened parental visiting hours to help reassure the child. The new visiting hours—from 10 a.m. to 5 p.m.—are expected to work reasonably well, without interfering with hospital routine.

There are new methods of anesthesia. The basal anesthesia is given in the child's room, and the child's mother is waiting in the room when he awakens after anesthesia. Services of a psychiatric team are available for more intensive work when necessary.

The other two programs discussed were New York State's legislative support of community mental health services and the use of drugs in treating psychotics.

Dr. Lemkau explained the legislative structure of New York's first organized statewide attempt to give public support to psychiatry outside of mental hospitals.

State law provides for: (a) education and consultation with social agencies that need and can use psychiatric services in casework; (b) promotion of psychiatric outpatient services in hospitals; (c) promotion of rehabilitation for persons who have been psychiatrically ill; and (d) psychiatric sections in general hospitals. Specifically excluding specialized mental hospitals, the program is aimed at the spread of psychiatric influence and information in general medical practice and in community services.

Although, in effect, the State subsidizes the program, there is no State direction. A board is to be set up in each community for the administration of the law. Problems of the board involve integrating the program with city health centers, cooperation with the schools,

Chairman: Frank Fremont-Smith, M.D., medical director and executive secretary, Josiah Macy Foundation.

Participants: Henry Brill, M.D., assistant commissioner of the department of mental hygiene, New York State Department of Health; Paul V. Lemkau, M.D., director of the New York City Community Mental Health Board and professor of public health administration, Johns Hopkins University; S. Z. Levine, M.D., professor of pediatrics, Cornell University Medical College.

and, possibly, the removal of barriers between bureaus in a city.

Dr. Brill discussed the place of drug therapy in mental health programs. The two new drugs, reserpine and thorazine, that are being used for treating extremely disturbed patients have benefited them, he said, "in a way we have never seen before. That, to us, is a miracle."

In hospitals using the drugs, the need for electric shock treatment, physical restraint, and seclusion has to a certain extent been reduced. And more patients have been made accessible to psychotherapy. This has increased the need for psychotherapists.

Reserpine is derived from a plant, *rauwolfia serpentina*, which has been used in India for more than 100 years for the treatment of mental disorders and hypertension. It has been known in this country for only 2 or 3 years. Chlorpromazine, or thorazine, known in this country only a little over a year, was new in central Europe 2 or 3 years ago.

Brill concluded with the observation that the new drugs have definitely proved that pharmacology has a place in the treatment of mental disorders.

Nutrition

The elements of a nutrition program consist of appraising the diet of the people in an area and formulating steps for improvement if necessary.

Chairman: H. D. Kruse, M.D., Sc.D., executive secretary, Committee on Public Health, New York Academy of Medicine.

Participants: Norman Jolliffe, M.D., director, bureau of nutrition, New York City Department of Health; Charles Glen King, Ph.D., scientific director, the Nutrition Foundation, and professor of chemistry, Columbia University; Herbert Pollack, M.D., Ph.D., associate professor of clinical medicine, New York University.

Appraisal includes clinical examination for deficiency diseases, biochemical examination of blood and urine, and determination of nutritional status by a study of food values for each country, according to a table of values.

To improve nutrition in each country, it is desirable to fit domestic production of needed foodstuffs into a diet and way of life acceptable to local custom and tradition.

People may not know they are suffering from malnutrition, Dr. King said. If Central American children survive the first 5 years—and half do not—they are chronically ill. These survivors have plenty to eat and are not hungry, but they do not realize they are undernourished.

Because weaned infants are fed a diet of corn, in the form of tortillas plus beans and some fresh fruit, they soon show signs of serious protein deficiency. Their total protein intake may be high, because beans are high in protein value, but it is not complete protein or sufficient to develop normal bodies.

Within 6 months, height, weight, and skeletal development show retarded growth. The food intake pattern shows vitamin A and riboflavin deficiencies, confirmed by blood and urine analysis. Iodine deficiency results in a prevalence of goiters.

The United Nations Children's Fund attempted distribution of dry milk powder. Some was sent to the schools; however, it was found that the nutritional damage had occurred before the children entered school.

In evaluating the dietary of a people, the results of the biochemical surveys of the body fluids can be predicted from the clinical symptoms, and vice versa, according to Dr. Jolliffe. The prediction must be confirmed, however.

A clinical examination of 6th grade students in Formosa showed that 78 percent of the children had lesions at the corner of the mouth, known as angular stomatitis. This symptom is an almost sure sign of riboflavin deficiency, particularly when a magenta tongue and lesions around the nose and scrotum are also observed. Urine examination, on the other hand, indicated a riboflavin deficiency in 68 percent of the children. Formosa has a high incidence of anemia,

which sometimes produces similar symptoms, or the percentages might have been even closer.

To determine vitamin C deficiency, physicians look clinically for marginal gingivitis—tenderness and bleeding of the gums—and then biochemically for vitamin C in the blood or urine. According to Jolliffe, when the percentage of marginal gingivitis is found for a study group in western countries, the physician can “hit on the nose” the percentage of vitamin C deficiency found in the urine. A Newfoundland survey showed how this close relationship works: Marginal gingivitis was 38–40 percent; the body chemistry indication was 30–35 percent.

In Formosa 30 percent of the children showed marginal gingivitis, but there was no blood chemistry indication of a vitamin C lack. Actually there was only 1 real case of scurvy in the school population of 1,000 and no scurvy generally in the population.

Getting the dietary status, Dr. Kruse said, can be a crude matter of totaling the amount of food produced and the amount imported, then dividing the total amount by the number of people. Other methods are asking persons to write down what they eat, interviewing individuals about their eating habits, and questioning careful local observers about what people eat.

Local dietaries are sometimes puzzling. Dr. Pollack told of a dietary in Formosa reported to be extremely low in calcium. The average intake was 250 milligrams a day. There were no signs of deficiency although they should have been present. Perhaps the metabolism of the Formosans differs from that of other people, or perhaps there is some unknown calcium in the diet.

By accident, it was found that rice millers in the Far East use a “stone powder,” actually chalk or calcium carbonate, to facilitate the flow of rice in the mill, adding it in the amount of 1 percent by weight. Even after washing and cooking, 1 gram of rice contains about 1 milligram of calcium.

Thus, with an ordinary diet of about 500 grams of rice, the calcium intake from rice alone is 500 milligrams. This amount, added to the

250 milligrams from vegetables, makes a respectable 750 milligrams of calcium a day, considered to be adequate for a man 5 feet 3 inches tall, living in a land of intense sunshine.

When the question was raised about milk substitutes in the Far East, where milk production is low and not expected to be adequate for some time, Dr. King said that milk formed an excellent educational nucleus for a nutrition program since it is the most efficient food for children in its content of vitamin A, calcium, riboflavin, and protein.

Much can be accomplished in the next 25 years in countries that seem unable to support livestock, he added. Poultry and cattle can be raised if they are fed silage and legumes. Coconut and soybean “milks” are constructive substitutes in the meantime. Soybean milk, however, has an appetite-depressing effect unless it is fermented or cooked.

The addition of fish to cereals and soups would very readily raise the protein content of the diet. A poultry industry could be built up quickly once the importance of continuous egg and bird production was understood in the far eastern countries where people sell birds for cash. Cottonseed and palm nut presscake would provide good protein supplements to rice and corn diets.

Jolliffe pointed out that, if cattle production were increased in order to increase milk production, land that is now producing directly for food would have to be put into grain production. Far eastern countries could not afford an unfavorable food ratio of production for animal feed, he said.

King replied that modern technology enables more food to be grown on less land, thus making more land available for grazing. Submarginal land could also be used. In one far eastern country, where it was thought that milk production could not be increased, eliminating the nonproductive stock and keeping records on each cow's production in 3 years brought about an increase in average milk production from 1½ pounds per cow per day to 20½ pounds.

Kiyoschi Saito, deputy director of the Institute of Public Health of Japan, said that

Japan tried feeding soybean milk to infants but found that this substitute retarded long-range development even though it seemed adequate for brief periods. Then Japan tried to increase the production of cow's milk because, although 85 percent of the babies are fed at the breast, 15 percent depend on cow's milk. Infant mortality decreased along with the sanitation of cow's milk. In 1954 the rate was 48 deaths per 1,000 births, as compared with 150 deaths 25 years ago. The price of milk has dropped to 20 cents a quart, which is not considered expensive.

The necessity of providing transportation and refrigeration must not be overlooked, Pollack said. Milk production suffers in a country which uses a cow both for carrying and supplying milk. In planning improved agricultural techniques, it is well to remember that when farming is mechanized, fuel is necessary, spare machine parts must be stocked, someone who knows how to fix a machine must be at hand.

When fish farming in ponds in the flooded rice paddies of the Far East was mentioned as another possible way of increasing the protein in the dietary, Pollack doubted the value of such a practice, saying that the nitrogen needed by the fish would not be replaced in the soil.

Dr. Roberto Munoz Urrutia of Chile mentioned that 20 years ago a Chilean consumed about 50 liters (about 50 quarts) of milk a year. Now the amount is about 102 liters. In 5 years the average Chilean is expected to be drinking about 150 liters a year.

There has been no improvement in transportation, in refrigeration, or in number of cattle in Chile. Instead, people are drinking the milk that formerly was wasted and using dry milk and dried skim milk. These changes are the result of consumer, producer, and government education. Once the problem was understood, it was easy to solve.

Chile is now working on introducing more fish into the diet to give the people more protein. Pilot experiments with an odorless, tasteless fish flour showed that children like and tolerate a bread flour containing a 10 per-

cent fish flour (presently imported from South Africa), yet do not know they are eating fish in bread.

Tuberculosis Control

New types of chemotherapy have brought about a decrease in the death rate from tuberculosis, according to Professor Amberson. Now only 1 death is reported annually for each 5 or 6 new active cases, whereas formerly the mortality was 1 death for each 2 new active cases. In some areas, the panel reported, tuberculosis was disappearing completely in children and young adults.

Among the new drugs under study for the treatment of tuberculosis is pyrazinamide, which has been actively investigated by Dr. McDermott and his associates, Dr. Chaves told the delegates. Pyrazinamide is one of several chemical substances capable of modifying the course of tuberculosis. The drug at first appeared to be ideally suited for widespread use, but, unfortunately, it has proved to be too toxic to be used generally or indiscriminately.

Whether pyrazinamide can be successfully modified is still a question. Nevertheless, the demonstration in animals, by a laborious but precise technique which shows that it is possible to eradicate tuberculosis infection by this method, represents an unprecedented achievement.

Other drugs, such as isoniazid, are being used

Chairman: Walsh McDermott, M.D., professor-elect of public health and preventive medicine, Cornell University Medical College.

Participants: J. Burns Amberson, M.D., professor of medicine, Columbia University College of Physicians and Surgeons; Aaron D. Chaves, M.D., assistant professor of clinical public health and preventive medicine, Cornell University Medical College, and supervisor of clinic, bureau of tuberculosis, Department of Health, New York City; Carl Muschenheim, M.D., associate professor of clinical medicine, Cornell University Medical College.

today to treat tuberculosis. Replying to McDermott's question as to what forms of pulmonary tuberculosis should be treated with drug therapy, Amberson said that today there is a tendency to treat all tuberculosis with chemotherapy. However, he pointed out, drug therapy should be delayed until a complete diagnosis is available. The objection to immediate drug therapy is that the patient may be committed to a regime of treatment before a diagnosis of active tuberculosis is established; hence, before therapy is begun, one must be sure that active lesions are present. If the lesions are old scars, chemotherapy is not needed.

McDermott said that isoniazid could not be considered as a tuberculosis vaccine. However, Amberson pointed out, many patients are responding completely to chemotherapy and bed rest. Patients with lung cavities of from 3 to 4 centimeters may show no further improvement, and for such patients it would be necessary to consider lung collapse or surgery.

Blood and Tissue Banks

The possibility of transmitting the virus of infectious hepatitis in whole blood transfusions or in fibrinogen is a blood bank's most serious problem today, according to Dr. Kellner. Blood is never knowingly accepted from donors who have had the disease, since virus may still be present, he specified.

The greatest danger, Kellner said, is in the transfusion of whole blood. He indicated that he would chance the risk of hepatitis virus in the fibrinogen fraction (sometimes used to help coagulate the blood in cases of hemorrhaging

after childbirth or after lung or liver operations) if someone were bleeding to death. Attempts have been made to sterilize fibrinogen and some is now virus free, he noted.

In answer to a question about the use of blood transfusions for leukemia patients, Kellner reported that many leukemia patients are kept alive with transfusions, although blood is no cure for leukemia. Some children with leukemia are kept alive for 10 to 15 years by blood transfusions every 2 or 3 weeks, he said.

Asked if fibrinogen would help to coagulate the blood of hemophiliacs, Kellner replied in the negative, adding that hemophiliacs lack prothrombin, another important element in coagulation which acts on the fibrinogen to form fibrin.

Concerning the possibility of using animal blood, Kellner indicated that he did not expect ever to use whole blood from animals. During the war, an attempt was made to use one fraction—the albumin of cow's blood—but even this evoked serious sensitivities, and it was discontinued, he reported.

An eye bank's greatest problem is in getting a sufficient number of eyes, according to Dr. Troutman. The eye bank at Manhattan Eye and Ear Hospital in New York receives only 30 to 40 eyes a week, and there is always a waiting list of about 500 people, he reported. Throughout the country, there are an estimated 10,000 to 20,000 persons who would benefit from corneal transplants.

Troutman explained that in addition to permission for an autopsy, the law requires that a donor separately will his eyes to a bank. It is sometimes felt that donating the eyes may interfere with the autopsy permission, he said.

In obtaining an eye, which is done within 3 hours of the donor's death, complete surgical procedures are used for sterilizing the tissues. The eye is taken out whole and placed in a sterile bottle on a moist ring of cotton. It is then refrigerated at just above freezing (32°–45° F.) until the corneal graft is made. The eye must be used within 3 days.

Sometimes eyes are received at the eye bank floating in a solution, Troutman remarked. These, he said, are not usable.

Chairman: Aaron Kellner, M.D., director of laboratories, New York Hospital.

Participants: Edward B. C. Keefer, M.D., instructor in surgery, Cornell University Medical College; Richard C. Troutman, M.D., assistant professor of clinical surgery in ophthalmology, Cornell University Medical College.

He pointed out that no attempt is made to sterilize the eye because of the thickness of the tissues. But even so, there is a very low incidence of infection, and the infection that does occur is usually attributable to stitch abscesses and has nothing to do with the eye itself.

New techniques are being used in making the grafts with a split thickness of cornea, he said. This makes the operation promising in cases where formerly it was not. Troutman mentioned as another technique under investigation quick freezing of the cornea alone, which would enable it to be kept longer. After being treated with glycerol, the cornea is quick frozen, held at a temperature of -79°C ., and thawed just before use.

Asked if the eyes of newborn babies are ever used, Troutman said they are, even those of still-born babies, although the eye bank prefers those of fetuses that are at least full term. Eyes are usable as long as the cornea is clear, and there is no relationship between the age of the donor and the clarity of the cornea, he said. Statistically, however, there is some evidence that the transplant is better when the eyes are a bit older, he added.

The eye bank at the Manhattan Eye and Ear Hospital, which was established in 1945, is a nonprofit private enterprise. Donors are not paid for their eyes, and they are given to patients at no cost. Transportation for them to and from the main bank and the branch banks is furnished free by the Red Cross and the airlines. The bank is national and also handles some overseas distribution on a rotational and emergency basis.

Blood vessel banks, and more specifically banks for storage of the largest artery in the body, the aorta, were discussed by Dr. Keefer. He listed three ways of preserving arteries: by refrigeration, which permits them to be kept for 6 weeks; by freezing, which enables them to be kept for a year (at -70° to -80°C .) in dry ice; and by freeze-drying under vacuum, which enables them to be kept indefinitely. Arteries to be preserved by the latter method are sterilized by ethylene oxide, high-intensity electron beams, or beta-propiolactone.

Control of Cancer

Memorial Center for Cancer and Allied Diseases—the first institution of its kind in the United States—is extending its efforts toward improving the rate of cure of cancer and toward defining and eliminating the causes of the disease. Sloan-Kettering Institute is the research subdivision of Memorial Center.

Curing cancer involves the search for a better means of curing local cancer and for techniques which, it is hoped, will come from future research for curing disseminated cancers. Curing local cancer involves early diagnosis and extirpative measures currently employed, such as surgery and radiation.

Despite the massive effort to educate the public, improve cancer detection methods, and treat early cancers, the resulting decrease in the death rate is almost wiped out by the continuing increase in the rate of respiratory cancers, Dr. Rhoads pointed out.

At Sloan-Kettering Institute, Rhoads said, an effort has been made to regard and handle cancer cells according to the Henle-Koch postulates for the presence of infectious agents: that is, (a) to detect the presence of the organism in affected tissue, (b) to cultivate the organism successfully in a culture medium, (c) to induce the disease by inoculation of an organism with the culture, and (d) to induce an acquired resistance to the disease.

Cancer cells conform to the Henle-Koch postulates in that the cells are identifiable in human tissue. They can be grown in a test tube in which the colonies show forms similar to

Chairman: C. P. Rhoads, M.D., scientific director, Memorial Center for Cancer and Allied Diseases, and director, Sloan-Kettering Institute.

Participants: Emerson Day, M.D., director, Strang Cancer Prevention Clinic, and chief, division of preventive medicine, Sloan-Kettering Institute; Leopold G. Koss, M.D., director of cytology, Strang Cancer Prevention Clinic; Brewster Miller, M.D., director, professional education, American Cancer Society.

those of other cultures, and they can also be grown in eggs.

A culture can be implanted in the membrane of a chick embryo. The hatched chick will bear disseminated cancer nodules. These chicks are sent to other laboratories for biological and chemotherapeutic study.

Cancer may be induced in both animals and human beings by back inoculation with the test tube culture. The culture grown in the test tube shows the morphology of the original tissue long after the death of the person from whom the tissue was removed.

Sloan-Kettering harvests weekly about 3½ pounds of different types of cancer tissue from animals in which cancer has been induced. Implants are sent for confirmation to other laboratories.

The work at Sloan-Kettering and similar investigations have led Rhoads and others to believe that it is proper and profitable to seek control of disseminated cancers by chemotherapy. Selective destruction of cancer cells in animals has already been achieved by chemical methods at Memorial Center, but a chemical method for completely destroying cancer cells in man is still to be found.

In describing the work of the American Cancer Society, started in 1913 and now represented in all States and in Alaska, Dr. Miller first presented statistics on the incidence of cancer and then described the society's fund-raising methods, allocation of funds, sponsorship of research, and methods of education.

Public education methods include advertising the "seven danger signals," publication of informative literature, maintenance of information centers, use of radio and television, production of a film on breast self-examination, and considerable professional educational material.

On examining the society's material for the public, diplomates of the American Board of Psychiatry expressed these opinions: 11 percent disapproved, 7 percent saw some harm in the material but had no opinion as to whether the harm outweighed the good, 16 percent felt the material was harmful to some extent but thought the good outweighed the harm, 43 per-

cent thought the material was good. Twenty-one percent expressed no opinion.

Dr. Day is convinced that worldwide statistical surveys and other studies may produce clues to the prevention of cancer. The Strang Cancer Prevention Clinic, which is aimed at presymptomatic detection of cancer, receives about 40,000 annual visits from some 22,000 persons, he reported. The clinic's record of proved diagnoses varies with the ease of accessibility of the cancer site.

At the clinic the examining physician is expected to record a complete history and perform a systematic physical examination. Proctosigmoidoscopy, by which tissues in the rectum and colon are made visible, is a particularly successful technique, and, although now used for all persons over 45 on a return visit, Day believes it should be part of the basic examination pattern for everyone, at least once. Basic examination includes laboratory examinations of blood and urine and X-rays of the chest.

Cytological examination of a smear taken from female genitals is the closest to a successful detection method so far developed. Two-thirds of all the detection of cancer of the female genitals made at the Strang clinic is solely from microscopic examination of the cells aspirated or swabbed from the cervix and vagina. There were no other leads to such diagnosis.

Dr. Koss, whose speciality is microscopic study of cancer cells, described the principles behind the Papanicolaou smear test. Any growing surface tissue (epithelial tissue) has a constant turnover of cells—new cells replace the cells that are shed. Cancer cells are shed much faster than the cells of normal tissue, are not as adhesive as the cells of normal tissue and are much more easily removed, and have a tendency to accumulate in a body "receptacle" from which they can be collected. In lung cancer, the cells accumulate in the lumen of a bronchus. When the person coughs, the cells are brought up to a point where they can be collected. When the uterus is cancerous, the cells collect in the vagina.

Papanicolaou's enunciation of technical standards for the preparation and interpreta-

tion of the morphology of cancer cells and his directing of attention to organs that were not being explored by existing diagnostic means represent a great step forward in cancer detection. Extensive experience and training are needed, however, to handle cytology successfully, Koss pointed out.

Next to cancer of the breast, cancer of the cervix is the most common type of cancer in women. In a few decades no woman should die from this form of the disease, Koss believes. It is now recognized that early cervical cancer is a surface phenomenon: at this stage it does not penetrate the underlying tissue and is 100 percent curable. The cells behave like those of invasive cancer and are easily recognized by cytological examination.

A recent development in cancer cytology is the promise of a machine to screen cell and nucleus diameters mechanically rather than have them examined in the tedious way now employed. Such a machine is currently being tested.

National Pharmacopoeias

The importance of an international pharmacopoeia which lists standards for approved prescription drugs and their indicated usages was the theme of this session.

Dr. Cook gave a brief history of the development of this essential element in world health

progress. Discussion started in Europe more than 100 years ago and led to the formation of the International Pharmaceutical Congress. The congress met in Chicago in 1893 and resolved to develop an international pharmacopoeia. The problem was again considered by the League of Nations, but the work was interrupted by World War II. After the war, when the United Nations was created, one of the first steps taken by the World Health Organization was the reorganization of the pharmacopoeia program.

In 1951 the first volume of the First International Pharmacopoeia was published. It provides standards for about 200 basic drugs, but only a few preparations. Volume II is now in preparation.

Dr. Miller pointed out that fewer than 20 countries today have pharmacopoeias of their own. He said this means that many countries do not have legal standards of purity for drugs, and added, "These countries are in a delicate position because they must import drugs on faith. The International Pharmacopoeia therefore should become a major contribution to public health."

It was pointed out that many of the countries which do not have a national pharmacopoeia use one of those developed by some other nation. However, Dr. Brady documented from his own experience the difficulty of practicing medicine and prescribing drugs in areas where there is no official publication.

Dr. Taylor described the work of the Combined Pharmaceutical Contact Committee of which he is chairman. This group assists in the preparation of the United States Pharmacopoeia by making recommendations for establishing standards and then, on a voluntary basis, conducting the research necessary to set such standards. Although the committee has no official status, its recommendations are usually accepted. Taylor said that he described this methodology in detail because it worked so well in the United States, and other nations might want to adopt it in preparing pharmacopoeias of their own.

Cook outlined the system used in the compilation of the International Pharmacopoeia. A

Chairman: Lloyd C. Miller, Ph.D., director of pharmacopoeial revision, United States Pharmacopoeia.

Participants: Frederick J. Brady, M.D., assistant chief, Division of International Health, Public Health Service; E. Fullerton Cook, D.Sc., chairman (retired), Committee of Revision, United States Pharmacopoeia, and former member, WHO Expert Committee on the International Pharmacopoeia; Frank O. Taylor, D.Sc., chairman, Combined Pharmaceutical Contact Committee of American Drug and American Pharmaceutical Manufacturers Associations, and member, Committee of Revision, United States Pharmacopoeia.

tentative text was drawn up by an Expert Committee on Unification of Pharmacopoeias and the permanent Secretariat on Pharmacopoeias of WHO.

The tentative text was carefully revised by members of the committee with the help of specialists. All suggestions and criticisms were referred to Geneva and published in the official WHO circulars. These were then considered at the next meeting of the committee.

The galleys and page proofs of both volumes I and II were similarly handled by the committee and, in addition, the page proof of volume II was sent to the governments of all 85 member nations, inviting criticisms, comments, and suggestions. Cook added that if this policy is continued during the present revision of the First International Pharmacopoeia, the second edition would truly represent world judgment and justify the adoption of its standards in many national pharmacopoeias.

English, French, and Spanish editions of the International Pharmacopoeia are to be issued by WHO, with the hope that its sales will eventually cover its cost. WHO has also authorized translations by other nations, but only under WHO supervision; a German edition of volume I will soon appear. The Spanish edition of volume I is also promised soon. As the WHO program developed, the earlier committee of 7 pharmacopoeial experts was expanded, and an advisory panel of at least 30 specialists from 17 countries was appointed. These are experts in particular subjects and contribute information by correspondence or by attendance at sessions of the main committee.

The preparation of texts for the International Pharmacopoeia, however, is not limited to contributions from these appointees. Assistance and advice come from many other sources including the International Union of Pure and Applied Chemistry, the International Organization for Standardization, the World Medical Association, the International Pharmaceutical Federation, and from divisions of WHO, such as the groups studying malaria, tuberculosis, venereal diseases, plague, and so forth. Also a large number of other specialists located

in strategic points throughout the world contribute. The details of some tests for identity and purity or some assays, as incorporated in various national pharmacopoeias, may differ in minor details to meet different conditions, but the maintenance of equal quality, purity, and strength for essential drugs is the primary objective of the International Pharmacopoeia.

Administration Techniques

Public health administration in the United States is "a happy marriage of voluntary citizen groups, other community groups, and official health agencies," Dr. Baumgartner pointed out. Public health programs are either aided or made possible by citizen and industrial groups. In New York City, where adequate government inspection of restaurants and eating places is impractical, programs of self-inspection for poor sanitary practices by restaurant operators, schools in the fundamentals of sanitation for management and employees, and employment of trained sanitary inspectors by chains and large restaurants have combined to assure clean, sanitary eating places with minimum official health activity.

In discussing attitudes of citizens toward public health, Dr. Baehr said that support of voluntary health organizations stems from the rugged pioneering development of this country. The first villages and settlements found it necessary to plan sanitary and disease

Chairman: George Baehr, M.D., president, Health Insurance Plan of New York.

Participants: Leona Baumgartner, M.D., commissioner of health, New York City; Herman E. Hilleboe, M.D., commissioner of health, New York State; E. Gurney Clark, M.D., professor of epidemiology, Columbia University; Nathaniel H. Cooper, M.D., director of health and welfare, Health Council, New York City; William C. Spring, Jr., M.D., professor of public health administration, Johns Hopkins University.

control measures cooperatively. Even after government assumed much of this responsibility, people expressed interest in their health by forming voluntary organizations to solve specific health problems. Baehr emphasized that "this peculiar American pattern of citizen participation and understanding underlies the great development of public health in this country" and that without it, the great forward strides which have been made would never have been possible. He cited, as an example, the role of the National Foundation for Infantile Paralysis in the development of the Salk poliomyelitis vaccine.

Dr. Hilleboe stressed two other types of public health administration carried on in the United States—relationships with State and local medical societies and interlocking directorates in health programs. Hilleboe cited two requisites for successful cooperation, that medical societies are not offended by either official or voluntary health groups and that all groups are talking about the same thing.

In the New York State Health Department's bureau of cancer control, the director serves as chairman of the voluntary cancer society. Thus, one individual can participate in planning, securing funds, program operation, and program evaluation. The State health commissioner meets with the executive committee of the State tuberculosis commission, 80 percent of which is nonprofessional, and assures cooperative planning, action, and policy. Hilleboe emphasized the two-way nature of such cooperation by explaining the practice of establishing special committees for the State health department, drawing upon voluntary group representatives on the committees for local thinking and expression.

Hilleboe outlined the State's responsibility in synchronizing its program with national and Federal programs and at the same time in assuring that city and county health programs are in tune with State plans. He stressed that poliomyelitis control involves problems other than vaccination, in particular, hospital treatment and care of chronically ill patients. Hilleboe outlined the procedure for the care of poliomyelitis patients, wherein the first 30 days

of hospital care are subsidized by the National Foundation for Infantile Paralysis and all care after that by New York State in its State Hospital for Crippled Children or, on a 50-50 matching basis, by local government in other hospitals.

Dr. Clark described the principal problems in venereal disease control. By 1953, after major accomplishments in control of venereal diseases, appropriations for the control program were drastically decreased. The resources of the American Social Hygiene Association and the American Venereal Disease Association were combined with those of the Association of State and Territorial Health Officers to take new bearings. Their surveys showed that, in the last half of 1954, 43 States experienced an increase in venereal disease, two-thirds of the States could not find ways of compensating for decreased Federal funds, and one-third had inadequate treatment facilities. This information resulted, Clark pointed out, in recent increases in Federal grants to States for the control of venereal disease, as well as in a better-informed public.

Dr. Cooper discussed overlapping, duplication, and failure to fill important gaps in health services resulting from the growth of voluntary agencies working in the same fields. He described the development of community and State health councils as a means of coordinating the programs of all citizen groups working toward better health.

Dr. Spring asked for caution in using statistics which tend to lead the public to believe that all disease and sanitary problems are solved or nearly solved. He stressed the work still to be done and urged that health workers demand continuing opportunities for disease control even in the light of greatly reduced disease incidence. Clark emphasized this point by citing the near-epidemic proportions of venereal disease in some towns and cities, although the general rate has dropped appreciably. In New York City venereal disease rates in some neighborhoods are higher than the rate for the city as a whole.

Clark pointed out the problems in areas where there is a desire for home rule and a reluctance

to lose local autonomy by turning health protection over to more distant governmental groups. In these cases, programs seemed to be leading toward health units composed of governmental health services voluntarily financed. Where home rule localities are not large enough to furnish tax money for adequate health service, a potential exists in voluntary fund raising and voluntary financial support for otherwise official government health programs.

Baehr emphasized that the most significant value of voluntary agencies lies in the participation and understanding of citizens, which have been responsible for the development and security of the official public health services in this country.

Several speakers noted the increasing importance of international efforts. The work of the International Union Against Venereal Disease in the exchange of information is an example of international cooperation. Baehr pointed out that voluntary citizen groups, such as the United States National Citizens Committee for the World Health Organization, although constituted in one country, work toward better health for the world as well as for the Nation.

Rehabilitation Services

The present concept of rehabilitation evolved at the end of World War II, when it became apparent that the previous definition of ade-

quate surgical and medical care for the badly injured was not complete, according to Dr. Rusk.

It was determined that a man should not be discharged from medical care until he had reached the peak of his latent capacity, he said. It was discovered that this capacity should be determined with reference to both the man's disabilities and his capabilities.

The need for rehabilitation after World War II was dramatically demonstrated, he noted, by the fact that there were more than 2,500 paraplegics, over 2,000 more than after World War I. However, because of improvement in therapy, more than 1,760 of the paraplegics from the Second World War are now living, whereas only 2 of the First World War cases survived for a comparable period of time. Moreover, of the World War II cases, more than 1,200 are no longer in bed but have returned to civilian life.

Emphasizing the international aspect of the program of the Institute of Physical Medicine and Rehabilitation, Rusk pointed out that in rehabilitation there is an international language in which all can work out a program together. As many physicians from other countries are involved in the institute's program as are medical men from the United States, he remarked.

The institute no longer calls its work rehabilitation but considers it the third phase of medical care—the program that takes the patient from bed to a job, Rusk noted. This work is such that it must be done by a team. It involves an understanding not only of the medical diagnosis of each case but also of the patient's emotional problems.

When a patient comes to the institute, his medical diagnosis is reviewed by the team. Then the patient receives a psychological examination, and his case is reviewed by social workers.

Dr. Deaver described a series of tests he has devised called the Needs of Daily Living. Each patient is studied and graded on the basis of these tests, he said. The patient then comes before the staff of the institute and a training plan is outlined. Prosthetic and other devices

Chairman: Howard A. Rusk, M.D., director, Institute of Physical Medicine and Rehabilitation, New York University-Bellevue Medical Center, and professor of physical medicine and rehabilitation, College of Medicine, New York University.

Participants: Donald Cobalt, Ph.D., assistant director, Institute of Physical Medicine and Rehabilitation; George Deaver, M.D., in charge of the children's division, Institute of Physical Medicine and Rehabilitation.

are considered, and the possible development of the patient's capabilities is anticipated.

The institute designs many of its own prosthetic devices, some of them of an unusual nature. For example, for a man who had lost flexion of his fingers, a device consisting of straps of woven glass cloth impregnated with resin was designed. It fits over the back of his hand and over three fingers, permitting him to hold a pencil or a spoon or fork.

Dr. Cobalt pointed out that a wheelchair should be prescribed for a disabled or paraplegic patient just as carefully as a drug. The wheelchair should be planned to enable the patient to help himself to the greatest extent possible. One patient, a poliomyelitis victim, is now able not only to adjust his prosthetic devices without aid, but also to handle his demountable wheelchair. He can wheel himself to his car, get into the driver's seat, fold his chair, and bring it into the car after him.

In enabling people to live and work with what might seem to be insurmountable incapacity, the staff of the institute has the aid of nature itself, Rusk emphasized. Nature offers a tremendous overcompensation for physical defects as is shown by the blind, whose senses of smell and touch are greatly developed. Moreover, the conditions of civilization today are such that the average person needs to use only approximately 25 percent of his physical capacity, Rusk noted.

At the session, a number of current and former patients of the institute demonstrated their ability to handle prosthetic devices or to compensate otherwise for their disability. One was a 5-year-old boy recently arrived from La Paz, Bolivia, whose hands and feet are attached directly to the trunk of his body. A handsome, alert youngster, he has learned to move about by rolling like a tumbleweed, a technique that he happily demonstrated for the delegates to the World Health Organization. The institute is now developing devices whereby he will be able to walk upright, and other devices whereby he will be able to live normally.

Rusk asked the Vice President of Bolivia to consider the payment of a big fee for the institute's care of the boy: the establishment of rehabilitation centers in Bolivia where handi-

capped children can be retrained. The Vice President replied, "We will pay the fee."

Pharmaceutical Production

Pharmaceuticals are only as good and as safe as the quality controls used in their manufacture, Dr. Brady said in pointing out that such controls account for 10 to 15 percent of production costs for pharmaceuticals in this country.

The application of the controls and the techniques used in the production of antibiotics were observed by the visitors during a tour of the Pfizer laboratories prior to this session. Fully described during the laboratory and process demonstrations were all the steps in the development and production of an antibiotic, from the search for, and isolation of, promising micro-organisms used to produce these drugs, through the packaging of final products.

During the discussion, Dr. Weber pointed out that three factors influence quality and quantity in the production of antibiotics: the particular strain of micro-organism used; the type of nutrient medium; and the type of equipment used in the fermentation and concentration processes. Pharmaceutical manufacturers producing antibiotics are constantly working toward improvement in all these factors. Essentially, Weber added, antibiotics must be toxic to disease organisms, nontoxic and well tolerated by humans, and not too difficult to produce.

Gaunt expressed the hope that antibiotics that will be effective against virus infections

Chairman: Frederick J. Brady, M.D., assistant chief, Division of International Health, Public Health Service.

Participants: W. E. Gaunt, Ph.D., director of quality control, E. R. Equibb & Sons division of Olin Mathieson Chemical Corporation; W. Brooks Fortune, Ph.D., director, control division, Eli Lilly & Co.; E. M. Weber, Ph.D., director of biochemical research, Chas. Pfizer & Co., Inc.

and bacteria now resistant to known drugs will be found soon. Special research leading to these goals is in progress and is also part of the screening program for all new antibiotics.

The question of whether a specific country should build production facilities for the manufacture of pharmaceuticals or import them depends not alone on building factories but also on the availability of raw materials, transporta-

tion, highly skilled personnel, and a potential market of sufficient size to support large-scale mass production which will make possible a low price that the public can afford. The speakers pointed out that the high standards of pharmaceutical production in the United States depends on a successful balancing of these factors together with cooperation between manufacturers and governmental organizations.

Guests at Post-Assembly Technical Sessions

Dr. Abdul Zahir, *Afghanistan*; Dr. G. M. Redshaw, *Australia*; Dr. Josef Gratzner, *Austria*; Dr. P. Van de Calseyde, *Belgium*; Dr. Hernan V. Del Carpio, *Bolivia*; Dr. Raymundo A. Moniz de Aragao and Dr. Orlando Fontes, *Brazil*; Dr. Nealsmoeuk and Mrs. Nealsmoeuk, *Cambodia*; Urban Nelson, *Canada*; Dr. Don Lionel Joannes Kahawita; *Ceylon*.

Dr. Roberto Munoz Urrutia, Mrs. Roberto Munoz Urrutia, and Dr. Alfredo Riquelme, *Chile*; Dr. Joannes Frandsen, Dr. Oluf Andersen, and Dr. Bendt Sorensen, *Denmark*; Dr. Frederico Alvear-Perez, *Ecuador*; Dr. M. H. Aboul Ela, Dr. El Demerdache Ahmed, Dr. Mohamed Othman Shoib, Dr. Fathi A. Soliman, Dr. Nour El Dine Tarraf, and Dr. Hassan Saad Yusef, *Egypt*.

Dr. Richard E. Trail, *England*; Maurice B. Sedewilth, *France*; Dr. Otto Buurman, Dr. Otto Olsen, Dr. Fritz Bernhardt, and Prof. E. G. Nauck, *Germany*; Dr. Athanase Mantellos, *Greece*; Dr. Julius Sigurjonsson, *Iceland*; Lt. Col. C. K. Lakshmanan, Mrs. C. K. Lakshmanan, Dr. B. B. Dikshit, Dr. Vasant N. Panse, Mrs. Vasant N. Panse, Dr. Tara Chatterjee, Dr. Ganesh des Gothi, Dr. Balwant Singh Kohli, Dr. K. S. Ajit Prasad, and V. K. B. Pillai, *India*.

Dr. R. Mochtar, R. Tulay Waworuntu, Dr. Willy Hadisumarto, and Dr. Raden Roekmono, *Indonesia*; Dr. A. T. Diba, Dr. J. S. Saleh, Mohammad M. Goodarzi, and Dr. N. Ambarsumian-Melik Hacobian, *Iran*; Dr. Simon Btresh, Dr. Shabbetai Ginton, and Zeev Schor, *Israel*; Prof. Giovanni A. Canaperia, Dr. Raffaele Vannugli, and Dr. Maurizio M. Formica, *Italy*; Dr. Kiyoschi Saito and Dr. Kohei Toyokawa, *Japan*; Dr. Subhi Amin, *Jordan*.

Dr. Haing-in Paik, Dr. Chai Ho Ahn, Dr. Sook Bang, Dr. Nae Kwan Chsung, Dr. Chung Bin Chu, Dr. Hwa Young Chun, Dr. Chang Shin Kim, Dr. Do Yun Kim, Dr. Hyung Rin Kim, Dr. Pyung Ki Kim, Dr. Kook Hoon Ko, Dr. Myung Soo Lee, Dr. Pong Shik Lee, Dr. Samuel Y. Lee, Dr. Seung Hoon Lee,

Dr. Myoung Sun Moon, Dr. Soo Hyun Pai, Dr. Lee Gap Park, Dr. Myung Jin Park, Dr. Gyung Byung Roh, Dr. Hyun Jin Roh, Dr. Pil Soo Shin, Dr. Sun K. Song, and Dr. Kang No. Yoon, *Korea*.

Dr. Yousef Bauji, Mrs. Yousef Bauji, and Dr. S. Hayek, *Lebanon*; Fathi Abidia, Dr. Clement Noger, and Mrs. Clement Noger, *Libya*; Dr. Luis Cantellano, *Mexico*; Dr. Etienne Boeri and Mrs. Etienne Boeri, *Monaco*; Dr. Abdelmalek Faraj, *Morocco*; Dr. C. Van Den Berg, Prof. H. W. Julius, and Dr. N. A. Roozendaal, *Netherlands*.

Manuel Luna, *Peru*; Dr. Rafael Tumbokon, Mrs. Rafael Tumbokon, Dr. A. C. Regala, Dr. Gabino Balbin, and Dr. Josefina A. Nava, *Philippines*; Dr. Augusto de Silva Travassos, Mrs. A. de Silva Travassos, and Dr. Antonio de Carvalho Dias, *Portugal*.

Dr. D. Gerardo Clavero, Dr. Florencio Perez Gallardo, and Dr. Julio Bravo Sanfeliu, *Spain*; Dr. Ahmed Ali Zaki, *Sudan*; Dr. A. G. W. Engel, Dr. S. O. af Geijerstam, Dr. M. P. V. Tottie, and Dr. Bertil Roos, *Sweden*; Dr. R. Tarazi, Mrs. R. Tarazi, and Dr. Dia E. El-Chatti, *Syria*; Dr. J. Heng Liu and Dr. T. C. Kao, *Taiwan*.

Maj. Gen. Vibulcheep Boon-Long, Dr. Svasti Daengsvang, Dr. Charanpat Isarangkun, Dr. Sunitya Sinhabaedy, Dr. Songkram Supchareon, and Dr. Smarn Suwanrit, *Thailand*; Dr. T. Zaouche, M. Ahmed Balma, M. Rachid Azouz, and Dr. J. Daire, *Tunisia*; Dr. N. Karabuda and Dr. T. Alan, *Turkey*.

Dr. J. J. Du Pre Le Roux and Dr. F. W. Schulenburg, *Union of South Africa*; Dr. Victor Andres Belaunde, Dr. M. G. Candau, Philippe de Seynes, and Dr. Harry S. Gear, *United Nations*; Dr. Ricardo Cappeletti, *Uruguay*; Dr. Nguyen-van-Nguyen, *Vietnam*; Dr. Andrija Stampar and Dr. Joza Brilej, *Yugoslavia*.

| *United States technical assistance in Chile demonstrates how public health activities may merge with community or area development.*

Public Health in Chile

By E. ROSS JENNEY, M.D., M.P.H.

THE RIBBON of land that is Chile is a much more logically bounded nation than it appeared to be when we first noticed its odd shape in our school geographies. In spite of its bizarre stretch from the bleak deserts of the north to the wet forests of the south, it forms a true geographic unit in the sense that it is a terrace between the world's longest mountain wall on the east and the emptiest reach of ocean on the west. It is strikingly like our own west coast in reverse latitudes, and the similarity of the Chilean and California central valleys brings frequent comment. But, unlike our west coast, it lies very much alone, a narrow, walled-off strip of sovereignty.

Chile does not have, as does our west coast, the immense advantage of being a part of a huge nation stretching to the Atlantic, which can supply capital and markets. Nor has it had, from the founding of Santiago in 1541 down to recent years, the advantage of those cultural drives that in the United States blocked the transplanting of European feudalism. Landed

estates—the *fundos*—were carrying family names into the third colonial generation when the Pilgrims touched Plymouth Rock, and until 30 years ago no change of the *patrón-peón* relationship was in sight. This rigid land tenure system molded economic and social life for four centuries, but it failed to cope with the needs precipitated by an increasing population in the 20th century competitive world. Failure was cloaked for a time by rich mineral revenue, first from nitrates and then from copper, but the country's economic inadequacy was eventually reflected in constantly increasing food deficits.

Although a paradoxically progressive and unusually comprehensive social legislation has been spread over this scene, it was supported in its early days by export products largely developed by foreign capital. Much of the national income has been derived by negotiation abroad rather than by economic planning at home, a practice which perhaps has had the effect of stultifying the concepts of self-development. Between the remnants of Iberian feudalism and the beginning of trends toward socialism, planned community and area development had no sponsor. This situation may be a major key to the slow progress in environmental sanitation.

Health Priorities

In planning technical assistance in public health, the first priority for any area is always the major plagues that can be assailed with

Dr. Jenney was on assignment from early 1953 to early 1955 in Santiago, Chile, as chief of the health and sanitation field party of the Institute of Inter-American Affairs, Foreign Operations Administration. His current assignment has taken him to Rio de Janeiro, Brazil, where he is chief of the health, welfare, and housing field party of the IIAA, now a part of the new International Cooperation Administration, Department of State.

simple, effective techniques at small cost. Malaria and yaws have become classic examples. But where there are no such challenges, what then? What should we do in Chile, where no major scourges await penicillin or DDT? Here a literate, progressive, democratic, white population of 6 million people live in a favorable climate. There are no cultural blockades to hamper health measures. Indeed, highly trained Chilean technicians are drawing foreign students to their country, and many are serving abroad as public health consultants. In such an environment, less developed only in the economic sense and not handicapped by any natural health hazards, the impelling need is to contribute some technique that does not degenerate into a mere operational convenience and a vehicle for dollar credits. The problem, then, is to determine priorities on the basis of public health's most significant impingement on the economic dilemma without losing the integrity of the program by actually departing from the field of public health.

The health problems of Chile are not those of geographic environment and insect vectors. The major factors in disease incidence are those commonly associated with economic stress in a rapidly growing, overcentralized, somewhat stratified white society living in a temperate climate. Medical care has produced a substantial decrease in the incidence of those diseases which yield to therapy or which can be controlled by immunization. Poor progress has been made in health situations which are best handled by community effort inspired by local civic enterprise, that is, in environmental sanitation, housing, and nutrition.

A Socioeconomic Problem

Excreta disposal methods and water sources in rural areas have improved little since the colonial period. Latrines are often placed over irrigation ditches, which are the usual source of domestic water. The plentiful underground water sources have scarcely been touched. Population increase is greatly exceeding housing construction, and this situation is aggravated by disorganized population shifts resulting from industrialization and urbanization. Mushroom shanty towns—the *callampas*—

This well provides the first underground water ever seen in Peumo. It was dug by the men of the household, and cement capping and pumps were bought on credit from the Servicio.

surround Santiago, Concepción, and many other cities. Recent agricultural deficits and inflationary prices have added to an existing dietary deficiency. A definitely low health standard in nutrition coupled with poor sanitation is reflected in the notably high infant mortality rate, which was 252 per 1,000 live births in 1936 and has only recently dropped below 150.

The health services of Chile are almost completely socialized. The huge Beneficencia system, which had taken over the health services once provided by the church, was absorbed by the new National Health Service in 1953. Thus, sick benefits, hospitals, medical service, and public health were centralized in one large federal agency employing more than 33,000 persons. Many years will be required to put this organization in working order in a decentralized pattern. In the major cities medical services and facilities are of a high order, al-

though seldom elaborate, but this standard drops rapidly to a low level in country districts and to a near nil in the remote areas. Among the latter are the desert towns of the north, where water may be sold by the liter, and the forest lands of the far south, where 100,000 people live on the remote shores of the world's most intricate labyrinth of inland waters.

To find a sound footing for technical assistance in public health in a socioeconomic milieu of this type is a severe challenge. In such a highly centralized population (nearly one-third live in Santiago), one can expect little help from urban interests in planning programs for rural areas, where the present need is greatest and where the future hope of the economy most likely rests.

The Health Servicio

The United States, through the Institute of Inter-American Affairs, has been providing technical assistance to Chile since 1943. As in other Latin American countries, the cooperative health program of the two governments is carried out through a Servicio, a special agency of the host government. During the first several years of the program, a commendable series of demonstrations was produced—complete health centers, sewage systems and disposal plants, rural and urban water systems, tuberculosis sanatoriums, strategic hospital construction and equipment projects, a building for a dried milk plant, assistance to the School of Public Health in Santiago, and others. Training of Chileans in health was an important part of these demonstrations, and more than a hundred trainees were sent to the United States. Although there can be no doubt as to the success of this period and although the projects have been turned over to the appropriate agency of the Chilean Government, the demonstrations, as such, soon reached their own limit of feasibility. An approach to more basic problems was sought.

In any economy there are gaps that need closing and bottlenecks that need widening, and some of these can be remedied in part with public health measures. When such a gap or bottleneck is identified and when the value of the remedial measure as a demonstration in relation to its cost is determined, a priority is es-

tablished. This approach is, to be sure, one that views technical assistance in public health as one aspect of economic betterment.

In Chile, rural sanitation and community self-sufficiency appeared to be the developmental gaps pertaining most directly to both the socioeconomic scene and to public health. Improvement in rural sanitation required control of excreta disposal and the tapping of underground water sources, the latter having an important bearing on agriculture as well as health. Development in community self-sufficiency required a plan to demonstrate the advantages of full utilization of local autonomy and to stimulate community initiative and sense of social responsibility. These objectives were combined by the health Servicio in a community development project in a rural area southwest of Santiago. This project, called the Peumo project after the town where the work is concentrated, was begun in 1951 with Dr. Theodore I. Gandy as chief of party.

The Peumo Project

The area from which a site for a community development project was selected includes about 3,750 square kilometers of land and has a population of nearly 150,000. A few hours' drive from Santiago, it provided both the prerequisite of representative rurality and the administrative advantage of being accessible to the Servicio headquarters. The area is a fertile one. Citrus fruit, avocados, olives, and rice were grown extensively, but practically no vegetables were raised for home consumption. Contaminated surface water was used by more than 90 percent of the population in and around Peumo, and sanitary disposal of excreta was almost nonexistent. The early effectiveness of educational techniques used in approaching these two problems permitted a rapid extension of the project into other fields, including agronomy, home economics, and housing construction. In the process of extension, the project spontaneously evolved into a community development program acquiring local acceptance and participation, step by step.

No effort was made to define sharply the categories of activity: they fell easily into the basic pattern of health education, sanitary engineer-

ing, agronomy, and self-help housing. Agronomy soon included all phases of home economics. Operation of the project was based in a local headquarters, which contained offices, workshops, warehouses, a guest house, and recreation facilities. Existing citizen committees were utilized, and new ones were created to facilitate local participation. The resident chief of the project was an engineer on the staff of the National Health Service.

The transfer of technically trained Chilean personnel from the urban centers to this rural area resulted in the project's staff becoming involved in a host of activities that were peripheral to the first intent—suggesting recreational devices, designing a market, and planning improvement of the local hospital, for example. The quick wit of the community in availing itself of this indigenous but previously unavailable talent suggests that at least one cause for the lack of development in rural communities stems from an urban concentration of specialized skills rather than from any local recalcitrancy to technical innovation, lack of aptitude, or obtuse “cultural obstacles.”

Similar experience in community development has been derived at San Felipe, where in 1947 Chilean authorities, with assistance from the Rockefeller Foundation, began a project in which agronomy was combined with health center activities. The home economics phase of the San Felipe project has been notably successful in securing local response.

The health education phase of the Peumo project was so effective that there has been a consistent backlog of orders for latrines, wells, and pumps. Latrines are made with concrete base and riser with a seat of the type conventionally used in flush toilets. The wooden house has a pressed-asbestos sheet roof. Wells are capped with concrete and are supplied with the kind of hand pump commonly used in rural areas in the United States. The property owner digs his own latrine pit and well, and he buys the latrines and imported pumps on credit. Deep wells are drilled for large farms and for small community water supplies. A pattern now emerging is for communities to raise all or part of the funds for development of a well and water system before they request assistance.

Sometimes the Chilean Ministry of Public Works cooperates in such projects.

The program in agronomy began with spraying, fertilization, and cultivation of orchards, thus winning acceptance by initial concentration on improving the yield of cash crops. From this beginning, it branched easily into the purchase of seed for home gardens, food preserving, and home economics in general, all carried out by women's clubs. In an area accustomed to importing vegetables, the savings made in the home budget were quickly appreciated. Farmers soon formed cooperatives for collective purchasing of agricultural supplies and equipment heretofore seen only on the large estates.

Cement-block machines are provided for the self-help housing program. A cooperative of families is divided into three groups, and each group pools its labor force to construct one house at a time. Woodworking machinery is made available to the cooperative, and all materials are supplied on credit, the cost being reimbursed in modest monthly payments.

The Peumo project demonstrated two important lessons that may be assumed to be generally applicable to Chilean rural life. The first of these is that the use of local participation in an attempt to introduce a single improvement may lead spontaneously to a more inclusive community development project in which short-term impact can be combined with long-term advantages. The second lesson is that a Chilean rural community is eager and able to achieve group action in response to proffered assistance, to mobilize its resources, and to produce solutions to community problems with technical guidance and modest credit. Success in this respect is facilitated by choosing a locally felt need for initial action and only later fulfilling the possibly more basic needs, the knowledge of which has been engendered by education. This approach is what Foster terms “taking advantage of the pragmatic nature of people,” 1 of 12 essentials he lists for community development (1).

Under other circumstances, the health Servicio might have considered reproducing the Peumo project in various locations throughout Chile to exploit the potential of this method of stimulating self-help. The disadvantage of this procedure would be that its success would

An agronomist explains how to grow vegetables among trees, as part of the Peumo project. Vegetables were formerly purchased from a distant town at high prices.

be dependent on the effectiveness of demonstrations arranged in a spotted distribution pattern. In a country 2,600 miles long, with valleys isolated from one another by a rugged terrain, the spread of even the most contagious idea is geographically handicapped. Instead, the health Servicio chose to take advantage of the opportunity to participate in an area development program initiated by the Ministry of Agriculture and the agricultural Servicio.

The Area Development Program

The plan for an area development program in Chile came into being in 1953. It evolved from the decision of the Ministry of Agriculture and the agricultural Servicio to concentrate their cooperative efforts in a large area of the country in order to produce a significant demonstration of methods which might correct the agricultural deficit so embarrassing to the national economy. Several national and international agencies are now participating in the program, which covers the three provinces of Maule, Ñuble, and Concepción in south central Chile, with a population of about 750,000. Although the agricultural phase has been in full swing for 2 years, the health Servicio has only recently joined the program.

This area development program, or Plan

Chillán, as it is called, offered an opportunity for integrating rural sanitation demonstrations with agricultural activities in a flourishing program sufficiently significant to attract national and international attention. With such integration, each community can sense the relation between its own efforts in health and the efforts of the area toward general economic betterment. The economic interdependence of health and agriculture can be demonstrated. This vitally important concept, it is felt, can be understood more readily through the medium of a large collective endeavor than through segmented programs located here and there.

The basic philosophy of the technical assistance program for public health in Chile, then, is this: A health project expanded into a community development program can carry improved technology to the community more effectively when it is devised as a partner in a team with agricultural and other activities. It can travel further into the national consciousness by this means than as an independent project. Even when a health project is very much a minor partner in a program, it is not in danger of losing its identity: on the contrary, it profits by its association with an endeavor that reaches national recognition and enjoys central government support.

Past experience has illustrated advantages of

integrated activity. In our own Tennessee Valley Authority enterprise, for example, each phase of the program, including health, achieved greater recognition through its association with TVA. In addition, the pooling of resources in a single economic objective draws host government ministries together and provides the opportunity for what may well be the greatest contribution of technical assistance, that is, the demonstration that integrated activity is a primary requisite of progress.

Summary

With a successful pilot project in community development behind it, the health Servicio in Chile is now directing its major effort toward giving rural people a stake in economic affairs by developing underground water and by stimulating concepts of community responsibility in health, as part of an area development program.

These priorities were not derived by attempting to round out a health service in all its branches. Rather, they evolved from an effort to find one or two negotiable, long-range concepts that most certainly and most directly would improve the economy and living standards through health channels.

At the same time, there is a growing conviction among workers in Chile that where health problems are part of a socioeconomic complex (as opposed to concise environmental problems yielding to specific technical methods) they can be solved most readily by incorporating health activities in a broad endeavor, such as an area development program.

Rehabilitation Gains

In the first year after enactment of the Vocational Rehabilitation Act of 1954, the State-Federal rehabilitation program has tooled up under the new law, adjusted to related legislation, and laid the foundation for the future, according to the Office of Vocational Rehabilitation, Department of Health, Education, and Welfare.

The new legislation is designed to bring about a progressive expansion in the vocational rehabilitation programs. Improved rehabilitation services, support of training courses and traineeships for badly needed rehabilitation workers, and special research or demonstration projects are making it possible to increase the number of handicapped workers returned to productive employment.

Approximately 58,000 disabled persons became gainful workers during fiscal 1955—an approximate increase of 2,000 over the preceding 12 months. Federal grants amounting to \$30 million are available for the basic support of State and Territorial vocational rehabilitation programs in 1956. An additional \$2.6 million, to be matched with State funds, is scheduled for use in expanding rehabilitation centers.

The related legislation is the Social Security Act of 1954 and the 1954 Medical Facilities Survey and Construction Act. The State agencies determine whether a handicapped person is eligible to have his period of disability eliminated from the calculation of his monthly social security benefits. They are also concerned with surveys and plans to determine the needs for construction of comprehensive rehabilitation facilities.

The Food and Drug Administration

—A Protector of Public Health—

By BRADSHAW MINTENER, LL.B.

ONE can hardly overestimate the importance of food, drugs, and cosmetics as a part of the human environment. Purity of these products is a health essential, yet any of the many thousands of products can deteriorate or be debased or contaminated in ways that will be injurious—even fatal—to the user. And, of course, any of them can be adulterated or mislabeled to serve the ends of deception and fraud.

Concern for health was largely responsible for the passage of the original Pure Food and Drugs Act of 1906. It had become known that poisonous preservatives and dyes were being used extensively in food products, that drug addiction was growing because of the unrestricted sale of remedies containing narcotics, and that a great many people were suffering tragic consequences because of their reliance on the claims being made in the labeling of widely advertised medicine. There is no doubt that the protection of health was and is the primary objective of our Federal food and drug laws, which will have their 50th anniversary in 1956.

The relation of drugs to health is direct and

obvious. The law requires them to be pure, fully potent, and labeled with adequate directions for safe and effective use. Food is required to be sound and wholesome, free of filth or harmful contaminants. Cosmetics, similarly, are required to be made from ingredients that are safe for use on the human body. Therapeutic devices must be labeled for their safe and effective use in treating diseases for which they are recommended. All these objectives are sought via the regulatory mechanism of prohibiting the shipment of misbranded or adulterated articles in interstate commerce.

In addition to the direct health importance of the foregoing requirements, the Federal Food, Drug, and Cosmetic Act imposes many requirements that have an indirect bearing on the health of the Nation. For example, it prohibits false and misleading claims on drugs which may lead the public to rely upon ineffective products rather than to seek competent medical care. Through food standards the law seeks to maintain the integrity of food so that consumers will get the nutritional values they have a right to expect. The enrichment of food under the law has made a decisive contribution to the elimination of deficiency diseases which once took thousands of lives every year.

Health violations—those which may be injurious to consumers—hold first place in the Food and Drug Administration's enforcement policy. Second are the sanitary violations, including those that may not be dangerous to

Mr. Mintener, assistant secretary for Federal-State relations, Department of Health, Education, and Welfare, delivered the address on which this paper is based at the 73d annual convention of the Proprietary Association held in White Sulphur Springs, W. Va., May 24, 1955.

health but offend common decency. Third are the economic violations—the marketing of products that cheat or swindle the consumer in some way, particularly products that cannot be detected by the reasonably alert purchaser.

While priority is given to those problems and cases involving health, there is an inevitable overlapping of these three fields of action. A sanitary violation may be a health violation. An economic violation, such as the substitution of an inferior or worthless ingredient in a food or drug, may also be a health violation. FDA inspectors are trained to work on all three. An inspector who is working on a suspected health violation will not overlook what he may find in the way of a filth violation or a serious economic violation. Sometimes the same product may violate in all three respects. For example, in the enforcement of the standards for cheese promulgated under section 401 of the act, the Food and Drug Administration is interested in this product from the following different standpoints:

Health—whether the manufacturer has met the requirements for using pasteurized milk or storing the cheese a sufficient length of time to cause the death of any pathogenic organisms which may be present.

Sanitation—whether the cheese was made from clean milk or cream in a sanitary plant. This has its obvious relation to health.

Economic—whether the product has been made from the ingredients required to be used in that particular kind of cheese and contains the minimum fat content and not more than the maximum moisture content permitted by the standards. Such requirements can be tremendously important in preventing the debasement of food in order to gain an economic advantage.

In the past there have been various proposals to split up the work of the Food and Drug Administration among other Government units according to functions or to products. Actually the present arrangement is much more efficient because one inspector ordinarily handles all of these different kinds of work and is not concerned entirely with food, or with sanitation, or with economic frauds. He works on all of them, but of course health comes first. Due to limitations of funds and staff, FDA now does very little by way of enforcing the law against

economic violations, and it has had to reduce somewhat its work against sanitary violations. It is trying to maintain full protection against health violations, but even in this area there are some activities which should be strengthened.

The Food Field

What are some of the specific health activities carried on by the Food and Drug Administration in the food field? At the top of the list would be the efforts to prevent the use of poisonous or deleterious ingredients and contamination by dangerous micro-organisms. A few years ago the alertness of an FDA inspector prevented the shipment of a large lot of frozen peaches to which thiourea had been added to retard darkening. Thiourea is an acutely toxic chemical, capable of causing death.

On numerous occasions food and drug inspectors visiting food plants have spotted careless use of sodium fluoracetate (compound 1080). When used properly this compound is a very effective rodenticide, almost instantly fatal in extremely small amounts. Of course, it should be used only in locations where there cannot be any possibility of spillage on stored food products. Last fall thousands of pounds of frozen broccoli were voluntarily destroyed by packers after the inspectors found that several farmers had sprayed their fields with the wrong insecticide.

During a recent inspection of a plant making frozen chicken pies the FDA man found in the cold storage room a large number of pies that had soured due to accidental delay between making and freezing. None of the pies had been distributed, and the owner voluntarily destroyed the lot when he learned of their condition. Many people could have been made seriously ill if these pies had left the plant.

In the poultry and rabbit program the Food and Drug Administration is concerned with keeping diseased poultry and rabbits out of food channels. As a matter of fact, in all of the food programs, the agency is concerned with possible routes of contamination and hence possible vectors of infection as well as the adequacy of processing to prevent both the transmission of disease organisms and spoilage of the food which might cause illness.

Somewhat closer to the interests of the proprietary drug industry is the program of checking on the enrichment of staple foods with vitamins and minerals to insure that these foods contain the full amount of these essential food elements. Also there is the dietary food program designed to insure adequate labeling of these foods to protect the health of diabetics, hypertensives, and others with special dietary requirements. Recent labeling regulations for low sodium foods and the vitamin testing activities carried on by the Division of Nutrition illustrate the health significance of the work done in this area.

The basic requirements of the Federal Food, Drug, and Cosmetic Act with respect to drugs may be summarized as safety, effectiveness, and correct labeling. Obviously, these are closely related to each other. Safety means safety for use according to the directions given on the label or recommended to the physician. Efficacy means effectiveness for the conditions for which the drug is offered or recommended. Obviously, a drug which lacks the potency declared on its label, or is otherwise ineffective, may be unsafe, particularly if used for serious illness.

One of our serious public health problems is reliance upon ineffective remedies and treatments promoted by quacks and charlatans, some of whom masquerade as scientific authorities. The Food and Drug Administration can deal with only one aspect of this broad problem by enforcing the law against interstate shipment of quack remedies and worthless devices.

The Drug Field

Some of the many programs in the drug field are concerned especially with the adequacy of controls over the compounding and labeling of drugs. The wrong ingredient or the wrong label can have disastrous consequences. So can the accidental contamination of drugs or the lack of sterility in products whose use requires them to be sterile. Sometimes in the interest of public health and safety it becomes necessary to clear the market of a drug that is dangerous because it is defective or misbranded. During the past fiscal year there were 32 such episodes. In all of these, fortunately, the records of the

manufacturer were found adequate to trace all shipments, and it was not necessary to issue public warnings. In most instances the drug firms themselves were the first to notify the Food and Drug Administration when adverse reports were received regarding one of their products.

The law, of course, contains the multiple seizure provision in section 304(a) which enables the Government to remove from the market products which the courts have found to be adulterated or misbranded or, as the law says, "when the Secretary has probable cause to believe . . . that the misbranded article is dangerous to health, or that the labeling of the misbranded article is fraudulent, or would be in a material respect misleading to the injury or damage of the purchaser or consumer." This section is obviously of great importance from a public health standpoint since it enables the Government to act effectively when the shipper of the goods is unwilling or unable to correct a violation.

Distribution of new drugs before their safety has been established pursuant to section 505 is an offense that is rarely encountered. When it is considered that the ten-thousandth new drug application became effective in June 1955, it is clear that the last 15 years have seen an outstanding advance not only in medical research but also in drug regulation for the protection of public health. It is particularly fortunate that many high-powered therapeutic agents discovered during this miracle drug era have been restricted to use under medical supervision. At the same time as experience is gained, it is found that some of these new drugs can be safely used by the layman. When that is the case the law requires that such drugs be labeled with adequate directions for such use. Recently, a definite procedure has been established for making this change in the status of a new drug. This regulation provides for public notice of such changes, allowing an opportunity for interested persons to state their views regarding the proposed change.

Among many other health responsibilities is the testing and certification of coal-tar colors to insure their harmlessness and suitability for use in food, drugs, and cosmetics. The testing and certification of insulin is vital to health because of the necessity for precise dosage in the use of this drug.

Antibiotic drugs, which are administered to millions of persons for prevention or treatment of serious diseases, are likewise tested and certified by the Food and Drug Administration, thus guaranteeing to manufacturer, physician, and patient that they were safe and fully effective when they left the manufacturer's establishment.

There is the sampling and testing of such therapeutic devices as surgical sutures for required tensile strength and clinical thermometers for correct readings.

The cosmetic program is directed primarily toward protection of health. FDA investigates particularly cosmetics which may be dangerous—those containing new ingredients, the safety of which may not be fully established, or those misbranded by seriously misleading claims.

Then there is the enforcement program against the illegal sale of prescription-legend drugs by pharmacists and others, especially such habit-forming and dangerous drugs as the barbiturates and amphetamines.

Enforcement of the Caustic Poison Act is another of FDA's health responsibilities. The poison label and antidotes on certain household chemicals have helped greatly to reduce the toll of injuries and accidental deaths of children. I have been glad to learn of the interest the proprietary industry is taking in educating the public against carelessness in the use and storage of common household remedies. Many people seem to be oversold regarding the complete safety of some of these products, and they leave them where they can be readily sampled by young children.

New Problems

This discussion would not be complete without consideration of new health problems involving foods and drugs. Some of these are with us now. Others loom on the horizon and must be anticipated by study on the part of both Government and industry.

Only a few weeks ago several thousand commercial packages of foods were exposed to an atomic explosion at the Nevada proving grounds. Similar tests on drugs have already been made and reported. The tests are made,

of course, to learn what protection is provided by packaging and other factors against radioactive contamination. FDA already has considerable experience in this field and is conducting a series of training courses for State and local health workers to prepare them for their responsibilities in this area of civil defense.

An FDA Food Industry Advisory Committee, named by the National Research Council, is collaborating in studies of the vulnerability of food-processing plants to atomic, chemical, and bacterial warfare attack, and likewise of the decontamination measures needed in the event of such attack.

But civil defense is not FDA's only concern with regard to atomic energy. Radioactive drugs are becoming of increasing importance, and the radiation sterilization of foods is now the subject of intensive research by other Government and private organizations. FDA is not as active in this general area as it should be considering its health responsibilities. Similarly, such new developments as the increasing employment of hormones and other potent drugs in livestock feeds, the increasing use of chemical additives in commercial food processing, and the proposed use of antibiotics as food preservatives demand that FDA's research facilities be expanded so that adequate attention will be given to the health side of these new developments.

We cannot consider the health responsibilities of the Food and Drug Administration without being impressed by the tremendous size of the job which this organization tries to accomplish. And when we consider the size of the organization—around 800 people working on enforcement operations, about 200 of them available for inspection work—we wonder how they do it. The fact is, of course, that they have been able to do only a partial job. For example, in 1954 they were able to inspect about 10 percent of the approximately 96,000 plants and warehouses which do a substantial interstate business in food, drugs, or cosmetics. At that rate each plant would be inspected about once in 10 years.

This obvious discrepancy between the size of the job and the facilities for the job led to the appointment of the Citizens Advisory Committee on the Food and Drug Administration.

This committee of 14 distinguished, public-spirited citizens, financed by a special appropriation of Congress, has made a thorough investigation.

Based on its findings, the committee has recommended a substantial increase in the facilities and staff of the Food and Drug Administration to be accomplished in a period of 5 to 10 years.

The committee also recommended much greater emphasis on use of the techniques of trade and public education to accomplish the objectives of the law. For example, it recommended action to inform the public in specific terms against quackery, especially where real hazard to health is involved. To promote

understanding of the prescription requirements of the law, the committee recommended that more effective means be found for educating physicians and pharmacists concerning these requirements and for developing mutual understanding between them and the public. Finally, it recommended increased representation of the Food and Drug Administration at meetings of State and local food and drug or health officials.

If these and other recommendations of the citizens committee can be carried out, I am sure there will be better understanding of the role of the Food and Drug Administration as a public health agency and better cooperation by all who are concerned about the effective enforcement of our pure food and drug laws.

Poliomyelitis Vaccination Assistance Funds

Funds have been allotted to each State under the \$30 million Poliomyelitis Vaccination Assistance Act signed by President Eisenhower August 12, 1955.

The law apportions the money in accordance with a formula which considers the number of unvaccinated children under age 20 and expectant mothers in each State, the relative per capita income of the State, and the per capita cost of vaccine. Of the \$30 million appropriated by Congress, \$25 million is available only for the purchase of vaccine, and \$5 million may

be used for the costs of planning and conducting poliomyelitis immunization programs or for the purchase of vaccine. The funds are to be used by February 15, 1956.

While the vaccine may be administered by private physicians and by nonprofit organizations as well as by public agencies, the law provides that in vaccination programs conducted by public agencies no "means test" may be used to limit eligibility. Persons who are under 20 or are pregnant are eligible.

New Home for Communicable Disease Center

By THEODORE J. BAUER, M.D.

NEW headquarters for the Public Health Service Communicable Disease Center has been authorized by Congress, and construction is expected to begin as soon as financing and construction bids are approved. Site of the new facilities is a 14-acre plot donated by Emory University and located adjacent to its campus in suburban Atlanta, Ga. The headquarters will consist of six separate buildings grouped together and interconnected.

The Communicable Disease Center is a division of the Bureau of State Services. CDC attacks the problem of communicable diseases by conducting investigations and demonstrations, providing training, offering consultation, and giving epidemic and disaster aid to State and local health departments. The center came into being in 1946 when its predecessor, the Office of Malaria Control in War Areas (MCWA), was terminated following the close of World War II.

MCWA began its malaria control activities on March 17, 1942, from headquarters in At-

lanta. During its first year, projects were under way, employing more than 2,600 men in 93 areas in 15 States, the District of Columbia, and Puerto Rico. These projects benefited 450 war establishments, including military, industrial, housing, and recreational installations, and afforded protection to several million persons connected with the war effort. In early 1946, MCWA launched an extended program, with a budget of \$12 million and a staff of 4,500 persons.

Housing for MCWA activities was temporary and scattered. Office space was at a premium in the early days of the war. As the organization grew, so did its demand for additional space. Temporary and makeshift facilities did not pose an insurmountable problem for a wartime organization concerned primarily with field operations. However, with the transition to CDC's broad communicable disease control program, the need for space to house laboratory, training, and other pertinent activities became acute. The number of technical and laboratory personnel had increased steadily, while the number of unskilled and skilled laborers and other nontechnical personnel had declined sharply.

The new headquarters will provide the facili-

Dr. Bauer is chief of the Communicable Disease Center, Public Health Service, Atlanta, Ga.

ties needed. In the main building, ① in the sketch, with a net area of 105,014 square feet, a broad peripheral area devoted to office space will rise 5 stories high, while the central portion which it bounds will be 4 stories high. The outer area will provide space for training facilities and for personnel who perform administrative and other services essential to support of the operating branches; the central area is to house research and training laboratories. The training facilities will consist primarily of lecture rooms and demonstration laboratories to be located back to back with a projection booth between. Lounge-reading rooms in this area will be readily accessible for use by all lecture and laboratory groups.

The auditorium and cafeteria, ②, will be in a 2-floor building designed to provide facilities convenient for both employees and visitors to the center. The auditorium will be adequate for large classes and conferences, and the cafeteria will offer accommodations for the regular staff, as well as for trainees and guests. In addition,

there will be a lobby, a kitchen, and a service area. The net area for this structure is to be 7,482 feet.

The audiovisual services buildings, ③, will be a 4-floor structure designed to accommodate the specialized equipment and operational processes used in the production and distribution of motion pictures, filmstrips, exhibits, and other visual or audio materials. This building will house a sound stage for indoor production; a soundproof recording room, and a photomicrographic studio protected against vibration; facilities for film processing, printing, and editing; a film distribution center; and a training area with adequate flexibility to meet the increasing demand for training in the production and utilization of films. Total area of the audiovisual services building is to be 25,407 square feet.

It was imperative to plan for space apart from the main building where studies requiring the handling of highly infectious materials could be pursued. Two buildings, ④ and ⑤,

were designed to meet this need: the virus building and the infectious disease building. Each is planned to provide maximum safety for workers within the building and to minimize the potential hazard to others at CDC.

The infectious disease building, to contain 5 floors, will be situated apart from the main building but connected to it by open corridors at each floor level. It is designed to house laboratories for studies on infectious diseases other than viral and to provide quarters for experimental animals required in this work. Here, also, special studies on potential agents of biological warfare will be conducted. A net total of 14,836 square feet of space is provided for laboratories, 7,255 square feet for animal quarters, and 5,246 square feet for central services.

The virus building will be a 5-floor structure also, and is designed to house the bulk of the Virus and Rickettsia Section laboratory activities including reference diagnostic work, training, consultation, and methodology research. It provides a net total of 27,937 square feet of space for these activities.

The power house, ⑥, will be located apart from the other five buildings. It will house a gas-fueled central heating system and equipment to provide hot water, distilled water, com-

pressed air, and refrigeration. Its 2 floors will contain a gross area of 10,580 square feet. Storage will be provided for a supply of oil to be used in case of temporary failure of the gas supply and for electrical generators as a source of power in case of failure in the regular supply.

All of the buildings will be air conditioned, and adequate parking space on the grounds will be provided for employees and visitors.

Utilization of space in the buildings has been planned to meet the need for versatility posed by varied activities associated with communicable disease control. Animal space and much of the office space can be converted for use as laboratories if necessary. The buildings can be expanded without disruption of activities. This includes vertical extension of the central laboratory portion in the main building and the addition of an office wing.

The construction of these buildings will allow the CDC, for the first time, to assemble its headquarters activities at one location. Now they are located in some 65 buildings in Atlanta and Chamblee, Ga., and at Montgomery, Ala. Many of these buildings are temporary structures, unsuitable for laboratory work, and expensive to maintain.

Air Pollution Control Act

An Air Pollution Control Act, approved by the President July 14, 1955, provides for a 5-year \$25 million Federal aid program in this field.

The law also authorizes an annual appropriation of \$5 million to the Department of Health, Education, and Welfare for administering the law and for grants-in-aid to State and local government air pollution control agencies and to other public and private agencies and individuals for research, training, and demonstration projects.

The provisions encompass the development of methods for eliminating or reducing air pollution, surveys of specific air pollution problems upon request of State or local air pollution control agencies and recommendations for their solution, and collection and dissemination of information useful in combating or preventing air pollution.

| *One of the youngest of the voluntary national health agencies, United Cerebral Palsy, is making a fight against the crippling condition that affects more than half a million people in the United States today.*

United Cerebral Palsy

—Its Growth and Present Status—

By GLIDDEN L. BROOKS, M.D., and ISIDORE ALTMAN, Ph.D.

CEREBRAL PALSY has been defined by Phelps as "comprising a group of conditions which affect the control of the voluntary motor system and which have their origin in lesions of various parts of the brain" (1). Among the more common clinical signs are lack of balance, awkward posture and gait, uncontrollable movements of the arms or legs, and impaired speech, hearing, and vision. At least half of all cases also suffer some degree of impairment of mental capacity. In addition, disturbances of perception may be present.

The nature and extent of the disability depend on the location and the extent of the damage to the brain. The damage may occur before, during, or after birth, or subsequently as the result of a head injury, encephalitis,

poisoning, or other brain-injuring situation. However, the great majority of the cerebral palsied sustain brain injury during the prenatal or paranatal period. Among the likely etiological factors are anoxia, brain hemorrhage, prematurity, blood incompatibility (Rh factor), and malformation of the brain.

The precise incidence and prevalence of cerebral palsy remain to be established. Estimates based on the few scattered surveys that have been made indicate that the prevalence rate is approximately 3 to 3.5 cases per 1,000 population and that there are about 570,000 cases in the United States today. The Children's Bureau has estimated that "somewhere in the neighborhood of 285,000 children under 21 in the United States in 1952 have cerebral palsy either from birth or as a result of subsequent brain damage" (2).

Cerebral palsy presents many more kinds of problems than just those of medical care. It presents special problems in the fields of education, psychology, vocational guidance and training, and recreation. Because of the involved relationships between parent and afflicted child, programs are also needed for family education and counseling. An added problem is the provision of transportation and

Dr. Brooks has been medical director of United Cerebral Palsy Associations since 1953. Prior to that, he was coordinator of hospital clinics and professor of hospital administration of the Graduate School of Public Health, University of Pittsburgh. Dr. Altman is assistant professor of biostatistics of the Graduate School and statistical consultant of United Cerebral Palsy.

its attendant costs, for many of these children could not otherwise be moved to and from their various activities.

The Associations

United Cerebral Palsy Associations, Inc., came into being in 1949. The reasons for its existence and for the existence of similar organizations have been ably expressed by Courville (3): "A new trend in the attack on disease, one introduced even before the beginning of World War II, is the association of lay and professional groups in an attempt to answer the questions posed by some particular disorder. The lay representatives owe their interest as a rule to the fact that some member of their own family is a victim of the disease in question. The professional groups are those whose special training or interests naturally incline them to its study. It is this common concern for the social as well as the medical effects of a given condition which unites the two groups in seeking a solution to the problem."

United Cerebral Palsy was founded through the efforts of parents of the cerebral palsied. On April 1, 1954, it had 356 affiliates, with affiliates in all States and the District of Columbia. It has grown, in terms of contributions from the public, from an organization with an initial income in 1950 of \$1,022,000 to one with an income in 1954 of \$8,242,000.

Autonomous Affiliates

The local affiliates are autonomous, raising their own funds and expending these funds as they see fit, except that 25 percent of their income is used for participation in the national program. It is they who assume the responsibility for seeing that services are provided for cerebral palsied persons who live in their communities. State offices have been established in a number of States mainly for the purpose of stimulating and coordinating local activity. These are supported by locally determined percentages of income, generally about 5 percent. The national office promotes the growth of the organization, provides specialists for advice and assistance to local affiliates in the development of services, fund raising, public relations, and

legislation, and fosters a research and training program through grants.

The objective of a local affiliate is to make certain that the needs of the cerebral palsied are being met. This means mobilization of community resources through financial support of agencies providing some of the services, seeking legislation for services that government should provide, case finding and evaluation of resources, and the actual establishment and operation of facilities where this is deemed the most effective means of providing services.

A Selected Local

Because United Cerebral Palsy is still a rapidly growing organization and because size and growth of program vary considerably from community to community, it is difficult to assess the success with which the objective just stated is being achieved. Instead of a nationwide examination, the activities of one of the older affiliates will be described as indicative of the trends in the development of affiliate programs.

The selected local United Cerebral Palsy agency made a total expenditure of \$70,000, in round figures, for services in the year ending June 30, 1954—\$24,000 for medical services, \$35,000 for education, \$5,000 for recreation, \$1,000 for parent education and counseling, and \$5,000 for transporting cerebral palsied persons to places where they could receive these services.

The medical program to which the affiliate contributed \$24,000 is administered by a children's hospital connected with an outstanding medical school. Its cerebral palsy unit provides screening for purposes of diagnosis and all the facilities and personnel necessary to speech, occupational, and physical therapy. During the year, 267 patients were served on an outpatient basis; of these, 129, or 48 percent, were under 5 years of age. It is important to successful prognosis that the child be brought to treatment as early as possible.

The funds for education were devoted largely to the maintenance of a nursery school, with 28 children, in the medical center mentioned above. The \$20,000 contributed by the affiliate made up a fifth of the nursery school's total budget. Another \$10,000 went for educational purposes in

a hospital devoted to the rehabilitation of handicapped children. The remaining \$5,000 helped to maintain an industrial school for crippled children, which last year had 43 cerebral palsied enrollees.

Recreational activities consist in bringing children to a center one day a week for games, art work, and even dancing. One of the notable achievements of this particular affiliate is the formation of a choral group made up of cerebral palsied adults. Other affiliates contribute to the general support of summer day camps and residential camps or meet the costs for a number of cases.

Parents meet at bimonthly intervals to hear authorities speak on various aspects of cerebral palsy. In addition, individual counseling is provided on social and health development of the child and on such specific problems as feeding, dressing, and exercising. The parents themselves contribute a considerable amount of voluntary services in raising funds, furnishing transportation, taking the children on outings, and the like.

While this local organization incurred no expenditures for services of a vocational nature, cerebral palsied adults have been placed in employment or for training through consultation with rehabilitation agencies and workshops in the community. A number of affiliates of United Cerebral Palsy maintain sheltered workshops where training and jobs are provided to fit the capacities of the handicapped individual, while other affiliates provide counseling or offer vocational services.

Thus, the affiliates of United Cerebral Palsy make a contribution to public health progress through the active support of diagnostic and treatment centers and other services to alleviate a handicapping condition which is costly to the community, both economically and socially. They make a further contribution through support of a research program which seeks to find the causes of cerebral palsy and thereby to prevent it.

The National Office

The function of promoting research and the training of professional personnel, on the whole, is vested in the national office. The

method followed in making research grants is patterned for the most part after the system developed by the National Institutes of Health. Applicants for grants must have a university affiliation or be connected with some other responsible and recognized institution to which the money is actually paid. Applications are received and rated by a research advisory board made up of distinguished neurologists, surgeons, pediatricians, and specialists in other fields related to cerebral palsy. A medical executive board reviews the recommendations of this and other advisory boards and makes final recommendations to the lay governing body. Up to September 30, 1954, United Cerebral Palsy has spent almost \$1,400,000 for its research and training program.

To date, the emphasis of this program has been mainly on basic neurological research, oriented toward the goal of prevention. The number of grants made for research into problems of education, social development and adjustment, and mental status is expected to increase. Research projects currently under way fall into five broad groups of studies:

1. The physical structure of the normal and damaged brain.
2. The chemical structure of the normal and damaged brain.
3. The function of the normal and damaged brain.
4. Causes of brain damage.
5. The nature and characteristics of the cerebral palsied.

The training program consists of (a) direct grants to the American Physical Therapy Association and the American Occupational Therapy Association for training recruits in their respective fields; (b) summer workshops for teachers and therapists at eight colleges and universities; (c) fellowships for dentists and dental hygienists; (d) support of postgraduate courses for therapists; and (e) miscellaneous training programs.

The program division of the national office, which is charged with developing principles of program services and with general supervision of the research and training grants, carries on active liaison with other national agencies in such related fields as public health, education, and rehabilitation. It is represented on com-

mittees and boards of the National Health Council, American Public Health Association, International Council for Retarded Children, American Occupational Therapy Association, and other similar organizations. United Cerebral Palsy recognizes full well that it will take the concerted efforts of many national agencies, in cooperation with government, to conquer the disorder in which it is particularly interested.

One of a Group

United Cerebral Palsy is now one of a group of prominent voluntary national health agencies which perform an important function in public health. By concentrating on a single disorder or group of disorders, these associations can provide or support a high level of service and bend special efforts toward ultimate eradication. In the community, they bring together a devoted group of lay and professional people in a dedicated cause.

As for cerebral palsy specifically, Surgeon General Scheele, in addressing the 1954 convention of United Cerebral Palsy, had this to say: "It is an old public health axiom, proved seventy times seven, that however massive and complex a problem may be, it will eventually be

solved by attacking its various elements one by one. The success of the attack depends upon the breaking down of the broad problem into a series of research problems and solving them. This approach is especially valuable in the attack on cerebral palsy . . .

"The idea of preventing a large share of the cases of cerebral palsy now occurring each year may seem like a dream. But I believe that it is a distinct possibility. I believe too that medical research is on the threshold of other important discoveries that will greatly improve the status of many victims of cerebral palsy. Only through persistent research effort in the many specific areas of cause and prevention, treatment and rehabilitation can we truly vanquish this enemy that causes so much heart-break and suffering."

Scholarships in Cancer Research

The National Research Council's Committee on Growth is accepting applications for American Cancer Society grants to assist young scientists during the critical early period of their careers in cancer research.

Awards are made for 3-year periods at \$6,000 annually with possible renewal for 2 additional years. Applications should be submitted by institutions on behalf of candidates not later than January 1, 1956. Forms and information may be obtained from the Executive Secretary, Committee on Growth, National Academy of Sciences-National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D. C.

Occurrence of Influenza July 1954 to June 1955

BY DORLAND J. DAVIS, M.D., DR.P.H.

SPECIFICALLY diagnosed influenza has been reported to the Influenza Information Center of the World Health Organization Influenza Study Program in the United States since 1948. This information comes from investigators and diagnostic laboratories located in universities, hospitals, and Federal and State agencies, including Army, Navy, and Air Force installations. The weekly summaries of these reports and those received from other countries are published in the Communicable Disease Summary of the National Office of Vital Statistics, Public Health Service, and distributed to health officials and interested research workers in the United States and other countries. As part of the worldwide effort sponsored by the World Health Organization, this program seeks to improve the reporting of influenza and the exchange of newly isolated strains of influenza virus for investigational purposes. The present communication will consider the experience in the United States in the period July 1954 to June 1955.

During the previous winter season, 1953-54, influenza was almost totally absent from the

United States and Western Europe. In the year before that, 1952-53, influenza A occurred in epidemic proportions in the United States, principally in the midwest and the south, with a small but noticeable concurrent increase in mortality rates. During the late winter of 1951-52, influenza B occurred widely in the United States in localized outbreaks with no appreciable fatality rate. In the season before that, 1950-51, there were epidemics of influenza A in the United States, particularly the northeastern part, which had been preceded by sharp outbreaks in England and Western Europe.

Influenza was reported during the winter months of this last year, 1954-55, in scattered areas of the United States, particularly the eastern seaboard, and was almost exclusively due to type B virus. The first suggestion of influenza came from New York State during the third week of December, with an outbreak of influenza-like respiratory disease in a school. During the first part of January, high rates of absenteeism due to illness were noted in junior and senior high schools in Washington, Norfolk, Boston, and other cities of the eastern seaboard. The clinical features of the illness were of short duration and resembled influenza. Virus isolation and serologic studies later showed that many, if not the major proportion of cases, were due to influenza B.

The first reported isolation of influenza B virus in the country was from an unvaccinated patient at the Great Lakes Naval Training Station, Ill., whose onset occurred during the last week of December. This strain was antigenically similar to the strain recovered the previous year at the same installation. Influenza B continued during January in the eastern part of the country, and scattered reports of localized outbreaks were received from the midwest. In military installations, the rate of respiratory diseases remained relatively low, but cases of influenza, principally type B, were diagnosed serologically and by virus isolation at a number of posts throughout the United

Dr. Davis is executive secretary of the Influenza Information Center, WHO Influenza Study Program in the United States. National Institutes of Health, Bethesda, Md. He is also chief of the Laboratory of Infectious Diseases, National Microbiological Institute of the Public Health Service. In the December 1954 issue of Public Health Reports, Dr. Davis discussed the occurrence of influenza for the period July 1953 to June 1954.

Specimens for Influenza Diagnosis

The specific diagnosis of influenza type A, B, or C can be made only by laboratory examination.

The laboratories collaborating in the Influenza Study Program have facilities for specific diagnosis. Their locations may be obtained from State and Territorial health departments or from the Influenza Information Center, National Institutes of Health, Bethesda 14, Md.

The two most commonly used methods are specific isolation of the virus and demonstration of a rise in specific antibody by the hemagglutination inhibition test or the complement fixation test.

Samples for virus isolation should be obtained as early as possible in the acute phase of illness by collecting throat washings or throat swabs in a small amount of sterile bacteriological broth, skim milk, or serum-saline solution. These samples should be frozen at low temperatures unless taken to the laboratory within a few hours.

Two consecutive serum samples (drawn from a minimum of 5 cc. of blood) are necessary for serologic diagnosis. Single samples are of no value. The first sample should be taken as early as possible during the illness and the second about 14 days after onset. Separate serum is desirable. Clotted whole blood may be forwarded if time of transit is short, but it must not be frozen.

All such specimens should be sent to the nearest collaborating laboratory.

States. Influenza vaccine had been administered routinely to all military personnel early in the winter season.

In early February, reports continued of outbreaks, particularly among junior and senior high school students, and a number of colleges reported high incidence of respiratory illness, which later was shown to be due to influenza B virus. The disease was reported in Maine, Michigan, the southwestern States, California, and Oregon, and must be presumed to have occurred in many other States. In some areas such as Michigan, isolated cases of influenza B were diagnosed without the recognized occurrence of sharp outbreaks during this same period. Although in most areas of the country the incidence declined in the latter part of

February, cases continued to be diagnosed in some areas, including California, during March, April, and May.

For the first time in 2 years, influenza A virus was recovered from a patient in a New York State institution, with onset on March 1. Shortly thereafter, influenza A virus was also recovered in another institution in New York, and complement fixation tests on paired serums identified three other cases of influenza A in the same institution, having onsets in the middle of March. In April, additional cases of influenza A were diagnosed serologically in New York and California, and sporadically in military installations. No other isolations of influenza A virus were reported during the remainder of the July 1954-June 1955 period.

Influenza C was recognized serologically in areas where special effort was made to diagnose it, and one isolation was reported, but there was no evidence that it was a cause of epidemic respiratory disease.

Isolations of influenza virus and positive diagnostic serologic tests (any technique) reported by civilian and military laboratories participating, continental United States and Alaska

Month and year	Isolation of virus, type			Positive serologic tests, type		
	A	B	C	A	B	C
1954						
December-----	0	1	0	2	38	6
1955						
January-----	0	83	0	9	100	4
February-----	0	68	1	14	108	3
March-----	3	9	0	12	121	3
April-----	0	0	0	7	33	4
Total-----	3	161	1	44	400	20

The table shows a total of 629 reports of both virus isolations and serologic diagnoses of influenza from all the cooperating laboratories, including military laboratories, and gives a rough indication of the prevalence of the disease in the winter months. A total of 161 strains of influenza B, 3 strains of influenza A, and 1 strain of influenza C were isolated, and 400 positive diagnostic serologic tests for influenza B, 44 positive serologic tests for influenza

A, and 20 positive serologic tests for influenza C were reported.

Reports from the World Health Organization Headquarters, Geneva, the Canadian WHO Influenza Information Center, and from the World Influenza Center, London, indicated that influenza B began to occur sporadically in northern England and Wales in November and continued during December and January. In January, influenza B outbreaks were occurring in Canada, northern Holland, and later in the month, in Germany and Yugoslavia. As in the United States, the disease attacked principally school children. In February, WHO reports indicated continued outbreaks of influenza B in Europe, including Finland, and in different parts of Japan, particularly Tokyo. In March and April, influenza A infections were recognized serologically and by virus isolation in several widely separated areas of Great Britain, particularly southern Wales. It is of interest that the experience with influenza infections was similar in the United States, Canada, and Western Europe. Briefly, this was the occurrence of scattered outbreaks of influenza B, sometimes of considerable intensity, occurring chiefly among school children, beginning in the early winter and continuing

through February. In March, a few influenza A infections were recognized in both Great Britain and the United States, the first due to this type in 2 years.

Antigenic studies at several laboratories showed that the isolated strains of influenza B were similar to each other and very close to the B/GL/1/54 strain isolated in the Great Lakes Naval Training Station in March 1954. They differed somewhat from those isolated in 1950-52 and even more from the B/Lee strain of 1940. Preliminary antigenic analysis of the influenza A strains recovered in this country and Europe indicate general similarity to each other but also some variation from those recovered in previous years. Detailed studies are being undertaken to define more precisely the antigenic patterns of these recently recovered strains in the expectation that they may be important during the coming year.

Data collected by the National Office of Vital Statistics reveal that the number of deaths ascribed to influenza and pneumonia increased moderately in February, but most of this may be regarded as the usual seasonal increase in deaths from respiratory disease. The total mortality rate during the winter months was not noticeably increased.

Veterinarians' Entrance Salaries Raised

All Federal agencies were authorized last month to increase the starting salaries of grade GS-7 professional veterinarians from \$4,930 to \$5,200 annually. Veterinarians already employed at this grade will receive a minimum of \$5,200 a year.

The United States Civil Service Commission acted under legislation authorizing Federal recruitment at above minimum rates for particular jobs in areas in which the Federal Government is at a competitive disadvantage with private industry. The action became effective October 23, 1955.

Study by the Civil Service Commission revealed that \$5,200 a year more nearly approximates the salaries offered by non-Federal employers at the entrance level than the starting salary authorized by the Commission last June.

Effect of Topical Fluorides On Teeth Matured on Fluoride-Bearing Water

By DONALD J. GALAGAN, D.D.S., M.P.H.,
and JACK R. VERMILLION, B.S., M.P.H.

EARLIER STUDIES have been concerned with the effect of topically applied fluorides on dental caries experience in the permanent teeth of children in areas with fluoride-free water supplies (1-7). These investigations demonstrated that four applications of a 2-percent solution of sodium fluoride to the teeth of children not previously exposed to fluoride reduce the incidence of new caries in sound teeth by 40 percent.

The effect of topical fluoride therapy on teeth matured on fluoride-bearing water has not been thoroughly explored. There is a single report in the literature suggesting that topically applied fluorides do not influence caries experience in such teeth (8). Therefore, a study was designed to test further the caries inhibiting effectiveness of a 2-percent sodium fluoride solution applied directly to teeth of children continuously exposed to water having an optimum concentration of fluoride.

The study was conducted in Tucson, Ariz., from January 1953 to April 1954. The water supply in the southside section of Tucson contains 0.7 p.p.m. fluoride, an optimum concentration for the particular climatic and environmental conditions existing in south central

Arizona (9, 10). In the southside section there is a fairly large school population from which to draw continuous residents with a common history of exposure to fluoride-bearing water.

The application technique developed in earlier Public Health Service studies was used in this test (11). In alternate children, teeth in the right quadrants were treated four times with a 2-percent sodium fluoride solution after an initial prophylaxis. The teeth on the opposite side were given four applications of tap water at the same sitting. In the remaining children the teeth on the left side were treated with sodium fluoride, the control teeth with tap water. The children were examined just prior to treatment, and again 1 year later. The treated quadrants were not identified during either examination.

The study group consisted of 350 continuous resident children aged 7 to 16, and equally distributed by sex and age. At the end of the 1-year period, 282 students were available for re-examination. Of these, 142 had been treated on the left side of the mouth and 140 treated on the right side. The results of this study are based on analysis of these 282 children, whose age distribution follows.

Age	Number of children	Age	Number of children
7	10	12	33
8	39	13	30
9	38	14	15
10	44	15	22
11	47	16	4

A summary of the incremental dental caries during the study year is presented in the table. Ninety-two of the 2,342 noncarious treated teeth and 101 of the 2,324 noncarious untreated teeth became carious during the year. The observed difference shows a 9 percent lower caries incidence in the treated teeth. However, this difference is within the limits of chance variation and might have occurred had the children been given no treatment at all.

The data presented here neither confirm the

Dr. Galagan is assistant chief, Division of Dental Public Health, Public Health Service, and Mr. Vermillion is dental public health representative at the San Francisco office of the Service.

Dental caries experience during the study year in fluoride-treated and untreated permanent teeth and percent less new caries experience in fluoride-treated teeth of 282 school children in Tucson, Ariz.

Mouth quadrants	Noncarious teeth, April 1953	New carious teeth, April 1954	Percent less new caries experience in treated teeth
<i>Upper jaw</i>			
Treated.....	1, 207	48	7. 7
Untreated.....	1, 199	52	
<i>Lower jaw</i>			
Treated.....	1, 135	44	10. 2

previous finding (8) nor indicate that topical fluoride applications are effective when used on teeth matured on fluoride-bearing water, since the 9-percent reduction demonstrated may be attributable to chance variation. Further study of greater numbers of children is indicated before any conclusions can be drawn.

An unusually large number of children are required to demonstrate significant changes in caries experience in fluoride areas where caries activity is already low and the potential for caries prevention is small. It would be possible to demonstrate statistical significance of a 9-percent incremental difference between treated and untreated teeth if it were observed in a minimum of 2,900 Tucson children. It will be difficult to determine precisely the effect of topically applied fluorides on teeth matured on fluoride-bearing water until a fairly large community has had a fluoridated water supply for 15 years or longer.

Experience of Public Health Workers

By EDWARD M. COHART, M.D., WILLIAM R. WILLARD, M.D.,
and ERLEEN F. JAMISON, M.P.H.

• Few workers entered public health at the beginning of their careers. About one-fourth had had at least 10 years' experience in other fields before coming into public health. Most commonly such experience was in hospitals and related institutions and in business and industry.

• The most frequent determinants in the choice of a public health career were chance, personal contacts, and the inherent attraction of the work. Only 2 of 595 workers could attribute their choice of this career to formal vocational guidance.

• Laboratory personnel differed from other health department personnel in that a relatively high proportion of them entered public health fortuitously at the beginning of their careers.

• The average health department staff worker had spent 9.2 years in public health. Personnel at higher administrative levels had an average of 14.6 years of public health experience.

• High-echelon personnel felt, to a much greater extent than did staff personnel, that

opportunities to learn about administration and about the community had been their most valuable experiences. Staff personnel stressed opportunities for learning specific techniques.

• Salaries of high-echelon personnel tended to increase with years of experience, except in the medical and administration services. This did not hold true for staff personnel, among whom the worker with long experience not infrequently earned less than his less-experienced co-workers.

These were the findings of the study of the work experience of public health workers that was conducted in the course of the Yale Public Health Personnel Research Project. Such information is one of the foundations for a better understanding of the problems involved in the recruitment and efficient utilization of workers. The findings of the present study cannot be considered conclusive, but they do offer clues for further investigation. Moreover, the study served to demonstrate the application of the method evolved by the Yale project for obtaining knowledge of the public health worker and his job.

Detailed data from the study of work experience are presented in the following pages. The information was secured from more than 600 professional and semiprofessional workers in State and local health departments and visiting nurse associations in Connecticut, Maryland, Michigan, and New York. The sample and the method used were described in the May issue of *Public Health Reports*, pages 447-452.

Total Work Experience

Ninety percent of public health personnel in high administrative positions (supervisor and

Dr. Cohart and Dr. Willard, co-directors of the Yale Public Health Personnel Research Project, are, respectively, associate professor of public health, Yale University School of Medicine, and dean of the College of Medicine at Syracuse, State University of New York. Miss Jamison, a research assistant with the Yale project, has been consultant in maternal and child health, nursing division, Philadelphia Department of Public Health, since 1953. The Yale study was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

² Total percentages are only approximations, because the staff-level sample was not equally representative of all services.

higher rank) and 60 percent in staff positions (junior and senior staff) had had at least 10 years' total work experience (table 1). Half of the former and one-third of the latter had worked 20 years or longer.

Length of work experience did not differ materially for personnel in State and local health departments, nor did it differ significantly among the services for high-echelon personnel. At staff-level, however, the members of the laboratory service tended to have had less experience than personnel in the other services. Three-fifths of this group, as compared with one-third of the workers in the other services; had had less than 10 years' experience.

Experience Outside Public Health

A large proportion of the workers did not enter public health at the beginning of their

careers. Five-sixths of the personnel had worked in other fields (table 2). More than half had less than 10 years of such experience, and about 20 percent, 10 to 19 years. Less than 10 percent had had 20 or more years' experience before they entered public health. There was no essential difference between the workers in State and local agencies or between high-echelon and staff-level personnel in this respect, but

again the laboratory service differed from the other services. Forty-four percent of the high-echelon and 33 percent of the staff laboratory workers, as compared with 12 percent of the personnel in the other services, had worked only in public health.

Approximately 25 percent of the personnel had worked in other fields than public health for 10 years or longer. This percentage does not appear to be inordinately high in the light

of the general job mobility that prevails in the United States.

The contention that most physicians in public health enter the field after a long period of private practice is not borne out by this study. Only half of the physicians interviewed had been in private practice at any time during their careers. Only one-third had spent as long as 10 years in fields other than public health, and only 10 percent, as long as 20 years.

Hospitals and related institutions and business and industry were the most common areas in which public health personnel had worked (table 3). About 40 percent had been employed in each of these areas. One-half of the physicians and three-fourths of the nurses had been employed in hospitals. More than half of the workers in most of the other services had been employed in business or industry. One in every six workers had been employed by a Govern-

ment agency other than a health or welfare department, hospital, or school. One in seven had worked in a school, and a similar proportion in a college. Roughly, 5 percent had been employed by a welfare or social agency.

State and local personnel showed no major differences in past experience, but significant differences were found between high-echelon and staff workers. A larger proportion of staff than of high-echelon personnel had worked in business or industry, but the reverse was true in relation to previous employment in colleges.

Reason for Entering Public Health

The three most frequent determinants for entering public health were chance, personal contacts, and the attraction of the work (table 4). Each of these was given by slightly more than 20 percent of the workers. Less than this per-

centage gave favorable working conditions as their reason for entering public health. About 10 percent stated that they entered public health because of specific education and training for this career. Three other factors, namely, a "calling" to do public health work, political appointment, and the use of a public health job as a means of education or training for another career, played negligible roles.

Chance as a reason for entering public health requires no amplification. Those who gave attraction of the work as their reason for entering public health were expressing one of the two concepts: either that the content of public health work was inherently varied, challenging, and satisfying, or that the work provided opportunities for helping people. Of those who gave personal contacts as their reason for being in public health, the majority stated that these contacts were with public health workers. A small number stated that they entered public

health because of casual informal counseling, but only 2 of 595 workers could attribute their entry into public health to formal vocational guidance.

The most attractive aspect of working conditions in public health appeared to be the hours of work. One-quarter of those who gave working conditions as their reason for entering public health mentioned this factor specifically. Salary and job security were each mentioned by one-sixth of these workers.

Reasons for entering public health did not vary with either governmental or administrative level. The one outstanding difference among the services was that a greater proportion of laboratory workers than of personnel in the other services entered public health fortuitously. Whereas less than one-quarter of all public health workers came into the field by chance, chance accounted for the entry of two-fifths of the laboratory workers.

Public Health Experience

Sixty-three percent of the personnel in administrative positions and 33 percent of the staff had had 10 or more years' experience in public health (table 5). Thirty percent of the former and 15 percent of the latter had been engaged in public health for 20 years or longer. High-echelon personnel had spent an average of 14.6 years in public health; staff personnel, an average of 9.2 years. Except for the fact that more State (84 percent) than local (44 percent) sanitation personnel in the higher administrative echelons had been employed in public health for 10 years or more, there were no significant differences between State and local personnel. Neither were there significant differences among the services.

The number of years that the personnel had spent in their present agencies is to be found in table 6. Approximately one-third of all high-

echelon personnel had worked in their present agencies for less than 5 years; one-quarter, 5 to 9 years; another quarter, 10 to 19 years; and one-sixth, 20 years or longer. Roughly half of the staff personnel had been with their present agencies for less than 5 years; one-quarter, 5 to 9 years; one-sixth, 10 to 19 years; and one-tenth, 20 years or longer. There was only one significant difference between State and local personnel. Almost half of the high-echelon sanitation personnel in State health departments had worked for the same agency for 20 years or longer, but none of the high-echelon sanitation personnel in local health departments had had such experience.

Three-quarters of the high-echelon personnel in public health for 10 to 19 years had worked for the same agency for a like period of time; half of those with longer public health experience had spent at least 20 years in their present agency. The experience of staff personnel was

similar. Three-quarters of those with either 10 to 19, or 20 or more years' experience had worked for their present agency for comparable periods.

Most Valuable Experiences

The workers were questioned about the attributes of their total work experience which they considered most valuable, and 1 to 3 answers were obtained from each respondent. These were classified in seven categories, as follows: (a) knowledge and appreciation of the community, which covers comments concerning communities and their components in general, as well as specific communities, and techniques for working with community groups and individuals; (b) knowledge and appreciation of organization and administration, which covers all phases of management and supervision; (c) development of a philosophy of public health or government; (d) learning about

interpersonal relations and development of qualities of personality that would promote good relations; (e) learning specific technical procedures, including the techniques of communication; (f) learning about public health generally and about working in a public health organization; and (g) a residual category, which includes statements too general to be classified under any of the other categories.

Either because their past experiences had been different or because they viewed their past experiences differently, high-echelon and staff personnel differed as to what they considered most valuable (table 7). Approximately one-third of the former and one-fifth of the latter were impressed with the general learning opportunities that their experience had provided. The opportunities for learning about the community and for learning about administration were considered important by one-third of the personnel at the higher administrative levels but by only one-eighth of those at staff level.

Whereas 15 percent of high-echelon personnel felt that their past experience was particularly valuable because of the opportunities it afforded them to develop a philosophy of public health, only 3 percent of staff personnel gave this reason. One-third of the staff personnel, as compared to one-fifth of the personnel in higher positions, emphasized the opportunities for learning specific technical procedures as being particularly valuable. Only in regard to experience in interpersonal relations were the staff and higher administrative groups similar. One-fifth of each group felt that their past experience was unusually valuable because of

the experience it gave them in interpersonal relations.

There were also a number of striking differences among the services. Among high-echelon personnel, members of the laboratory service mentioned knowledge of the community infrequently. A relatively large proportion of medical personnel emphasized philosophy. A larger percentage of sanitation and laboratory personnel than of medical and nursing personnel stated that the opportunities in their past experience for learning specific technical procedures were especially valuable.

Among staff personnel, members of the medi-

cal and health education services emphasized the opportunities for learning about the community, but such opportunities seemed to be of relatively little importance for sanitation, laboratory, and statistics personnel. Relatively few physicians and nurses mentioned learning specific technical procedures as important.

Salary and Experience

Because of salary differentials associated with service, the relation of salary to public health experience was investigated for the several services separately, as shown in tables 8 and 9. The average salary of staff nurses was less than that of any other service group of staff workers. The staff physician earned more than twice as

much as staff workers in the other services. A relatively smaller differential existed between the salaries of staff and high-echelon personnel in the medical service than in the other services.

Except that a significantly larger proportion of State than of local nurses at the higher administrative levels earned \$4,000 a year or more, and that a significantly larger proportion of State than of local sanitation personnel at the higher administrative levels earned \$5,000 a year or more, there were no significant State-local differences. Inasmuch as 19 percent of the State nurses and 25 percent of the local nurses had had less than 10 years' experience in public health, the salary differential for nurses could not be attributed to quantitative differences in experience. The situation was different

for sanitation personnel, however. Only 15 percent of the sanitation workers in State agencies, as compared to 56 percent of those in local agencies, had had less than 10 years' experience in public health.

As can be seen in table 8, there is a tendency in all the services, except medical and administration, for higher salaries for high-echelon personnel to be associated with longer experience in public health.

Table 9 shows the distribution of staff-level workers in accordance with salary and duration of public health experience. An unexpected finding here is that salary does not increase with increased experience in public health. Actually, in more than half of the services, the staff worker with 20 years' or more experience in public health earns less than the less-experienced individual. This may indicate, of course, that workers who have remained in staff positions for this long period of time have less ability than their co-workers, since, despite their experience, they have been unable to advance in the administrative hierarchy, but there may be other explanations. Only through promotion to a higher rank can the staff worker in a public health agency hope to better his earnings materially.

Summary and Discussion

As a part of the Yale Public Health Personnel Research Project, data on work experience were obtained from more than 600 professional

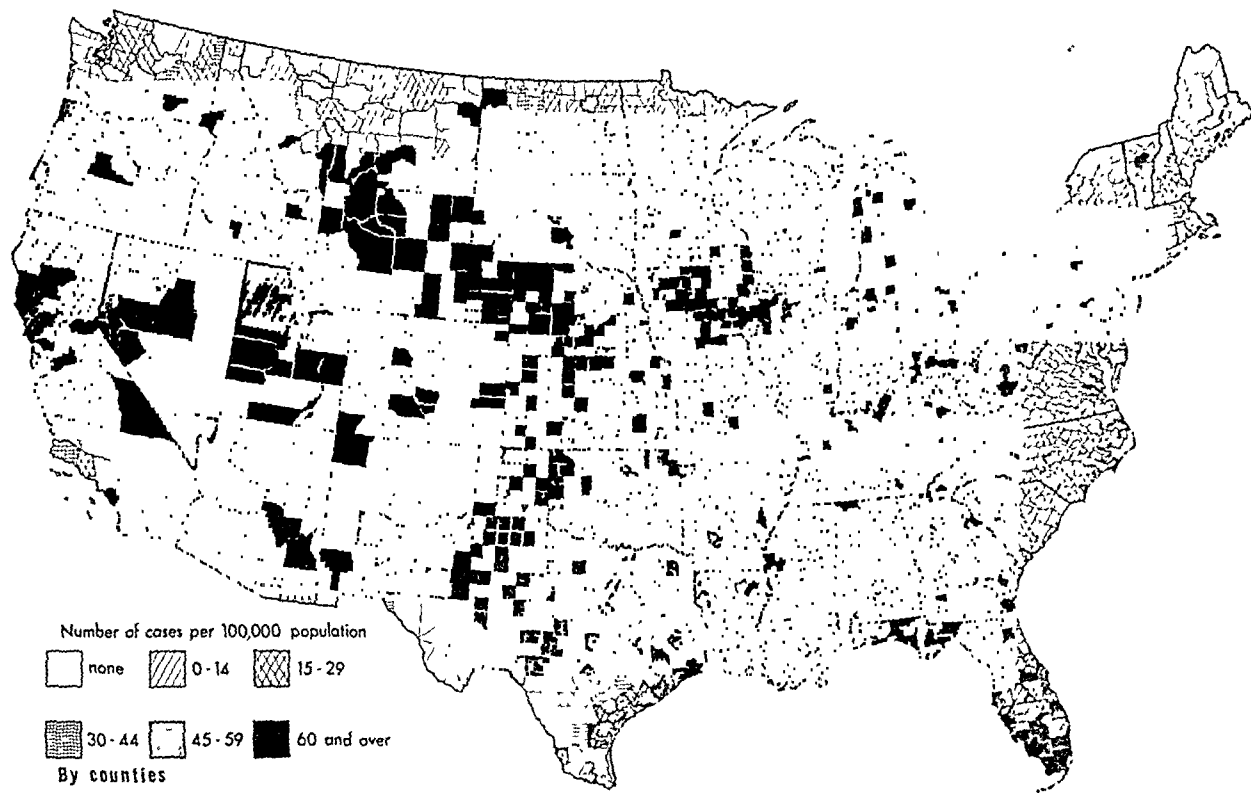

and semiprofessional personnel in State and local health departments and visiting nurse associations in 4 States. Although the data are not of a nature to permit firm conclusions concerning utilization and recruitment of personnel, they do bring to mind several questions that warrant consideration.

Perhaps the most important of the findings were those concerning when and how persons enter the field of public health. Few workers, it was found, entered the field at the beginning of their careers. Chance was one of the three most frequently given reasons for entering public health, whereas formal vocational counseling was mentioned by only 2 of 595 workers.

Can experience in fields other than public health contribute in a significant fashion to the success of the worker in his public health job? If so, public health administrators must make a conscious effort to make maximal use of the past experience of their workers. To what extent is this being done?

If, on the other hand, experience in fields other than public health is not essential nor even beneficial to public health workers, what can be done to alter the situation? The fact that chance played a major role in directing workers into public health certainly indicates a lack of systematic planning for recruitment of public health workers. It would not be unreasonable to assume that recruitment for public health could benefit by serious study and conscious planning.

Poliomyelitis in the United States, 1954

The year 1954 marks the end of an era in poliomyelitis incidence in the United States. The era began in 1894 when Caverly investigated and reported upon an epidemic in Vermont. Although there are records of the existence of poliomyelitis in this country prior to 1894, this epidemic apparently was the first extensive one to be recognized. During the following 25 years the etiological agent of the disease was found and epidemiological characteristics accurately described. During this period severe epidemics occurred in various parts of the country, particularly in the decade from 1907 to 1916. Incidence remained relatively low from about 1920 to 1944, when more widespread epidemics began to occur.

Dr. C. C. Dauer, medical adviser of the National Office of Vital Statistics, Public Health Service, prepared this report. His previous annual report on poliomyelitis appeared in the December 1954 issue of Public Health Reports, pp. 1185-1186.

Although various measures, including vaccination, for control of poliomyelitis had been proposed or developed prior to 1954, none was effective. The success of the field trials in 1954 of the most recently developed vaccine may not have an immediate effect in reducing total incidence significantly, but it is a sign of a new era in preventing paralytic effects.

Incidence of poliomyelitis in the United States in 1954 was slightly below the average for the previous 5 years. The death rate remained relatively low, about 1.0 per 100,000 population.

	Number cases reported	Case rate per 100,000	Death rate per 100,000

1954.....	38,476	23.9	¹ 1.0

¹ Estimated.

The map shows the distribution of poliomyelitis by counties in 1954. Large areas of relatively high incidence, that is, rates in excess of 60 per 100,000 population, were located in Florida, Texas, Iowa, Kansas, Nebraska, Wyoming, Utah, and Nevada. Many smaller areas also experienced high attack rates. Incidence was high in both Iowa and Nebraska in 1952,

when western Iowa and eastern Nebraska were part of a larger epidemic area, but these sections had relatively low rates in 1954.

The chart shows the mean incidence or attack rates per 100,000 population for the 5-year period 1949-53 and for 1954. During the 5 years the attack rates were relatively high in the North Central, Mountain, and Pacific States

Poliomyelitis morbidity rates per 100,000 population in the United States and by State.

In 1954, 5 States had attack rates in excess of 50, and all but 1, Florida, were in the areas where incidence had been relatively high during the previous 5 years. Four other States had attack rates of 30 or more per 100,000 population. The exceptionally high incidence in Florida was due to the occurrence of a large number of cases late in the season, that is, in October. These cases were reported principally in a few counties in the northern part of Florida. A large proportion of cases occurred in adults. Paralysis of varying degrees was reported in 80 percent of the cases in this area. In other States with a high incidence, the occurrence of the disease followed the usual seasonal pattern characteristic of the respective areas.

Of the 38,476 cases reported in 1954, 48 percent were classed as paralytic, 34 percent as nonparalytic, and in 18 percent the type of disease was not specified. The corresponding figures for 1953 were 44, 34, and 22 percent, respectively. There has been a gradual change over the past 5 years with respect to the number reported in the unspecified group. This change indicates that greater efforts are being made to classify cases as either paralytic or nonparalytic. In 1954, 11 States classified all cases as paralytic and nonparalytic, and 5 reported less than 1 percent in the unspecified group. In 1954 only 1 State reported all cases as unspecified in contrast with 17 who made no differentiation of any cases in 1951.

technical publications

Health Manpower Source Book

Dentists

Public Health Service Publication No. 263, section 7, 1955. By Elliott H. Pennell and Maryland Y. Pennell. 159 pages; tables. \$1.25.

This seventh section of the Health Manpower Source Book series presents data on the number, characteristics, and distribution of dentists in the United States. Mid-1952 distributions of non-Federal dentists are indicated for several county groupings and for the graduates of individual dental schools by year of graduation and current location of the dentists. The basic material represents enumerations from information supplied for individual dentists in the 1953 American Dental Directory published by the American Dental Association. In addition, United States census data are presented for dentists in the labor force to show trends from 1900 to 1950 and, for 1950, the characteristics of dentist in terms of age, race, sex, employment status, and income level.

Occupational and Related Dermatoses

Abstracts from the literature, July 1943 to December 1953, inclusive.

Public Health Service Publication No. 364. Public Health Bibliography Series No. B2. 1954. By Donald J. Birmingham and Paul C. Campbell. 183 pages. 65 cents.

A continuation of Public Health Bulletins Nos. 266 (1941) and 284 (1944), this publication carries forward abstracts of the literature on occupational and related skin diseases from July 1943 through December 1953. It is intended as a reference for dermatologists, industrial

physicians, and others interested in contact dermatoses.

Since practically every branch of industry, including agriculture, has exposures that may produce skin diseases, the volume of the pertinent literature necessitated limiting the articles chosen to representative papers in many subject areas. Wherever feasible the articles have been arranged according to the offending agent.

Staffing the General Hospital, 25-100 Beds

Public Health Service Publication No. 417. 1955. By Margaret K. Shafer. 32 pages; illustrated. 25 cents.

These staffing guides, developed from 1-day data collected in 22 selected hospitals of less than 100 beds, help hospital and health authorities plan health facilities under the Hospital and Medical Facilities Survey and Construction Program.

Charts show number of persons by department for various sized hospitals; hours of nursing care per patient per day; and percent of nursing personnel assigned by shift of service and by size of hospital. Tables further clarify staffing problems.

Sanitary Aspects of the Shellfish Industry of Japan

Public Health Service Publication. Unnumbered. 1954. By L. R. Shelton, Jr., and Richard S. Green. 51 pages; illustrated.

To provide background information for application of the legal responsibilities of the Food and Drug Administration on imports of frozen shellfish, and to advise the Japanese Government on sanitary practices, contributing to the protection of consumers, were the two

purposes of this survey, made at the request of the Japanese Government.

The information is particularly helpful to American importers and health officials. Of interest primarily to the Japanese are the recommendations on sanitary practices, most of which are already well-established in the United States.

Spanish Edition of Standard Methods

A Spanish language edition of Standard Methods for the Examination of Water, Sewage, and Industrial Wastes, 1955, will soon be available. The translation was made by Chemical Engineer P. J. Caballero, chief of the water and sewage laboratory in the Ministry of Hydraulic Resources of Mexico.

Its publication on a nonprofit basis has been authorized by the American Public Health Association, the American Water Works Association, and the Federation of Sewage and Industrial Wastes Associations. The Health, Welfare, and Housing Field Party of the Institute of Inter-American Affairs in Mexico is sponsoring the publication of this book at \$6. Order accompanied by a draft or check for the exact amount of the order on a United States bank should be addressed to: Dr. Trois E. Johnson, chief, Health, Welfare, and Housing Field Party, Institute of Inter-American Affairs, American Embassy, Mexico, D. F., Mexico.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Human Behavior Factors in Program Planning

By ANDIE L. KNUTSON, Ph.D.

TODAY, more than ever before, we need to understand how people act in matters that concern their health and why they behave as they do.

Many of the current problems of public health, such as the chronic diseases—heart diseases, cancer, diabetes, arthritis, blindness—cannot be identified, defined, and solved without the active participation and help of the public. This is true also of the problems of aging, industrial health, mental health, maternal and child care, nutrition, medical rehabilitation, accident control, and the hygiene of housing (1, 2).

If we wish to enlist the active participation of people in public health programs, we need to develop these programs to take care of their problems as they see them or to satisfy the needs they identify. In making decisions we also need to consider what resources people will use, what actions people are willing to take to solve their problems, and the type of health service organization they are ready to accept.

Several factors concerning human behavior

seem to deserve further consideration in planning public health programs to meet today's public health goals. While these factors are discussed separately here, they are so closely interrelated and interdependent that in life situations they cannot be isolated, one from another.

Uniqueness of the Individual

Each person is a unique individual. Each is born into society with his own peculiar pattern of biologically determined capabilities, abilities, and characteristics that make him from birth different from every other human being. As this individual develops and grows in his own unique way and in his own special world, he learns through experience particular ways of thinking and acting. These serve in applying the resources he has in taking advantage of opportunities to satisfy his needs and wants.

As he grows, the individual acquires a sense of belongingness or personal identification with specific groups within his surroundings—at first, perhaps, with his family and play groups; later they may include his school and work groups, clubs, union, church, PTA, political party, or professional organization. He becomes identified also as a member of a particular ethnic, occupational, and social group.

As he acquires a strong identification with such groups, their norms and values help to form his norms and values; their interests and wants influence his interests and wants. To a

Dr. Knutson is chief of Behavioral Studies, Division of General Health Services, Public Health Service. His paper, presented at the annual meeting of the Nebraska Public Health Association, Omaha, September 1954, is published here in somewhat abbreviated form.

large extent he adopts their purposes and goals as his own. Yet throughout he remains a unique individual, wanting, hoping, striving for and expecting—yes, and fearing—different things than anyone else. How he acts to apply his own pattern of abilities and talents to achieve his ends is also different in some ways from any other member of his special pattern of groups (3-5).

This uniqueness of the individual is of primary importance in public health planning. A person's health is one of the most intimate aspects of his personality. The nature of his concerns is a highly personal matter—so personal, in fact, that he may have difficulty in communicating with anyone about it.

The case finding, diagnosis, and treatment of chronic diseases may be seriously hampered because an individual with symptoms may have had unique experiences that make him afraid to acknowledge the symptoms; or his experiences may have led him to distrust the methods of diagnosis and treatment offered. He may have learned to place greater faith in less scientific ways of dealing with his health problems.

If the groups to which he belongs attach shame or weakness to certain health conditions, he may not be able to acknowledge—perhaps even to himself—that he has such a condition. For social barriers are often more effective motivators than physical force.

Differences Among Communities

A second major factor to consider in planning is that the members of each community also differ as a group in many ways from those of any other community. They differ in the nature and seriousness of their problems, in the extent and quality of their resources, and in the various possibilities they have for action in solving their problems.

They are likely to differ, also, in the pattern and quality of their leadership. While in some communities there may be many effective leaders, in others the leadership may reside with a few appointed or elected officials who may exert their control through a wide variety of groups. In some communities, nearly all the major decisions are made by one individual or by persons directly responsible to him.

The methods of communication available to members of different communities also vary so that no single means of communication can be assumed to be effective everywhere. The channels of communication available in a metropolitan center may include newspapers, theaters, radio, television, churches, political organizations, and a wide variety of similar formal media. In addition, many informal channels, such as discussions in informal gatherings or neighborly gossip at the corner drugstore or post office, may serve as channels of communication. On the other hand, people living in a rural community may lack many of the formal means of communication. They may depend more upon the informal methods—in fact, these informal means may in some instances be developed to the extent that they are even more effective than the formal channels of the metropolis. Do you recall the use once made of the old party line? Very little happened in the community without everyone knowing about it.

Communities also differ in the way the citizens prefer to organize to solve their problems. Citizens of an industrial community, for example, are likely to prefer patterns of organization different from those prevailing in an agricultural community. This is especially likely if the resources and qualified personnel differ in the two areas. If a rural area lacks the equipment and personnel needed to diagnose certain health conditions, it may be necessary to transport the patient to some central clinic or hospital. Or, in the absence of adequate medical facilities, individuals in the rural community may be forced to lean more heavily on the limited facilities that are available.

It is not always possible to interest the members of all communities in the same type of actions, even though similar problems may exist. People living in a community which has a very narrow margin of security cannot afford the same approach as those residing in a community that has more economic security. If the people of a community have undergone serious economic hardships in the past, its leaders are likely to be cautious in accepting long-range responsibilities that may threaten their future economic security. For example, the leaders of a community that now lacks a local health unit may honestly feel that they cannot

afford such a unit, even though it would seem to the outsider to be well within their means. Even though it may seem within their means today, they may fear that they will not be able to afford it tomorrow, or at some future date.

The members of different communities vary in the way they adopt new programs. In most areas of our country we moved gradually from crude railroads and steam engines to a modern railroad system and then to air transportation; from horse and buggy and dirt roads, to early models of automobiles; and finally to a modern highway system and streamlined cars. This pattern of developing a transportation system has not been the same for all communities. People in some areas have changed almost directly from ox carts to air transportation (6).

Members of certain communities now lacking adequate public health services may prefer to start with some other type of service than that the public health people consider basic. They may consider their present means of dealing with these basic public health problems adequate and consequently, may prefer to maintain the type of organization that is now set up for handling such problems, even though professional workers consider this organization inadequate. Some of the lay leaders may be more concerned about providing solutions to newer problems of public health than they are about providing the traditional basic health services. If this is true, they might move more quickly into the development of programs concerned with problems of the aging population, mental health, accident prevention, or the chronic diseases—in short, their primary concern may be with problems that many existing health departments are just beginning to identify as public health problems.

If this situation exists in some communities now lacking adequate public health services, public health leaders might find it easier to develop effective public health organizations in these communities by starting in the direction community leaders identify as being of concern. As these leaders become better acquainted with public health, they will be better prepared to consider ways of dealing more effectively with the problems public health leaders consider more basic.

Public Concern

A third major factor to consider in planning public health programs is that the people of the community need to recognize a problem and need to feel concerned about it before they are likely to take steps to solve it. Therefore, unless the problems, interests, or wants of the public are adequately identified and the public health program developed in terms of these, the public is not likely to be a willing participant in supporting and carrying out the program.

The matter of determining the public health problems in a community is, of course, basic to determining the kind of organization needed and the types of methods required to solve the problem. But the very process of determining public health problems with which the members of the community are faced from their point of view is beset with difficulty.

We must see that our questions or approaches do not limit the responses to our own ideas about problems or possibilities. This applies no matter what technique is used to identify problems or wants—questionnaires, interviews, projective tests, group discussions, or statistical analyses.

We are not likely to get an adequate and valid answer from the layman, for example, if we ask him to tell us about his public health problems or his public health needs. A man cannot report what he does not know or perceive. Unless he knows much more about public health than you or I did when we first entered this field, he will not be able to give an informative or meaningful answer to such a question. If the layman has any knowledge of public health at all, it is likely to be limited to what he has personally experienced. To a farmer, public health may mean milk inspection; to a parent, public health may mean what the school nurse does.

The fact that we are earnestly seeking to identify public health problems does not necessarily mean that we will be able to see them when they are presented to us. In any situation where professional and lay persons seek to cooperate, the differences in their patterns of thinking and perception are serious barriers to effective communication. At times, our professional patterns of thinking will prevent us from seeing the very thing we are seeking.

Johnson reports an incident which clearly illustrates this (?). A child with a persistent cough had his throat X-rayed for diagnosis. The radiologist reported there was nothing in the X-ray to show why the child was coughing. The cough persisted and the child returned to have another X-ray taken. Now, the shadow of a button was seen in the throat region. The button was removed and the coughing stopped. When the first X-ray was reexamined, the shadow of the button was seen there also but it had not been identified by the radiologist, who had assumed that the child had been X-rayed with his clothes on and that the button was on his shirt. The radiologist had failed to see the significance of the button for the problem at hand—that is, the diagnosis of the cause of the cough—because the other explanation seemed more reasonable. His perception had been in accord with previous experiences and was completely logical.

Close cooperation between the layman and the professional person is essential in identifying public health problems and the desires of the people of the community for action. Since representatives of the two groups are likely to identify different things in the same situation, two different patterns of problems and needs are likely to be developed when both are involved, perhaps at first independently. As these two patterns of problems are defined, both groups must join together for discussion in order to identify those on which there is common agreement and also to explore reasons for disagreement on others.

The layman on the one hand must acquire a better understanding of those problems and needs, identified by the professional person, that are so much concerned with his welfare. Unless the layman understands the need for some of the surveillance operations, such as immunization or milk and water control, he is not likely to give the public health person the support required to carry out programs of this type.

On the other hand, the public health person must recognize and understand those problems and concerns of the layman which may not at first glance appear to be within the scope of the established public health responsibility. If the layman places a high value on a medical reference service, a child accident prevention

program, recreation facilities for teen-agers, or prenatal care and well baby clinics, he is going to insist that action on these requirements be taken by someone.

Seeing the Solution

A fourth major factor to consider in program planning is that people are most likely to take a particular action when they see that action as one that will adequately solve their problems or satisfy their concerns.

People who see false teeth as the best solution for bad teeth are not likely to take adequate steps to preserve the teeth they have. Rather, they may look forward to getting rid of their teeth and substituting false teeth for them. Conversely, those who see fluoridation of the water supply as a good way to prevent dental caries in children and are concerned about it, perhaps, because they have children of their own, are most likely to support a community fluoridation program.

One would not expect the community leaders who do not see a need for local health units to seek assistance in developing such units. Even though they may recognize serious public health problems, they will not try to organize local health units unless they believe these units will be able to cope with these problems.

Opportunity for Action

Fifth, an opportunity for action must exist, and this opportunity must be perceived as both existing and possible. People must perceive the action as one they are both physically and psychologically able to take. For example, if the action involves attending a clinic, they must perceive the clinic as one they can get to at a time that does not interfere with their work or other essential activities. They must also see the clinic as one they are entitled to go to and one at which they feel welcome.

A person whose teeth are decaying may perceive the cost of repair as prohibitive even though it is possible to obtain adequate care at a price he can afford within the community. If he believes the cost is prohibitive, he is not likely to act, no matter what the situation actually is. By the same token, community leaders

may object to certain local programs. Even though they may appreciate the need, they may not agree that the proposed program is a reasonable possibility considering the resources they have available to them. If this were their perception of the situation, they might strongly oppose such a program as being unrealistic and seek some more meaningful way of satisfying their needs.

They might ask: "What is the use of talking about such a program when we simply don't have the funds, and we have no means of attracting the necessary personnel at the salaries we can pay? Isn't there some other way we can handle this problem? Would it be a good idea to make improvements in the way we are now handling it rather than trying something new that we won't be able to carry out?"

Any new services or organization developed within a community must also fit in with other programs going on in the community. If a service conflicts with such programs, its chances for success are more limited.

Meltzer found that community leaders must feel that a new program will help them in achieving their own objectives if they are to support it (8). Community leaders are not likely to give enthusiastic support to any program perceived as interfering with some of the things they personally wish to do or which they identify as responsibilities of their own organizations.

Thus, any action to be taken must not only be seen as possible but must also be seen as an action that does not conflict in any way with personal or group values of the people concerned. It is futile to urge the orthodox Hindu to boil the holy water of the Ganges to kill germs when his religion tells him not to boil holy water and not to kill anything. Likewise, it is useless to urge the orthodox Jew to serve milk to his children at all meals when this conflicts with his strict code which prohibits serving meat and dairy products at the same meal.

A midwestern farmer who places great value on his endurance and thinks it is sound practice to work off his indigestion after a heavy meal is likely to ridicule the idea of staying in bed with similar symptoms that may be related to a heart condition. If he takes pride in how healthy his children look, he may consider their

going for regular physical examinations or X-rays a sign of weakness in the family. It does not tie in with his frequent boast, "I've never been to a doctor in my life!"

A low-income family which identifies the public health clinic as a charitable type of organization and objects to the idea of accepting charity is not likely to patronize that clinic. It will not help much to tell them that the clinic has been designed to serve them and that they are welcome. The way they perceive it is the important thing.

By the same token, a community program must be organized in accordance with the customs and values of the community. For the customs and beliefs prevailing in a community are most effective forces in determining the types of actions the people of that community will take and the types of actions they will reject.

As Dorolle (9) has observed, "When we set about improving a people's health, we must put aside our own concepts of good and evil, better and worse, and not encroach upon the people's beliefs and cultural concepts. Everyone has the right to develop his own philosophy and to refuse any change in it which does not come from within himself; furthermore, it is useless to attempt to impose changes in cultural concepts from the outside. If such changes are imposed, they cause disequilibrium and misunderstanding which seriously compromise the work which is being attempted."

Patterns of Behavior

The final point I would urge you to consider in planning public health programs is concerned with the patterns of thought and behavior of people. The action to be carried out must be consistent with the usual patterns of thinking and acting of the people concerned.

Few of us are willing to take the time and possibly suffer the embarrassment of brushing our teeth immediately after the noon meal every day, even though we may believe the dentist who advises us that this is a desirable practice. Likewise a workman with a heart condition is not likely to take a rest period in the morning or afternoon as recommended by the doctor if he feels that doing so may cause him to lose

his job. Nor is such a workman likely to take time out for the free X-ray service offered him if he thinks there is a possibility that positive findings will lead to his discharge from work and complete disruption of his family life.

Foster has pointed out that the failure to treat sick children was one of the most bitter criticisms leveled at the public health centers in South America. "It illustrates a failure of the people served to understand the fundamental difference between preventive medicine . . . and routine treatment of the sick and ailing" (10).

The results of preventive medicine are often more difficult to perceive than the results of clinical medicine. From the standpoint of the family, the distinction we make as professionals may not be as real or understandable as we sometimes assume. It is likely that some people in our own country also fail to distinguish between prevention and cure and thereby have difficulty understanding the need for separate types of organizations and services. Further exploration of this possibility may be most fruitful.

In brief, then, the remarkable success the public health team has achieved in solving the problems of the communicable diseases and environmental sanitation has resulted in more adequate control of many of these problems. Today, more of the problems of public health can only be identified, defined, and solved with the active participation and help of the public. Fortunately, the public today is better educated, better informed, and better able to participate in the solution of such problems.

A colleague in the American Psychological Association has drawn an analogy about psychology which may have some meaning to public health. He has called attention to tremendous changes that have occurred in the theory

and concepts of psychology and the implications this has for research and program. This challenges us to review our tools and to recognize that many of them which were developed to test the hypotheses of a quarter of a century ago are not adequate to explore modern concepts.

Solving the new problems of public health may also require new tools. In some instances completely new approaches may be required to keep pace with the phenomenal rate of achievement of the period through which we are passing.

Disposition of First Admissions to a State Mental Hospital

This study of the experience of the Warren State Hospital, Warren, Pa., during the period 1916-50 has several purposes. The first is to acquaint epidemiologists, health officers, and other public health workers with some of the complex problems faced by mental hospital administrators in treating the increasing number of patients admitted to and resident in mental hospitals and in determining what happens to patients following admission. The second is to demonstrate a method for studying the flow of patients through the mental hospital and to apply this method to a study of changes in the rates at which first admissions to Warren State Hospital have been returned to the community or have died in the hospital. The third is to dispel the idea that the prognosis of patients committed to mental hospitals is hopeless. The fourth is to use the results of this historical study as a background for discussion of some basic epidemiological and clinical research needed to assist in the interpretation of the findings and in the formulation of public mental health programs directed toward care, treatment, and prevention of mental illness and disability.

A statistical analysis was made of the records of 15,472 first admissions to Warren State Hospital during the period 1916-50 to obtain an answer to the question, What has been the trend in the probabilities of separation from the hospital, either alive or dead, within specified periods following first admission for patients of specific age, sex, and diagnosis?

Patients were followed from the date of their first admission to the date of their first significant movement out of the hospital, defined as follows: the date of first release to the community on direct discharge or to convalescent care, whichever came first, or the date of death in the hospital. The date of placement on con-

valescent care was selected as an end point for this study because it represents a critical point in the life of the patient, when the staff agrees that once again he is ready to return to the community and to live outside the environs of the hospital.

MONOGRAPH

No. 32

The accompanying summary covers the principal findings presented in Public Health Monograph No. 32, published concurrently with this issue of Public Health Reports. The authors are with the National Institute of Mental Health, Public Health Service, Bethesda, Md., and the Warren State Hospital, Warren, Pa.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, United States Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and major universities and in selected public libraries.

Kramer, Morton; Goldstein, Hyman; Israel, Robert H.; and Johnson, Nelson A.: A historical study of the disposition of first admissions to a State mental hospital. Public Health Monograph No. 32 (Public Health Service Publication No. 445). 25 pages. Illustrated. U. S. Government Printing Office, Washington, D. C., 1955.

Four periods were selected in which to describe the movement of patients: 1916-25, a period before the introduction of any major treatment program; 1926-35, when Warren State Hospital began to lay heavy stress on industrial and occupational therapy for all patients; 1936-45, a period in which some of the therapies in use were standardized and other new therapies were introduced; and 1946-50, when the medical staff was enlarged considerably, and when there was intensified use of electroshock and group and individual psychotherapy.

Some of the conclusions of this study and the questions they lead to are:

1. Of patients admitted to the hospital during 1946-50, a larger proportion were released within 1 year following admission than the proportion admitted during 1916-25 who were released within 5 years following admission. In all periods, at least 50 percent of the patients were released within 5 years following admission. The youngest patients, those aged 15-34 years, have extremely high probabilities of release. Patients 75 years old and over have small chance of ever leaving the hospital.

2. For patients with functional psychoses, the probability of release in the first year following admission in the period 1946-50 was considerably in excess of the probability of release for patients admitted in each of the earlier periods.

Does this mean that the various therapies used in increasing volume in the most recent period—electroconvulsive therapy, insulin, group psychotherapy, and occupational therapy—have been responsible for this increase in release rates, or have other factors been responsible?

3. Patients with senile and cerebral arteriosclerotic psychoses have low probabilities of return to the community. Their death rates, particularly in the first few weeks and months following admission, are exceedingly high.

What are the social, economic, and familial factors responsible for bringing a high proportion of moribund patients into the mental hospital?

4. Functional psychotics, as well as other categories of patients not released in the first year of hospitalization, experience considerably reduced probabilities of release in the second and subsequent years of hospitalization. Also, patients admitted during 1946-50, who have attained their second and third years of hospital life, have approximately the same chances of being released in the following year as had similar groups of patients in the earlier cohorts of admission.

What are the etiological and other factors responsible for long-term hospitalization? What treatment methods can be developed to make it possible to return more of these individuals to the community? What can be done to improve the lot of the patient who cannot be returned to society?

Appraising Fly Control Programs

Since 1946, the effective use of chlorinated hydrocarbon insecticides in the control of the housefly, *Musca domestica*, and of various species of blowflies (*Phaenicia sericata*, *Phaenicia pallescens*, *Phormia regina*) has led to the establishment of community fly control programs throughout the United States. Experience has shown that successful fly abatement requires a composite approach which includes the development of adequate levels of environmental sanitation, chemical control, community education, and biological evaluation.

The evaluative phase is the subject of this monograph, which discusses the techniques *per se* and as each is applied in field operations. Most of the data illustrating the advantages and disadvantages of the methods relate to community fly control programs sponsored by the Communicable Disease Center in cooperation with State and local health departments during the period 1948-53.

The evaluation of a community fly control program serves to guide the selection and frequency of the measures employed and to assay their effectiveness. The latter function requires a routine, periodic assessment in contrast to the flexible, variable techniques necessary for guiding the control operations.

The three methods used most commonly to determine adult fly densities are the grill, reconnaissance, and fly-trap techniques. Either the Scudder grill or a reconnaissance type of survey based on the grill provides the most acceptable means of obtaining repeatable, reliable indexes to fly abundance.

For effective surveillance of a municipality, the city should be divided into areas of socioeconomic levels, such as business, high-class residential, and so on, and the sampling coverage should be related to the magnitude of the fly problem within the zone concerned. Evaluation

units of 10 to 20 blocks each are established for grill surveys, 1 to 2 blocks in each unit being inspected weekly. Three types of station blocks are designated: fixed block (block with highest fly potential within the evaluative unit); random block (any block within the evaluative unit except the fixed station block); and problem block (block with extremely high fly potential,

Public Health

MONOGRAPH

No. 33

The accompanying summary covers the principal findings presented in Public Health Monograph No. 33, published concurrently with this issue of Public Health Reports. The author is with the Communicable Disease Center, Public Health Service, Savannah, Ga.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

Schoof, H. E.: Survey and appraisal methods for community fly control programs. Public Health Monograph No. 33. (Public Health Service Publication No. 443.) 18 pages. Illustrated. U. S. Government Printing Office, Washington, D. C., 1955.

resulting from the presence of a dairy, abattoir, dump, and so on).

Survey data show that prevalence trends for fixed station and random station blocks are similar. However, random station blocks are much slower in responding to any sharp increase in fly prevalence. Because the fixed station block is a more sensitive indicator of the fluctuations in fly densities, it is preferred for operational programs.

Fly traps are less reliable than grill surveys in depicting quantitative trends but give a broader index to the qualitative aspects of the fly population.

The appraisal phase of a community fly control program must be considered as an integral part of the whole operation. Effective utilization of appraisal methods contributes to more efficiency and economy and, in turn, supports the health of the community.

PHS films

Organized Mosquito Control

16 mm. Film, color, sound, 17 minutes, 1955.

Audience: Public health workers and others interested in mosquito control.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St. NE, Atlanta 23, Ga.

The solving of mosquito problems on an organized basis is depicted in this film.

Sampling as a first step to determine species present, relative abundance, and types of breeding places are portrayed, as well as dipping for larvae to determine major problem areas, and the spraying of breeding places. Breeding sites are surveyed as determinants of flight ranges.

Three common methods of mosquito abatement are outlined—permanent control through water management, larviciding, and killing adults on the wing or in resting places. In addition, five major types of problem areas—fresh water swamps and depressions, salt marshes, lakes and farm ponds, irrigated fields and pastures, and urban areas—are illustrated. The hydraulic dredge at work, larviciding, and hand and power spraying are shown also.

An efficient manager, adequate funds, capable employees, suitable equipment, and up-to-date records are pointed out as contributing to the success of an organized mosquito control program.

Mosquito Stages of *Plasmodium falciparum*

16 mm. Film, black and white, sound, 10 minutes. 1954.

Audience: Medical, public health and parasitology students, sanitarians and laboratory technicians, and others interested in the study of living malaria parasites.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St. NE, Atlanta 23, Ga.

The appearance and behavior of living malaria parasites within the mosquito host are shown in this film. It depicts the female *Anopheles quadrimaculatus* obtaining a blood meal and the action of the mosquito mouth parts within tissues.

Gametocytes, gamete formation, and fertilization are observed, along with the development of the ookinete, oocyst, and sporozoites. Transfer of sporozoites to the salivary glands and their inoculation into the tissues of the host when the infected mosquito feeds are likewise viewed.

This is a companion film to M 138a "Erythrocytic Stages of *Plasmodium vivax*."

Mosquito Prevention in Irrigated Areas

16 mm. Film, black and white, 7 minutes. 1955.

Audience: Public health workers interested in mosquito prevention in irrigated areas.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE, Atlanta 23, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

That it is possible to achieve irrigation without the problem of mosquitoes is demonstrated in this film. It emphasizes that the one cardinal rule for controlling mosquitoes in irrigated areas is to avoid standing water by careful design and maintenance of the irrigation system, by accurate preleveling of fields, and by providing adequate runoff drainage.

A cement water-drainage canal.

The life cycle of the mosquito is shown, and 13 typical locations of stagnant pools or sluggish water where mosquitoes might mature in irrigated areas are illustrated.

APHA

WESTERN BRANCH CONFERENCE REPORT

The 22d annual meeting of the Western Branch of the American Public Health Association, attended by 450 representatives from 11 Pacific and Mountain States, 3 western Provinces of Canada, Alaska, Hawaii, and the Philippine Islands, was held in Phoenix, Ariz., April 19-22. Of the papers presented at the meeting, 1 is published in full and 7 others are briefed. Some of the papers are scheduled for publication in full at a later date in *Public Health Reports* or in other scientific and professional journals.

The newly elected officers of the branch are: president—G. D. Carlyle Thompson, M.D., executive officer and secretary, Montana State Board of Health, Helena; president-elect—A. Harry Bliss, associate professor and chairman, department of public health, University of California, Los Angeles; vice presidents—Mrs. Christie T. Corbett, generalized nursing consultant, Oregon State Board of Health, Portland; Robert Dyar, M.D., chief, division of preventive medical services, California State Department of Public Health, Berkeley; J. A. Kahl, M.D., acting State director of health, Washington State Department of Health, Seattle; secretary-treasurer—Mrs. Amy Darter, supervising bacteriologist, division of laboratories, California State Department of Public Health, Berkeley.

The branch will meet next on May 30-June 2, 1956, in Salt Lake City, Utah.

The Epidemiologist Looks at Smog

By LESTER BRESLOW, M.D., M.P.H.

ORDINARILY, the epidemiologist is confronted with a disease and is asked to determine its source or cause. In the case of smog, he is given an environmental condition and asked to determine whether this causes disease.

When the epidemiologist investigates a particular illness, his first task is to define the illness and its occurrence in time and place. Likewise, when he attempts to ascertain whether smog has deleterious effects on health, the first task is to define smog and its occurrence in time and place. Here the difficulties begin.

Air is perhaps our most taken-for-granted natural resource. During the past several decades, however, city dwellers have become aware of industrial and other air-polluting wastes. Occasionally, as in London, England, in 1952, Donora, Pa., in 1948, and Meuse Valley, Belgium, in 1930, the pollution has become severe enough to result in sudden death to large numbers. A vague apprehension, supported by some evidence, is also arising that prolonged exposure to moderate air pollution may cause insidious, harmful effects or even premature death.

For none of the air pollution disasters mentioned has there been a convincing identification of the substance responsible. Although some investigators have incriminated sulfur dioxide as an important factor, the evidence

is scanty. So when the epidemiologist is called upon to find whether the polluted air of an urban community such as Los Angeles is injurious to health, he really has no good chemical guidelines to pursue. We know that air pollution can kill, but we do not know what substance or combination of substances may be responsible.

In Los Angeles, the people have been increasingly concerned with eye-irritating properties of the air, the loss of visibility, and damage to plants. Smog in Los Angeles is even defined as the quality of air which produces these effects. Thus, a search has been initiated to determine what air pollutant causes eye irritation, decreased visibility, and plant damage. The substantial progress in this direction, however, does not materially aid the epidemiologist who is concerned with more serious effects that may be occurring. The materials which cause eye irritation, for example, may not be the same as those which cause other types of injury to health. Dozens of substances have already been found in the Los Angeles air, and many of these measured. The fact that certain of these are being identified as the factors causing eye irritation does not help to determine whether air pollution in Los Angeles can cause respiratory disease or death. Quite different pollutants may be involved in the latter if they occur.

One might assume the eye-irritating substances to be indexes of air pollution in general. By determining and measuring these substances, we would acquire knowledge on the degree of pollution from any and all substances. This assumption may be highly misleading. For example, the eye-irritating substances appear to be largely dependent upon sunshine. In the event of severe air pollution coincident with severe fog, as in the London episode, the

Dr. Breslow, chief of the bureau of chronic diseases, California State Department of Public Health, San Francisco, presented this paper at the April 1955 meeting of the Western Branch of the American Public Health Association. Other papers from the meeting follow in brief form.

substances, which are dependent upon solar radiation, might fail as an index at the very time they were most wanted.

Thus, the epidemiologist cannot be content with definitions of smog which are commonly accepted today. He must keep in mind the whole array of air pollutants—lead and other heavy metals, chlorinated hydrocarbons, and many other substances which have been relatively neglected in the attempt to determine the eye-irritating and plant-damaging substances in smog.

Not only do we have trouble defining smog, but we are beginning to realize its tremendous variation in place and time. The soot pollution of certain cities in the eastern United States is vastly different from the pollution of California cities with hydrocarbons and other types of waste. In any one community, for example Los Angeles, the air pollution as reflected in the chemical measures now available differs greatly not only from day to day but even from hour to hour, depending upon meteorological and other factors.

A Two-Part Problem

However crude his notion of the nature of smog, the epidemiologist still faces the question, does it cause ill health or death? This problem may actually be divided into two parts: (a) Does it cause immediate damage, that is, within a few hours or days; (b) does it cause long-range damage, after exposure for years and years?

To answer the first question one turns naturally to the usual indexes of ill health—excessive mortality, morbidity, and disability. Do any of these occur during or immediately after episodes of smog? At this point, of course, we come back to the vexatious problem, what is an episode of smog? For purposes of our initial investigation of the effect of air pollution on health we had available the results of an aerometric survey conducted by the Air Pollution Foundation at 10 stations in Los Angeles during the months of August through November 1954. We arbitrarily defined an episode of smog as a series of days during which several of the following were noted: Air pollutants such as lead, oxidant, nitrogen dioxide, hydro-

carbons, and carbon monoxide were recorded as present in "high" amounts; adverse meteorological conditions prevailed; and newspaper accounts indicated smog. The records unfortunately did not cover all days during the 4-month period, and correspondence between the various measures actually made was far from perfect. However, inspection of the data did permit the crude selection of three periods of relatively high smog—one each in September, October, and November 1954.

Air pollution disasters characteristically have affected most severely the elderly, and especially those with chronic cardiorespiratory diseases. Hence, our first thought was to determine if smog episodes resulted in excessive frequency of mortality from selected cardiorespiratory diseases among older people. No such effect from the three smog episodes could be found for the Los Angeles population 65 years of age and older. This failure to show any effect on mortality among those 65 and older may be contrasted with a very obvious effect on the mortality of this group by daily temperature fluctuations, which we did note. Further work is being done on this question of deaths among older persons, with particular attention to mortality among those more than 75 years of age and mortality for the several days following the last episode of smog which occurred at the end of November. Analysis up to the present time includes only deaths occurring in November.

We also examined the mortality experience of a group of frail, elderly individuals, such as those found in nursing homes. Sixteen Los Angeles nursing homes with a total of 358 beds reported the number of patients who died each week during the months of August through November 1954. One week of this period, the week immediately following the heavy smog of late October, did show an unusually large number of deaths. However, since the data cover only a limited period, not much significance can be attached to this observation until more work is done to determine whether corresponding rises occur during other episodes of smog.

Inspection of the infant mortality experience during the 4-month period of the aerometric survey gave no indication of any effect from air pollution.

Thus, only the barest suggestion was found that Los Angeles air pollution, during the fall of 1954, actually caused mortality.

In respect to morbidity we studied the findings of a household sickness survey which was being conducted throughout the State by the State health department. Preliminary inspection of the rates for respiratory illness and for illness among older persons in Los Angeles has not revealed any measurable effect from smog during August through November 1954.

If air pollution adversely affects the cardiac and respiratory systems, the proportion of persons admitted to hospitals with certain diagnoses might reflect this relationship. Examination of admission data for more than 29,000 patients in 9 large Los Angeles hospitals during the 4-month period showed no changes in the proportion of persons admitted with cardiac or respiratory diseases which were coincident with smog.

Limited data on industrial and school absenteeism revealed no relationship to the periods of smog.

Examination of available indexes, both mortality and morbidity, did not yield much evidence of a measurable effect on health from Los Angeles air pollution during the fall of 1954. This, of course, is not to say that no effect occurred. It may be that our measuring rods are too crude.

The opinions of Los Angeles physicians, expressed in a mailed questionnaire submitted by the county medical association, overwhelmingly support the idea of an adverse effect by smog upon health. A telephone survey of school administrators and teachers by the Los Angeles Board of Education during the October 1954 smog episode indicated a strong belief that smog was interfering with children's behavior and school performance. The pupils were said to be restless, irascible, and less attentive. Although not quantitative, this type of opinion evidence deserves some attention, if only to indicate the direction of more definitive studies.

Long-Term Effects

The foregoing discussion pertains only to part of the question, namely the immediate ef-

fects on health. Even though no such effects are measurable, and this cannot yet be stated, one must still consider the question of long-term effects. How does health respond to smog exposure continued year after year? Are there any chronic effects, perhaps of greater import than acute effects? This is a much more difficult question.

Stocks (1) has advanced some interesting evidence that air pollution in English cities may induce various lung diseases including lung cancer. He was, of course, dealing with relatively stable populations, for the most part exposed to one type of air pollution during their entire lifetimes. What may be the long-term results of the tremendous migration to Los Angeles during the past 10 years when air pollution of a different sort from that in England has apparently been increasing? The answer may be several years delayed, but the question is one we cannot ignore.

At least two approaches to the problem of chronic effects may be useful. One is to compare the mortality and morbidity experience of Los Angeles residents with some control group, for example, the residents of another California city. It is difficult to select a satisfactory control group, particularly because of the migratory habits of the population. Another approach is to compare the health experience of Los Angeles residents who have lived in the community only a short time with the health experience of those who migrated there many years ago, and who, consequently, have had longer exposure to Los Angeles air pollution.

Both of these approaches are now under consideration, in addition to further study of the possible immediate effects of air pollution.

In addition to the question of whether smog causes disease, particularly a measurable effect on morbidity and mortality, the epidemiologist may also be asked a related but somewhat different question, namely, is smog a health hazard? To this one may give an unequivocal answer—yes (2), because of its obvious immediate interference with the physical, mental, and social well-being of the people; its possible, but as yet undetermined, cumulative adverse effects upon health; and its disaster-making potential, should pollution concentration build up in any area.

State Health Councils

The merits and deficiencies of statewide health councils are of considerable current interest to health officers.

These councils are a means through which public health problems may become known and understood and through which citizen support and appropriate, cooperative action may be achieved.

Sound guidance for all health councils is found in the words of Dr. Florence R. Sabin: "Give the people the facts and they can be depended upon to act." That thought guides the public health servants of Colorado in their efforts to promote dynamic health leadership for the entire State.

Nature of State Health Councils

To describe the composition and objectives of numerous State health councils, let us start with a broad definition. The health division of the Denver Area Welfare Council defines a health council as a State or local federation of groups and individuals organized to plan and jointly promote health activities.

State health councils are now functioning in nearly two-thirds of the States. Usually, according to reports presented to the annual meeting of the National Health Council in 1952, a State council's membership includes statewide organizations primarily concerned with health

or medical services. These include medical and other professional associations in health fields, hospital associations, official health agencies, and voluntary health agencies. Membership may also include interested statewide organizations not directly dealing with health and medical matters. Often the latter type of organizations are associate members of the councils. They should be considered very important, since they show potentialities of being the best channel through which to develop widespread public interest in health needs and activities.

Local health councils are frequently included as associate members of the State councils. In any case, there should be close working relationships with the local councils and periodic State meetings attended by representatives of all the local councils. There are now in the United States about 700 local health councils and 250 health divisions, or committees, that are units of larger community organizations dealing with many civic improvement projects.

Some of the State councils charge annual membership fees; others, including the council in Colorado, leave the amount contributed to the decision of each member organization. Occasionally, a State council has a paid executive director and staff; in other instances, as in Colorado at present, the council's work must be carried forward through services donated by member organizations and, possibly, a paid stenographer or clerk. Necessarily, therefore, the nature and the costliness of the programs that can be undertaken by the councils differ.

In considering possible principal objectives, the following appear to be common to most of the State councils:

1. To educate the council members regarding programs and policies of the member organizations.
2. To serve as a State information center on health programs and problems.
3. To encourage joint planning among health organizations in order to eliminate gaps and overlapping in their programs.
4. To determine statewide health needs, arouse public support for proposed health programs, and promote needed health legislation.
5. To assist in the organization of local health councils, and to guide and encourage

By R. L. Cleere, M.D., M.P.H., executive director,
Colorado State Department of Public Health.

them in studying local health needs in relation to State programs.

6. To further local health units and other needed local health programs.

Health Council in Colorado

The accomplishment of health council objectives requires skill in public relations and community organization, a skill possessed in rare degree by Dr. Sabin. A few of her words, taken from a speech in 1950, serve to explain the purpose behind the Colorado Health Council: "We are interested in the organization of permanent health councils on a State basis, with a membership of representatives of all the private health agencies who wish to join. Such an organization is intended to maintain the interest of citizens in aiding, following, and giving constructive criticism and advice to all the governmental agencies."

The Colorado Health Council was organized and incorporated in 1950. Its future seemed assured by more than 20 member organizations, a board of directors composed of more than 40 key representatives of the member organizations, and an executive committee consisting of 6 elected officers of the council and 15 persons elected from the membership of the board. Meetings were held in 1950 and 1951, but, lacking a paid, full-time executive secretary and finding its officers and board members heavily burdened by other responsibilities, the council drifted into inactivity by 1952. It was reactivated at a meeting held by the board of directors in September 1954. Twenty members representing 15 organizations were present and the annual meeting was set for October.

At the October meeting, attended by 21 representatives of 16 organizations, elections of officers were held. Financial contributions toward expenses were urged, and three types of activities were authorized for the next 6 months. The projects are: (a) compilation and distribution of weekly and final reports on the health legislation presented in the 1955 General Assembly of Colorado; (b) compilation and cataloging of information on programs and activities relating to health throughout the State; and (c) review of the health goals set in the 1945-47 studies, together with

an evaluation of the progress made since then.

Office space has been provided by the State department of public health for a part-time secretary-clerk paid by the council. The first two of the projects have been carried forward under the direction of the chief of health education of the department, president-elect of the council. The third project, or progress study, is being made by a medical representative of the Colorado Heart Association, also a member of the council.

It is expected that the three initial activities will serve as a foundation for an expanding program. Council meetings are to be held four times a year, and, presumably, financial support of the council and active participation in its activities by the member organizations will gain momentum. Thus, a new start has been made, but only a start.

In my opinion, the council, if it is to become a major force for adequate appropriations and needed legislation from year to year, should have the following: (a) an executive secretary; (b) closer working relationships with medical society committees and spokesmen; (c) widened associate membership among general service organizations that have an interest in health but who are also recognized as representing a broad range of public opinion; and (d) a central purpose, that of consolidating the support of the member organizations behind needed public health measures, whether or not they relate to a particular member's field of activity. If a united, well-informed stand could be achieved by the council, appointment of an official Colorado Health Council spokesman at the annual sessions of the legislature probably would be desirable and effective.

In addition, it seems to me that the State council could acquire many helpful ideas by holding meetings with representatives of the existing local health councils. In Weld County, Colo., for example, there are numerous community health councils. These compose a larger association called the Combined Weld County Health Council, and the association works closely with the long-established Weld County Health Department. Thus linked, the local and county organizations get the facts to the people in a variety of ways. One method

was the "Health Days," sponsored by the association, held last April 29 and 30, with meetings and exhibits at the State College of Education in Greeley, the principal city of Weld County.

Mental Health

Nathan Ackerman in a recent article in *Social Case Work* quotes Clifford Beers as stating in "A Mind That Found Itself" the goals of mental hygiene to be:

Encourage reforms in the care and treatment of the mentally ill.

Disseminate public information designed to increase human tolerance for those afflicted with mental illness.

Promote research into the causes, motives, and treatment of mental disorders.

Create services directed toward the prevention of mental illness.

By way of contrast, Albert Deutsch in "The Mentally Ill in America" writes that the aim of some mental health programs is to provide:

"A world of peace and freedom from which the twin spectres of war and insecurity will be banished; a world of equal opportunity where people will be freed from stunting inhibitions and 'guilt feelings' rising from outworn prejudices and taboos; a world where children may lead healthy happy lives and grow into useful well-adjusted citizens; where the personality is permitted to develop maturely and freely, where the individual is given a sense of personal worth and dignity, and where his activities and ambitions are integrated with the development of group life. . . ."

Negative Effects

The original overselling of Beers' first formulations has produced a sometimes destructive

By Robert L. Stubblefield, M.D., director, Psychiatric Clinic, University of Colorado School of Medicine, Denver.

effect on public health thinking and planning. But true mental hygiene ideology cannot possibly be oversold. Rather, as Ackerman points out, some unreal premises—which might better not have been advanced—have been oversold.

For example, one can design a relatively well-defined program in only very few areas of mental health—such as in the prevention of some types of mental retardation by good prenatal health practices. But when one deals with psychoneurosis or with schizophrenia, the principles stated by Beers lead into seemingly insurmountable difficulties:

Should research be in biological areas, psychological and environmental areas, or both?

How can one create a research design to deal with so many variables?

What types of personnel should be trained?

In view of the difficulty in effecting even minor personality changes, what types of public education should be used?

In the United States

Every health official has some idea about the number of beds occupied in this country by chronic mental patients, particularly those suffering from schizophrenia and senility:

725,000 mental patients occupy nearly half of all hospital beds.

250,000 new mental patients will enter hospitals this year.

1 in every 12 children will spend some time in a mental institution.

Three-fourths of State mental hospital patients have been hospitalized for more than 2 years.

After 2 years, the odds against a patient's being released are 16 to 1.

These figures do not tell us the large numbers of mentally ill who pass through the courts or enter penal institutions. In addition, many pressing public health problems are made more complicated by the nature of the accompanying personality reactions.

Worldwide in Scope

The development of mental health programs is receiving much attention from the World Health Organization. A WHO committee has described their standard historical development.

Initially, there is mere provision of custody

for grossly disordered individuals. Then, there is provision for refuge in the shape of the insane asylum. Finally, there is the development of specific hospitals for the psychotic and of educational or working colonies for the mentally deficient.

The provision of facilities for the clinical handling of the psychoneurotics proceeds through similar phases.

"It is very probable," the committee suggested, "that the planned application of preventive measures at a stage of a country's development earlier than they tend to develop spontaneously would reduce considerably the need for the great expenditure on therapeutic facilities which otherwise arises as development proceeds."

Integration of psychiatric personnel into a State health program might be of much more value than the traditional development of a new structure in a health unit.

Particularly pertinent to our own western States are other observations of the WHO committee. It felt that the shortage of mental health workers retarded the development of mental health programs, now designed chiefly for urban and industrial areas, and that another great need is to explore the efficacy of such programs in predominantly rural settings.

Focus on Education

Any preventive program in mental health will be related to an educational process. In my opinion, most of our educational efforts should be concentrated on the individuals who have the most significant health roles with parents and children—on the pediatrician, the general medical practitioner, the public health nurse, and others. We should focus our attention on the child's preschool, kindergarten, and early elementary school experiences.

We have no doubt of the need for accurate early diagnosis of the chronic psychiatric illnesses and suitable therapeutic centers nor about the need for a program of research in normal personality development and the various mental illnesses. We need to explore the value of community mental health centers, such as those recently developed in Massachusetts which devote much professional staff time to

consultation with agencies dealing with chronic psychiatric problems.

Specific problems impede the development of preventive measures in mental hygiene. By tradition and practice, we are focused on the observation, diagnosis, and clinical treatment of an individual. Because of the length of psychotherapy and psychoanalysis we are somewhat skeptical about health education efforts. We have some stereotyped ideas about public health concepts and goals. We tend to discount psychiatric observations about the difficulties in effecting personality change and reorganization.

Public health personnel tend to move into the psychiatric team areas of function rather than to identify and publicize shortages of trained personnel and support research and training programs. But the current interest in these needs and in the development of sound programs is encouraging. I feel that we are on the verge of outstanding new positive relationships between the psychiatric disciplines and public health.

State-Local Relations

We are all familiar with and use, either consciously or unconsciously, certain principles in solving problems in public health. These principles—in the form of inquiry—are:

- Can the problem be identified or measured?
- Is there a technique which has been proved effective?
- Can this technique be applied on a mass basis?
- Can the results of the mass application of this technique be evaluated?
- Is this technique financially feasible?

These same principles can be applied to problems of State-local relations in public health. One problem is the incomplete or inadequate definition of State and local responsibilities.

By John R. Philp, M.D., M.P.H., assistant chief, division of local health services, California State Department of Public Health.

Another aspect of State-local relations is the process of developing opinion regarding the definition of public health. This process also affects certain public health standards—technical, program, personal, financial—which, in general, are nationwide. Some of these standards may be applicable only to local areas; others represent nationwide averages and may be completely inappropriate when applied to a given community.

Recent experiences in California illustrate methods for solving or preventing problems in State-local relations. In an attempt to define the responsibilities of the State agency in public health, each bureau, each service, and each division of the State health department is delineating its activities or the activities in its field of influence under three broad categories: services performed directly by the State agency; services performed jointly by the State and local agencies; and services for which the local agency alone is responsible.

Techniques

In assisting local areas and agencies, the California State Department of Public Health is using four techniques—financial assistance, program consultation, determination of manpower requirements, and surveys of health needs and problems. All of these can be applied on a mass basis, although some selection may be necessary because of practical limitations of time.

Allocation of funds to local health jurisdictions is based on the population served. Small jurisdictions receive a relatively higher amount per capita than larger health departments. To receive funds from the State, local areas must expend a specified amount per capita per year from their own funds, and the State board of health cannot adopt any standards which a local area must meet unless they are approved by the California Conference of Local Health Officers.

Program consultation is provided by the staff of the State health department. Methods vary and are being improved with experience. Review of local health programs by a team of consultants in several specialties is undertaken at the request of the local health officer. The

method to be used is discussed with and approved by the administrative staff of the local health department before plans are completed and the review is begun. This technique has been completely acceptable to local groups and leads to good State-local relations.

Estimates of manpower needs in sanitation have been made on the basis of existing problems instead of on a simple population ratio. Similar estimates will be attempted in the field of public health nursing and, eventually, for other types of professional and public health workers.

Surveys of health needs and problems in individual counties have been made on request of the counties. Teams of State health department personnel—usually a medical officer, a public health nurse, a health educator, a social worker, and sanitation personnel—visited the counties and compiled statistics and other information available in State and local agencies, made field observations of the environment and situations within the county, and interviewed selected individuals and groups. Upon completion of the survey, information from all sources was pooled and the findings reported.

Results

As a result of State financial assistance, since 1947, 16 California counties have initiated organized public health programs. No county has abandoned its public health organization. Through the conference of local health officers, a true partnership has developed between local and State agencies, and opinions of persons in the State and local health agencies regarding the team method of consultation service to local health departments indicate that help was received through the use of this technique. Final evaluation, of course, can only be made in terms of measured progress directly attributable to the use of this method. Evaluations of the relation of the State health department and the small rural counties are not complete, but analysis of the effectiveness of these methods and measurement of the results will be continued. The final answer as to the financial feasibility of these techniques can only come after further evaluation of the results obtained.

The Insurance Carrier

Industrial medicine once was concerned primarily with traumatic surgery or curative medicine, but in recent years the emphasis has shifted to preventive medicine. It is within this sphere that industrial medicine may produce the greatest contributions to health, as well as the greatest economic savings. Modern industrial management has come to realize that health maintenance in industry is good business. By increasing productivity and reducing employee turnover and absences, it brings increased earnings for both employer and employee.

The insurance carriers' contribution to progress in industrial medicine has been a direct outgrowth of their concern with accident prevention which reflected the need for compensating workmen for injuries suffered on the job. Today our loss prevention department employs about 400 trained people, including safety engineers, industrial hygienists, and specialists in such fields as radiation, noise, and applied research, in addition to a sizable medical staff.

Although engineering skills will continue to be important in accident prevention, they cannot control the attitude or reactions of the individual to various situations or conditions. They cannot control the actions of a preoccupied parent worrying about a sick child, an impending divorce, or an insurmountable debt. Nor can they do much to control the reactions or attitudes of one who is under par physically. A good medical program not only aids in accident prevention and occupational disease control, but can bring about marked improvement in the health of employees and their families at home. Thus, in our medical loss prevention department we now have 6 full-time physicians, 2 part-time physicians, and 24 nurses, who ad-

vise and consult with policyholders on all phases of industrial preventive medicine.

The activities of our medical loss prevention department are confined chiefly to the promotion of new medical programs and the evaluation of existing programs in policyholder plants. Recommendations are based on factual data obtained from surveys and studies of the individual plants. In each instance, we attempt to design a program to fit the specific needs of the plant, whether it be a first-aid program, a plant nurse, or a complete medical service. Factors taken into consideration are: number of employees, by sex; median age of employees; type and severity of occupational exposures; absenteeism; labor turnover; job placement procedures; and seniority and health clauses in union contracts.

The recommended amount of physician and nursing time spent in the plant depends upon the number of employees and the severity of occupational exposures. We usually recommend 1 hour of nursing time per day for each 75 employees and 1 hour of physician time per week for each 50 to 75 employees.

Economic Benefits

One of the primary benefits derived from an inplant medical program stems from better case control of minor injuries and illnesses. Good case control does nothing to prevent injury or illness, but it has a marked effect on the subsequent period of disability and thus reduces compensation and medical costs for the policyholder and the insurance company, as well as wage losses for the employee. Reduction in these costs alone will often defray the expense of the medical program.

For example, in a plant employing 575 people, there were 565 man-days lost because of injury during the year preceding the installation of a medical program, with medical costs for injuries amounting to about \$3,200 and compensation costs totaling \$3,100. During the first year after the medical program was begun, only 168 man-days were lost as a result of injuries. Medical costs dropped to \$1,450 and compensation costs to \$875, a saving of \$3,975. The cost of the medical program was \$2,500.

Direct costs for medical care and disability,

By Kenneth E. Markuson, M.D., M.P.H., division medical director, Liberty Mutual Insurance Company, Philadelphia, Pa.

of course, constitute only a fraction of the total costs of illness and injury. The National Association of Manufacturers has stated that each day's absence costs a plant $1\frac{1}{2}$ times the daily wage, and surveys have shown that the national rate for absenteeism is 9 days per employee per year. Thus, in a plant employing 500 people at an average wage of \$12 a day, the annual cost of absenteeism to the plant would be \$81,000.

It would be ridiculous to assume that a medical program could reduce absenteeism to zero, but we do have several plants in which a good medical program has been able to reduce the figure by 50 percent or more. Assuming even a reduction of 25 percent, a saving of \$20,250 could be realized in the aforementioned plant from control of absenteeism alone. To this are to be added the savings derived from decreased compensation costs, increased production from healthier workers, and improved morale.

The Greatest Potential

Savings in workmen's compensation are perhaps the most readily discernible benefits of an industrial medical program, but it is in the prevention of nonoccupational diseases that the greatest economic potential lies. A study by Dr. M. N. Howard, plant physician for the Socony-Vacuum Oil Co., points out the relative importance of the nonoccupational and occupational causes of disability: Of 6,092 man-days lost for medical reasons during 1949, 4.0 percent were lost because of occupational disease or injury; 6.7 percent because of nonoccupational injury; and the remainder, 89.3 percent, because of acute or chronic nonoccupational illness. Acute illness, including the common cold, accounted for 51.1 percent of the lost time, and chronic illness for 38.2 percent.

Establishing a plant medical service essentially for the control of toxic exposures is comparable to limiting service to the care of industrial injuries. Both of these services are important components of a plant medical program, but they do not embrace the broader aspects of modern industrial medicine. A modern industrial medical program should be designed to provide for adequate case control, the prevention of nonoccupational disease as

well as occupational injury and disease, the control of absenteeism and labor turnover, the maintenance of effectiveness of the individual worker, and the improvement of labor-management relations.

Veterinary Medicine

PHR The zoonoses, because of their relationship to disease incidence in man, have gained public health significance for veterinary medicine in the past 10 years.

Twenty-one States and four Territories created veterinary public health divisions in that period, and about 18 States now participate in a program of animal disease reporting.

Cooperation between epidemiologists and veterinarians has concentrated medical attention on many animal diseases which are communicable to man. Furthermore, certain diseases have recently been found to be transmissible to man from animals not previously implicated.

Virus diseases of veterinary public health importance include equine encephalomyelitis and psittacosis. The first is conveyed by birds or mosquitoes to both horses and man, often coincidentally. New questions about the epidemiology and transmission of psittacosis were raised when poultry plant employees developed the disease after contact with domestic turkeys. Preliminary investigations conducted by the Colorado State Department of Public Health suggest that antibody titers for psittacosis may be normal for some fraction of the population. Treatment of this disease with antibiotics temporarily inhibits antibody formation and reduces the number of reported cases.

Following the epizootics of western strain equine encephalomyelitis in Saskatchewan,

By Martin D. Baum, D.V.M., M.P.H., chief of public health veterinary services, Colorado State Department of Public Health.

Canada, and the 1941 outbreak there, a test against neurotropic viruses was devised which helps to differentiate between poliomyelitis and encephalomyelitis. Soon after the first equine outbreak, a number of humans evidenced a central nervous disorder which was thought to be nonparalytic poliomyelitis.

What appears to be of utmost significance is the observation that a number of children affected with the western equine virus developed mental insufficiencies—in some cases, within a few weeks after the acute symptoms developed. Pursuit of studies in adults who had been affected with the disease revealed that a high percentage had died, and some had become mentally ill. Saskatchewan public health workers believe that the neutralization test should be used whenever causes of mental change in patients are obscure.

Developments in rabies control include modified live virus avianized vaccines and a hyper-immune serum to be used in conjunction with the Semple series as well as improved diagnostic techniques, such as examination of the gasserian ganglion. Studies of the propagation of sylvatic rabies among insectivorous and frugivorous bats and other wildlife are also in progress.

A 1950 report from the University of Wisconsin tended to support earlier accounts of another virus zoonosis in man. Vesicular stomatitis, once considered peculiar to swine, horses, and cattle, was diagnosed among laboratory workers.

Q fever occurs in man as a result of airborne infection, from consuming unpasteurized milk from infected cattle, and from contact with cattle, sheep, and goats. Indeed, symptomless carriers among livestock are the principal reservoir of Q fever.

Some of the bacterial diseases which may be imparted to man by livestock are leptospirosis, salmonellosis, brucellosis, bovine tuberculosis, tularemia, and anthrax. Leptospirosis and salmonellosis also are carried by several species of animals. The presence of healthy or symptomless carriers of both hinders efforts to define the distribution of these diseases. The number of leptospirosis cases is rising, but a vaccine has been developed, using 1 of the 4 leptospira serotypes which cause the disease in the United

States, and field results are promising. It is possible, too, that a product effective against typhoid and salmonella carriers may become available.

Bovine tuberculosis is responsible for a condition found now and then in children and is usually diagnosed as cervical lymphadenitis. The disease persists despite measures to rid the livestock population of the condition and efforts to maintain the low infection rate of 0.5 percent enjoyed by all States. The current brucellosis incidence rate for United States cattle is 2.6 percent, enough to present a persistent public health threat.

Reports of *Vibrio fetus* in male dairy and farm workers have refuted the assumption that the malady was limited to females.

Continuing research in protozoan, mycotic, and parasitic disease control methods will undoubtedly expand the veterinary share of responsibility for public health and emphasize the place of well-trained public health veterinarians as part of the epidemiology team.

Questions in Tuberculosis

Within the last 10 years treatment of tuberculosis has changed notably. New surgical techniques have been developed, but more important has been the introduction of new drugs—streptomycin, para-amino salicylic acid, and isoniazid. Although there is still much to be learned about drug therapy, tuberculosis experts generally agree that it has made patients bacteriologically negative more quickly than other treatment, and that it has prolonged life and promoted healing of open lesions.

Our knowledge of tuberculosis as a disease is in a state of flux as a result of the use of these new drugs. They may conceivably have unforeseen influences on some of the indicators of tuberculosis. Does isoniazid make the tuber-

By Robert Dyar, M.D., California State Department of Public Health.

culosis bacillus nonpathogenic for guinea pigs in some instances? Does isoniazid reverse a tuberculin reaction? What happens if a recently converted tuberculin positive child is treated with this drug? Is it preventive?

There is some evidence that the disappearance of tubercles with drug therapy may not be permanent. If seemingly bacteriologically negative patients leave the hospital after a short period of treatment, or if they are never hospitalized at all, are they conditioned to handle themselves properly in relation to their family? Should institutional treatment be a prerequisite for home care?

Epidemiological Phenomena

Associated with the developments in therapy, though not known to be the result of the developments, are certain epidemiological phenomena of significance to public health workers. The following data from California, which I believe are indicative of what is happening throughout the country, will illustrate:

Since 1946, mortality has been declining more rapidly than morbidity. Since 1947, mortality rates have declined about 25 percent each year, but morbidity rates have decreased only about 2 percent. (There was an increase in morbidity from 1946 to 1947.)

The age-sex distribution of new cases of tuberculosis has changed. Rates in both sexes in the age groups under 5 years and 5-9 years have increased. This may be due to changes in nomenclature and morbidity reporting practices, but more likely it is because of an actual increase in cases. Rates in men 20-34 years and 55 years and over and in women 20-24 years have declined more than rates in any other age-sex specific group.

There appears to be a greater concentration of cases in terms of source. An abnormally high proportion comes from jails, penal institutions, and mental hospitals.

The total number of cases of tuberculosis reported annually is about the same each year. The number of tuberculosis hospital beds available (for subsidized care) reached a peak in 1952 and has declined about 3 percent since then. But utilization of these beds has dropped steadily since 1951, with a 10 percent drop from

1953 to 1954. At present, 1 of every 5 beds is empty. Data from selected hospitals indicate that the average length of hospital stay is declining, and there is unconfirmed evidence that fewer cases are being hospitalized initially.

Questions Raised

These epidemiological phenomena raise a number of questions that public health workers must consider if they are to fulfill their responsibilities in the control of tuberculosis. Many cannot yet be answered; many others must be answered in the light of problems and resources peculiar to each public health jurisdiction.

Indexes of control: How reliable are reported morbidity and mortality as indexes of what is happening in tuberculosis? Would not the results of periodic tuberculin testing give a better index of infectivity of tuberculosis, and indirectly of the effect of control programs?

Hospital facilities: Should we stop construction of tuberculosis hospital facilities? To what use can we put existing facilities as they are no longer needed for tuberculosis? Or can we assume that tuberculosis beds will become available for other uses?

Case finding: Is the mass survey outdated? Are surveys of selected groups justified? Should we continue routine X-ray examination of all hospital patients? Should we discard all case-finding procedures except the search for sources of infection by the case-contact investigation method? Can we rely on any single means of case finding?

Service programs: What effect does the increased responsibility for the care of tuberculosis patients in the home have on the service programs of public health? Are public health education programs geared to home care rather than hospital care? Are public health nursing services adequate in terms of skill, time, and staff to assume the increased responsibilities?

Family problems: How does the family react to the presence of a chronically ill person in the household? How is the increased load for care of the sick member absorbed by the household? Is professional help available to the patient and his family on financial, social, and emotional problems? What provision is made for the pe-

riodic determination of the infection status of children in the household?

Supervision and followup: Should followup procedures for the patients treated at home differ from those for the hospital patient? Are the tuberculosis registers providing the greater detail necessary to insure proper supervision of the patient at home?

It seems that present trends in the treatment of tuberculosis are shifting much of the burden from hospitals to health departments. If health departments are to meet their new responsibilities, they must review conscientiously their professional services and administrative procedures to be sure they are adapted to the problems of home care. They must review critically their present activities in order to eliminate the unnecessary and provide time for increased attention to tuberculosis. Additional staff, particularly nurses and social workers, may be necessary. Tuberculosis is a disease of rapidly declining mortality, but our best efforts will be required to erase the final, and most persistent, evidences of it. This is no time to view tuberculosis with complacency.

Water Treatment Trends

Population growth, urban concentrations, increased consumption of water for cleaning, bathing, and gardening, occasional drought, and industrial uses of water have placed heavy burdens on the water supply. These burdens are greatly influencing water treatment.

Dallas, Tex., last year developed an emergency supply of water from the Red River, 60 miles away. The waterworks people were obliged to work out a solution for the treat-

By H. W. Poston, senior sanitary engineer, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati, Ohio.

ment of this water of poor quality without the benefit of an appropriate treatment plant.

Tastes and Odors

The removal of tastes and odors from water is not at all helped by meager knowledge concerning the causative agents and the lack of definitive terms for describing odors. It is believed that most tastes and odors come from minute amounts of complex organic compounds. Actinomycetes, closely related to bacteria and fungi, are claimed by Silvey to be the source for unpleasant tastes and odors in water. Control over the conditions of reservoirs—keeping them clean and eliminating marginal and littoral vegetation—would destroy the main food sources for these organisms, he states.

The organic compounds recovered in the experimental work at the Robert A. Taft Sanitary Engineering Center are tested in distilled water to reproduce specific tastes and odors.

A musty component in water, probably an ester, has been recovered from the Ohio, Mississippi, and Scioto Rivers and the Great Lakes. Appearing to be of natural origin, it is not thought to be a product of industrial wastes.

Detergents

Coagulation problems associated with detergents have been reported in many localities. In Kansas, Culp and Stoltenberg found that synthetic detergents present in raw water to the extent of 3.0 to 3.5 p.p.m. would interfere with treatment. Gallaher reported similar difficulties in Wisconsin. Todd in West Virginia experienced foam to a depth of 4 feet on the raw water basin, difficulty in coagulation and settling, inability to remove iron, and failure to remove taste even when chlorine dioxide was increased to 4 times normal.

Langelier and co-workers conducted coagulation studies using sequestering agents such as sodium hexametaphosphate. Smith, Walton, and Cohen recently found that household detergents may cause difficulty in raw water coagulation at water treatment plants drawing on a surface supply. As the use of detergents con-

tinues to expand, their effects must be studied further.

Filtration

Necessarily, filter rates of over 2 gallons per minute per square foot are used in many plants during periods of heavy demand. Usually, at these times, the water is warm and coagulation problems are minimal. In many plants, water applied to filters meets the requirements of the Public Health Service's Drinking Water Standards insofar as turbidity and bacteria are concerned, owing to good coagulation and chlorination.

Baylis at Chicago, experimenting with filtration rates up to 5 g.p.m./sq.ft., concludes that, for water not high in turbidity and turbid waters properly conditioned, a filtration rate averaging 4 g.p.m./sq.ft., but not exceeding 5, will produce an acceptable effluent. The main reason for setting the maximum rate at 5 g.p.m./sq.ft. is the high initial cost of head occurring at higher rates rather than the passage of flocculated matter through the filter beds.

Jackson, reporting on the Dalecarlia Filter Plant (Washington, D. C.), concluded that water meeting the present standards of chemical quality, turbidity, and bacteriological purity can be produced at rates up to 5 g.p.m./sq.ft. over a range of temperature from 50° to 72° F., provided efficient pretreatment is maintained, superior free residual chlorination is employed, and qualified operating personnel are available. At high rates, anthracite (0.76 mm.) demonstrated more favorable characteristics than did sand (0.56 mm.) with regard to all phases of head loss, flow, and length of run, Jackson concluded.

Fluorides

Controlled fluoridation now applies to 1,000 water supply systems serving 20 million people. The fluoride content is maintained between 0.6 and 1.2 p.p.m. More than 500 communities are using water which contains a natural excess of fluorides. Pilot plant studies indicate that calcined alumina in contact beds was effective in limiting fluorides to a desirable level with low operating and construction costs. Other ex-

change media that can be used for fluoride reduction include calcium phosphates, anion exchange resins, and magnesium. The selection of a particular medium is based on local conditions, cost, water analysis, and capacity required.

Water Quality

Methods for determination of bacteriological water quality have not kept pace with the needs. A rapid and accurate technique has long been desired.

The Chicago Department of Water makes use of the electron microscope in obtaining rapid identification of coliform organisms, a method not practicable for most water supplies. The latest edition of Standard Methods of Water Analysis describes a tentative procedure using the membrane filter for enumeration of these organisms. This is essentially the method described by Jeter, Geldreich, and Clark in the April 1955 issue of the *Journal of the American Water Works Association*. By this method only 16 to 18 hours are required for a complete coliform test whereas 24 to 72 hours are required when using the MPN procedure. Large samples of water containing low coliform density can be concentrated by this direct-plating method.

Civil Defense Needs

Water supply methods for civil defense are not much different from normal objectives. They are merely intensified by large-scale evacuation of heavily populated areas, necessitating additional water supply at emergency evacuation centers. These emergency supplies must be available immediately if evacuees are to be kept from drinking from contaminated sources. Each area has a problem of locating sources prior to any emergency and of providing treatment.

The hazard of water contaminated by radioactive fallout material will not decrease as rapidly as the radioactivity in the water decreases, owing to the fact that the most dangerous of the radioisotopes capable of lodging in the body have relatively long half-lives. It may be dangerous to drink such water long after the

external radiation from fallout has decayed to innocuous levels.

Standard water treatment processes have been found to be of limited value in removing soluble radioactive materials from the water. If the radioactivity is not so closely associated with particulate matter as to be removed with the particles, expensive treatment such as ion-exchange or distillation might be necessary to produce safe drinking water.

Micro-organisms that might be used as biological warfare agents may include pathogenic bacteria, fungi, rickettsiae, viruses, and protozoa. These might be disseminated by the enemy in air, water, food, or by any other route that would permit the BW agent to reach the oral and respiratory tracts, or to penetrate the skin.

According to Berger and Stevenson, a BW attack may not be accompanied by readily detectable changes in the physical characteristics of the water. They say that substantial free

chlorine residuals in important segments of the distribution system represent the best current means of protection—which may not be complete, however, under all possible circumstances. Current routine bacteriological water quality examinations are not useful in detecting the presence of BW material.

Chemical warfare agents are considered less attractive as intentional water contaminants than a number of biological agents. Nerve gases, among the most toxic chemicals known, are one or two orders less toxic than some of the BW agents. Their toxic effects are felt promptly. The Army has developed and tested methods for removing nerve gases from water. Kits are available for detection of various chemicals in water.

The possibility that unknown chemical agents may be available may revise this estimate of a lack of serious threat to water supplies from CW agents.

PHS Advisory Council Appointments

Dr. Joseph F. Volker, Dr. J. Roy Doty, and Edward Y. Blewett were appointed October 1, 1955, to 4-year terms on the National Advisory Council, National Institute of Dental Research. Upon recommendations of the council, which is composed of 12 men outstanding in science, education, and public affairs, the Surgeon General of the Public Health Service awards grants to dental schools, universities, and other non-Federal institutions conducting research on diseases of the mouth and teeth.

Dr. Volker, president-elect of the International Association of Dental Research, is dean of the School of Dentistry and director of research and graduate study, University of Alabama Medical Center. Formerly professor of clinical dentistry and then dean, Tufts College School of Dentistry, from 1942 to 1948, at times over the past 9 years he has served as dental consultant to Czechoslovakia, Germany, Thailand, and Jamaica.

Dr. Doty is secretary of the Council on Therapeutics, American Dental Association,

with which he has been associated since 1943. He is the 1954 recipient of the distinguished alumni award of Monmouth College, Monmouth, Ill., from which he was graduated in 1927 and where he instructed in chemistry for 3 years. He was also associated with Louisiana State University School of Medicine, first as instructor and later as assistant professor of physiology. He is the author of numerous scientific articles.

Mr. Blewett has been dean of the College of Liberal Arts, University of New Hampshire, since 1939. In the preceding 12 years he served in numerous other posts at the university, as assistant to the president, alumni secretary, director of the summer session, and executive secretary of the university. He is a member of the executive committee of the New England Association of Colleges and Secondary Schools and in 1948 and 1949 was chairman of the arts and sciences' division, Association of Land Grant Colleges and Universities.

An experience in interprofessional team action directed toward rehabilitation of the adult poliomyelitis patient.

Social Considerations in Patient Management

By GEORGIA B. TRAVIS, M.A.

ANY prolonged illness which takes the young adult from his vocational preparation, from breadwinning or homemaking, and places him in the unaccustomed role of patient obviously makes great realistic and psychological demands upon the individual and his family. The degree to which equilibrium is disturbed depends on the interrelationship of several factors, namely, the nature of the illness, the age and personality of the patient, and the manner and degree of family and personal disruption created by the absence of the patient.

Medical management can determine, in part, whether the disturbance will prove catastrophic, leading to permanent, almost total, destruction of normal satisfactions for patient and family, or whether it will prove temporary, altering the pattern, yet not destroying the groundwork, for constructive living. Furthermore, the ability of the patient to utilize medical care to the maximum will depend on how adequately his

social needs are met. These are the reasons why hospital personnel are concerned with social needs.

We are especially alert to what we learn from working with any group of long-term patients because each experience becomes potentially valuable in planning the chronic disease programs of tomorrow. A focus on rehabilitation obviously will be necessary in these programs if they are to be constructive and no more expensive than necessary. Rehabilitation-slanted efforts require interprofessional team action, a method more easily praised than implemented and dependent for its success on medical leadership.

At Colorado General Hospital, a part of the University of Colorado Medical Center in Denver, the application of the multidisciplinary approach over approximately 10 years in working with poliomyelitis patients has yielded certain observations. Some may have wider applicability.

The hospital is small, having only 300 beds. It is tax-supported, and the only private patients there are those under circumstances of special need. The cost for these poliomyelitis patients, all adults, is paid by the National Foundation for Infantile Paralysis. This organization not only has made possible the financial support of the patients but also has aided the teaching activities. It has encouraged a team approach and naturally evolved.

Dr. Winona C

Mrs. Travis was director, medical social service, University of Colorado Medical Center, Denver, from July 1946 to August 1, 1955. She is now medical social consultant, disability freeze unit, Washington State Department of Public Assistance. Mrs. Travis is the author of "Cultural Framework of Maternal and Child Health Services in Australia" (Medical Social Work, January 1955), written as the result of a Fulbright lectureship at the University of Sydney in 1953.

the poliomyelitis unit, and, later, of Dr. James Stephens, the present director.

The Patients' Problems

In poliomyelitis the sudden onset, the need for isolation, the uncertainty regarding extent of paralysis, the respirator care in bulbar cases, and the community fear or panic during an epidemic create certain characteristic problems during the early stage. Later arise the problems connected with family, school, or job disruption, and anxiety as to the degree to which affected parts will respond to treatment.

Still later, among the dwindling group who remain in the hospital, arise the difficulties from monotony and vegetation, from the adjustment to being relegated to the status of uninteresting chronic cases after a dramatic period of great attention, from very deep fears about the future, and from competitive anxiety upon seeing other patients make faster gains.

Finally, whether patients with residual paralysis go home early or late, they have the problems of being discharged home crippled to a greater or lesser degree, to carry on with medical recommendations, and to take up the task of competing with normal people in the outside world.

Despite their similarity, each problem varies according to the patient. Let us look, for example, at what the sudden transition from full activity to respirator status meant to three individuals.

One patient, the mother of six children, one of whom was an infant, said that as she lay in the respirator all she thought about was that she had left the house for the hospital with only one bottle of formula mixed ahead for the baby. No one else in the family knew the formula.

Another patient said that one of his wife's best friends had died in a respirator 2 years previously, that he thought he would die and knew that his wife thought so too. His main concern was getting his mother to come from another State before his wife went to pieces.

The third patient, a waitress responsible for the support of her little girl, had been rushed to the hospital before she could make plans for the child. Because she could not speak, we did not even know of the child's existence until the

landlady telephoned that the little girl had no shoes. The mother could only shake her head and cry when the child was mentioned.

To need to depend for one's breath on something outside one's self is, indeed, the ultimate in dependence. It is not strange, therefore, that the patient who is rushed to an iron lung from the excessive activity which so often seems to precede onset is anxious about yielding up his life to the efficiency of a machine. The fear induced by even the rattle of an uneven caster is familiar to us.

This common reaction is highlighted by the feelings of a patient who unfortunately was in a respirator with faulty hatches which occasionally blew open, lowering the pressure so that he could not breathe or cry for help. The respirator was repaired as soon as the problem was discovered, but during his entire period in an iron lung the patient lay in a state of tension, listening for the clickety-clack of the hatch, particularly during the graveyard shift when a nurse came in the room only every 15 minutes. He said that he knew he would be dead 14 minutes if the hatch went out the minute after she left. The patient was actually traumatized by his experience and still has a lack of confidence in the chest respirator.

During the acute period of poliomyelitis the patient's uncertainty regarding the extent of paralysis which will develop is another common form of distress. Patients tell us that they wonder whether they will wake up the next morning with another limb paralyzed. They describe nightmares of finding they cannot move at all.

One pretty woman, who felt insecure with her husband and who relied on her charms to hold him, had facial paralysis so that her eye and mouth were drawn down and she could not manage her tongue. She was horror-struck over her appearance. When she asked the physician how much farther the paralysis would go, he told her honestly that he did not know. She later described her anguish over what would happen next. She told her husband that he did not need to visit a "monster," and he told us that she offered to get a divorce.

Isolation adds its problems to the acute stage. During the period of fear, distress, and regression which illness brings, the patient needs the

warmth and reassurance of his family. Complete isolation not only sharpens his distress but heightens the family's panic. The physicians here have greatly lessened the number of overwrought patients and relatives by permitting relatives to come to the patient's door during the isolation period.

The Value of Social History

Lack of space prohibits describing the damage poliomyelitis causes to family ties and the reasons for a gradual deterioration of the patient's morale. Our concern in this discussion is how to prevent the panic and worries and family damage of the early stage, with their concomitants of irritability and uncooperativeness, how to obtain the earliest possible hospital discharge, how to prepare the patient for adjustment to his handicap constructively when he goes home. We have not found all the answers, and we do not always put into effect those we do know. However, there are certain things we have learned to do or not to do, and these I will describe.

From the beginning the patient must be understood as an individual and treated accordingly. Although the initial social history obtained from family members and the patient is often far from conclusive, it does afford a base from which the hospital team can proceed. Therefore, the history should be taken within the first few days after admission.

The nature of the epidemic slants the initial histories in that above all else the hospital beds must be kept cleared during the height of the season, and, if most of the patients are improving rapidly, we must know which of them has a suitable home to go to, which patients might be eligible for another hospital, and those patients for whom community planning must be begun immediately if the bed is to be released as soon as the patient is medically ready. Because time is too limited during these early days to permit individual exchanges of information among members of the team, regular conferences are held for all professional personnel. Pertinent information is shared at these conferences, and the plan for the patient's immediate future is decided.

The initial history provides information

about the physical setup of the home and an estimate of the capacities of the family to provide convalescent care and make arrangements for outpatient supervision and physical therapy. In addition the social history gives the medical social worker information about urgent family problems which she needs to take care of so that the patient is not needlessly harassed. The history provides an understanding of what the patient is worrying about. This insight will help personnel deal considerably with irritable or demanding behavior. If the worries are, as they so often are, about the patient's own condition or treatment, the informed physician can clear up the patient's misapprehensions and gauge his interpretations accordingly. Attention to the patient's problems and fears lessens the trauma of poliomyelitis to the patient. It makes him realize that the institution is genuinely interested in him and, therefore, that he can relax and trust the staff. Through the lessening of the patient's anxieties, the demands upon medical and nursing personnel become a little less.

Sensitivity in Management

The administration of the hospital vitally affects meeting the patients' social needs. For example, installation of a telephone system, which made it possible for patients to talk to their relatives, proved to be a most constructive measure in reducing worries. Relaxation of visiting hours permitted a great degree of personal security for patients and relatives. Secretarial service for group conferences, facilitating a flow of abstracts to local referring physicians and discharge recommendations to local health and welfare departments and national foundation chapters, helps to assure the continuity of care which is so essential but so difficult to maintain at a time when it is even more difficult than usual to handle routine paperwork.

The management of transferring patients to another hospital deserves special mention. The pressure for beds and of time tempts making a hasty arrangement in which the patient has not shared. The patient receives an abrupt reminder of his powerlessness over his own destiny if he is notified that an ambulance will take

him to another hospital within a few hours. Other patients, identifying themselves with their departing companion, may greatly resent their own helplessness.

This is the kind of destructive experience which leads to an eventual apathy or a sense of futility. Fearfulness over being moved, even into another ward, is evident in both adults and children with long-time disease and can only be accounted for by the transference of former associations of security to the particular bed or ward or respirator in which the patient is lying.

It is difficult for the patients who remain in the ward to see their former co-patients get better more quickly and leave. The interim months after the peak of the epidemic, when patients having some residual paralysis go home or transfer to another hospital, are particularly trying in several ways. This period coincides with the time when the nurses who arose to the emergency become bored with enemas and baths.

From the standpoint of the patient's mental health, expressions of hostility are welcome, and griping is not discouraged. However, as hostility is so readily attached to immediate objects, the nursing service and the food receive the greatest impact. The physician and the nurse in charge have a great responsibility of interpretation to the staff members who are in the direct line of fire.

While the physician and head nurse are coping with these problems, the medical social worker and the occupational therapist can also be of help to the patient. By getting the patient to talk out his feelings and by listening with understanding, the medical social worker can give support to the patient who despairs about his future. Encouraging the patient to use his good extremities in constructive occupation, which happens incidentally to work off some anxiety, and devising activities that will take the patient's mind off his troubles are among the contributions of the occupational therapist at this time.

Group recreation is very important although we are providing it in only a limited way. Until the advent of television, movies were the patient's first choice. Movies were so desired that our patients have taken up collections

among themselves to rent films in order to supplement the movies the hospital has been able to provide. Television now provides the most important outlet for escape from reality. Religious services have proved of great benefit to some patients, as have the individual visits of the chaplain and the ministers. Volunteers who provide either group entertainment or individual friendly visiting have also been of real value.

When the long pull sets in for the badly handicapped patients, the hospital encourages families to take patients home for weekends or holidays. These patients are given passes to leave the hospital as soon as their physical condition permits. This policy of weekend and holiday leave requires substantial sacrifice from nursing personnel because the patient must be dressed and undressed at odd hours, often the busiest or least staffed times of the day.

Although the patient longs to go home, his first visit especially may be very difficult. For the first time, he goes up his own sidewalk and stairs as a cripple, rather than as a fireman or an electrician striding home for supper or as a mother with her arms full of groceries. However, the gradual adjustment to the outside world during hospitalization makes the eventual discharge much less difficult for the patient and less fearsome for the family. The trips outside have helped break the monotony. Most of all, they have helped the patient remain part of the family group.

The feeding of patients who have paralysis of the upper extremities is another management problem bearing on the patient's eventual adjustment. And more, it is a practical problem of no small magnitude. The patient should be fed when the tray arrives. Like being moved without warning, for one to lie watching the hot soup grow cold and the grease congeal around the meat is a dismal reminder of complete helplessness. To be fed like an infant is bad enough.

Planning Vocational Rehabilitation

Early vocational rehabilitation planning is another constructive measure which can be employed. The mills of vocational rehabilitation grind slowly so that aptitude testing and initiation of forms and counseling service need to be

set in motion early. Doing something or reading something which the patient feels is directly related to earning a livelihood after discharge brings much stronger motivation than activities which are busy work or amusement.

Furthermore, the successful vocational rehabilitation of the handicapped person is the greatest single process in restoring his means of earning money, having a daily occupation, and usefulness to his family, thereby achieving self-esteem and the respect of others. The remarkably ingenious talents of the physical therapist and the occupational therapist can be made to count if the occupational goal of the patient has been established long before he leaves the hospital.

Patient-Physician Relationship

Of all the measures which are employed to sustain and develop the morale of the long-term patient, an almost intangible one, but calling for deliberate action, is that termed supportive help. Morale is basically a matter of self-esteem. A philosophical maturity not ordinarily encountered in the young is required before people are capable of separating the value of personality or self from that of the beauty and usefulness of the body. The equating of physical worth with personal worth must be broken down if the patient is to value himself sufficiently to make the tremendous efforts which are and will be required of him.

We are indebted to those who have worked with other diagnostic groups, notably cancer patients, for the knowledge that one can help a patient make the separation of inherent value of body and personality by utilizing the knowledge that most people place upon themselves the value that other people place upon them. If, by the actions and attitudes of others, a patient is made to know that he is a valued human being, worthy of sustained consideration and interest, it does much to lessen his feeling of worthlessness. All hospital personnel do contribute, positively or negatively, to the patient's attitude toward himself.

The physician's role is particularly significant. The patient may be especially attached to a particular nurse or physical therapist, and it is the medical social worker's special job to

give the patient support. However, there is no one who has the meaning to the patient that the physician has. The doctor's small acts or words take on far greater importance to the patient than even the doctor may realize. In a teaching hospital this may pose a problem more serious than is readily apparent. The chronic patient lacks medical interest, and the intern or resident or staff physician who was so interested in him when he was acutely ill now may pass him by.

The change of resident physicians or transfer of the patient from an internist to an orthopedist, although intellectually comprehended as part of the system, may actually seem to the patient desertion by his most cherished friend, although the word "friend" does not connote the combination of dependency, veneration, and desperate hope which go into a paralyzed patient's feelings about his doctor. Knowing perhaps the reasons for the casualness which social workers sometimes display in transferring patients to other workers, I am aware that the physician may feel embarrassed or think he is being egotistical to consider how much he means to the patient. The doctor may not realize that it is not he as an individual but rather what the patient has vested him with that makes him so important.

The value the physician seems to set on the patient becomes to the patient a measure of his own worth. Because the patient must sustain a feeling of personal worth if he is to strive, the efforts of our sensitive physicians in going beyond the line of duty to show their continuous interest in the patients have been of immeasurable value.

Planning for Discharge

Discharge planning for the badly handicapped patient must be begun a long time before the patient is to leave. Suitable housing will be the most difficult need. If the patient will require a nurse, there must be room for her in his home. Arranging for a housekeeper or practical nurse is a time-consuming task. Financial resources usually cannot be secured quickly. The patient's long-time participation in working out details with the worker and his family helps his adjustment to the frightening

matter of leaving the haven of the hospital. The long planning also helps the family ready themselves psychologically. Severe disruption in family life can take place during the long absence of one member. If this has not been prevented or if it has been augmented, as sometimes happens, discharge may be very difficult to work out.

With a respirator patient particularly, obtaining and financing equipment may be another long-time matter. Any hospital without a medical social worker is practicing poor economy in respect to discharges because the majority of patients and families must have help in planning and carrying out discharge arrangements. Finally, it should be said that hospital discharge merely ends one phase of the patient's social needs. Before he leaves our care some professional person or persons in his own community must be found to help him with the difficult problems that lie ahead.

In conclusion, our goal with poliomyelitis patients is to send them home as quickly as possible and to send them there as fit as possible to meet the problems which await them. To do this, we must try to understand the patient as an individual and to adapt medical management accordingly. Social needs warrant not only the concern and activities of the medical social worker but the joint effort of the entire hospital staff as well. This joint effort is promoted by regular conferences in which all concerned with the patient's treatment share information about and decide on plans for his individual care. Our common effort is directed toward reducing worry, preserving family strength, reducing reminders of helplessness, providing mental stimulation, encouraging gradual adjustment to the outside world, sustaining the individual's belief in his own worth, and promoting early vocational and discharge plans.

New Aramite Tolerance

The Food and Drug Administration announced on October 3, 1955, a permissible tolerance of 1 p.p.m. of the pesticide chemical Aramite for 19 food crops.

The tolerance level applies to apples, blueberries, cantaloupes, celery, cucumbers, grapefruit, grapes, green beans, lemons, muskmelons, oranges, peaches, pears, plums, raspberries, strawberries, sweet corn (kernels, but not forage), tomatoes, and watermelons.

Commissioner George P. Larrick said no residue of the pesticide, however, would be permitted to remain on forage crops such as alfalfa. This is in line with FDA's policy that milk should be kept free of any pesticide because of its dietary importance to infants and invalids.

The tolerance level was set under a new law requiring the Department of Health, Education, and Welfare to determine what amounts of pesticide residue can safely be permitted to remain on food crops.

"Medical and social advances toward substituting treatment for the punishment of problem drinkers have not been matched in politics and in law."

Legislation and Alcoholism

By JULIUS ISAACS, J.D.

THE report of the Committee on Public Health of the New York State Bar Association (1) points up again the legal implications of public health practice applying to alcoholics. In understanding alcoholism, great progress has been made in the last 15 years. The affliction, now considered a major health problem, it is felt, can be treated successfully in many instances. Differences as to its nature and treatment do not prevent the accumulation of a body of knowledge which will help restore to health many whose lives are threatened by this disease. We must frankly concede that we do not know all the answers, but we have indications that we can find the right track.

We are learning to distinguish between alcoholism and problems associated with drinking that may be merely casual however toxic may be the concentration of alcohol in the blood. Such a distinction is essential if the courts, the physicians, and the social services are to prescribe appropriate treatment. There is no blanket definition, diagnosis, or treatment to

be applied to people who drink "too much": people who drive a car with a few drinks in them; psychotics who drink; homeless men who become drunk; criminals with a taste for liquor; or divorced people who occasionally tinkle. People with liquor on their breath, no matter how frequently they are in trouble, cannot all be lumped under the convenient label of alcoholics. To ignore the many distinctions among drinkers is to invite practical objections from judges, police, or anyone else who must cope with these persons.

Psychiatrists, social workers, Alcoholics Anonymous, and others will be the first to protest that techniques which have proved successful with certain well-defined kinds of drinking problems are of little avail in others. While we shift slowly from the traditional attitude that drinking should be punished to the modern view that addiction to alcohol should be treated as an illness, we cannot free the sane drinker from legal or moral responsibility as if he were a victim of a virus. The drinker with a problem, as distinct from the problem drinker, is not suffering from a disease of alcoholism. If, in the paragraphs that follow, the portrait of alcoholism is not always in sharp focus, it is because so much confusion persists between the drinking problem and the problem drinker. But a modern program for dealing with alcoholism, as well as with other social problems associated with drinking, will help public health and legal institutions to refine their concepts and tailor their practices to the patient.

Alcoholism, in the sense that it is an obses-

Judge Isaacs formerly sat in the New York City magistrates' court and the court of special sessions. He is chairman of the board of visitors of Hart Island for the Welfare and Health Council of New York City and a director of the Association for Psychiatric Treatment of Offenders. A lecturer on medical jurisprudence, municipal government, city planning, and criminology, he is retiring chairman of the Committee on Medical Jurisprudence of the Association of the Bar of the City of New York.

sion, is a major social tragedy. Compulsive in character, progressive in its damage to the alcoholic, his family, and the community, it exacts a costly toll. In "skid row" sections, in courts, jails, and city hospitals, we find the visible alcoholics, about 20 percent of the total number. The invisible majority, with no record of arrests or hospitalization, are hidden in offices and homes. Most of these refuse to acknowledge their condition, even to themselves, until the very last stages.

In penthouse or slum, the affliction strikes both genius and dullard, male and female (6 men to 1 woman). Most of the male alcoholics are in the prime of life, 85 percent being between the ages of 35 and 55. The alcoholic's life is curtailed by 2 to 12 years. The incidence of divorce is much above normal; 16 percent of the married male alcoholics are divorced and 25 percent separated. In New York City magistrates' home term court, 70 percent of the cases involve excessive drinking (2).

Alcoholism's annual toll of wage loss is estimated at half a billion dollars. The National Safety Council considers \$120 million alcoholism's annual contribution to preventable accidents. Attributable relief costs are \$22 million. Hospitalization for injuries and incarceration cost \$56 million. A good guess of the total enormous private and public cost to victims and society is well over a billion dollars a year (3).

Nevertheless, few States or cities have laws or procedures that provide for treatment and rehabilitation of the compulsive drinker. In trouble, his usual fate is a term of "reform" in prison. Medical and social advances toward substituting treatment for punishment of problem drinkers have not been matched in politics and in the law.

It is hardly practical to look upon prison to "reform" the parade of drunkards that passes before a police court. Park benchers, alms solicitors, and disorderly persons as well as workmen on a spree may be among the derelicts. Honest seamen temporarily on the beach and out-of-work longshoremen mingle with hopeless down-and-outers and periodic dipsomaniacs. Indiscriminate suspended sentences or short jail terms are futile for the chronic alcoholic. It is impossible even to separate the cele-

brators from the addicts. The defendants come before the judge in such numbers that he may not have time even for routine questions. As a first step, we need screening facilities to determine which defendants are in need of medical care and hospitalization. Adequate information, obtained before arraignment, would give judges information for proper disposition of cases. By such a procedure, confirmed alcoholics may be taken off the streets and committed to an institution for treatment if the legal mechanism for commitment is available and the legal criteria for commitment satisfactory.

The Hart Island Experiment

In a short-lived attempt to establish in August 1950 on New York's East River a place where a defendant might come for rehabilitation on a voluntary basis rather than go through the court's revolving door, New York City had a partial screening process. Here a special institution for handling homeless men whose problems were largely those of the indigent alcoholic was being created. These unfortunate people could voluntarily seek welfare department rehabilitation at Hart Island in preference to a correction department's jail. There was no compulsion to stay for any specified time. But one who left in less than 10 weeks could not return, and a suspended sentence might be executed. Medical care (including free eyeglasses and dentures when necessary), religious guidance, social therapy, Alcoholics Anonymous aid, vocational training, and job placement service were accorded to all. The rehabilitation program was humane, effective, and economically administered. It was a fruitful alternative to costly, barbaric, and useless successive jail sentences for those "offenses" which is society's label for the illness of alcoholism. Everybody had to work, selecting his job from the hundred or more work assignments for the operation and maintenance of the institution. Carpentry, electrical, laundry, kitchen, and dining room skills were on the way to being revived. With alcohol unobtainable, work to do, good food, recreation, and companionship, a change was soon noticeable. Weekly meetings of Alcoholics Anonymous helped in the struggle.

Resident employment counselors were there to obtain job referrals.

Since homeless men, such as those at Hart Island, rarely seek treatment and are afraid of being questioned, they are difficult to study. Accordingly, there is little scientific information about them as a group and their relation to alcohol. It was the recognition of this factor that led to the solicitation of the cooperation of the Yale Center of Alcohol Studies, which established a pilot study on the island.

The Yale center was not able to complete its work, for in the summer of 1954, because an increase in crime was held to require more jail space, Hart Island was overnight taken away from the New York City Department of Welfare and given to its Department of Correction. Thus, this potentially useful project ended before it was really on its feet. Whatever the needs of the correction department, the action eliminated a hopeful step in the treatment of alcoholism in New York.

In less than a 4-year period the widely heralded experiment at Hart Island appeared to offer a constructive approach. Since the experiment seemed to be sound in conception and efficient in operation, the Hart Island facilities were to be extended to include those who were not homeless but were willing to pay for rehabilitation there. It had been planned also to seek a State grant and a city budgetary appropriation for the creation of a halfway house to break the transition from the protected life at Hart Island to the competitive problems faced by the "alumni." This halfway house was to provide meals, lodgings, and recreation at cost in a controlled resocialization project until the Hart Island "graduate" had had a reasonable time to become secure in a newly achieved self-reliance—a self-reliance mixed with a dependence on an institutionalized way of life from which he must be freed at an individual pace. The Hart Island experience, as well as a somewhat similar project for study of homeless men sentenced to the Monroe County jail (conducted by the University of Rochester sociology department), might have provided the evidence needed to guide and obtain legislation for civil commitment to other nonpenal treatment facilities for wider varieties of the alcoholic sick.

This is the background to the note of disappointment implicit in the report of the New York State Bar committee. To explain that disappointment further, it is useful to make a brief survey of the history of legislation on the subject in New York.

Legislative Steps

New York State's progress toward enacting a sound alcoholism program has been slow. The penal law in force in 1897 provided: "Any person intoxicated in a public place is guilty of a misdemeanor, and may be arrested without a warrant while so intoxicated." In 1911, the words "is guilty of a misdemeanor" were deleted, *eliminating such offenses from a category of "crime" (4)*. However, these persons were still subject to arrest in a lesser category of offense, such as disorderly conduct that annoys others. In order to resolve any ambiguity, the New York State Legislature amended the penal law in 1955 to provide that a person intoxicated in a public place may be arrested without a warrant while so intoxicated. If the charge is sustained and the person found guilty, he is deemed to have committed an offense. The amendment (ch. 823, L. 1955) makes proof of annoyance to others unnecessary. The arrest gives the magistrate original jurisdiction. But the problem still is what to do with an alcoholic when he comes before the judge.

In 1910, the inferior criminal courts act gave New York City the power to establish a board of inebriety and hospital and industrial colonies for the publicly intoxicated. In 1911, the State's general municipal law (secs. 136–139b) provided for boards of inebriety by localities outside of New York City. These sections have *just been repealed (ch. 133, L. 1955)* since no city operated such a colony, and the administrative provisions of the law are out of date.

In 1911 at Warwick, a hospital and colony was established by the New York City Board of Inebriety. With the enactment of prohibition in 1920, the board was abolished and the colony closed. The board's first report was the only one filed. Its functions were transferred to the New York City Department of Correction, again a step back to punishment. That department has taken no action except to receive

at Riker's Island some alcoholics sentenced there on a variety of charges.

New York's education law (sec. 804) provides for the compulsory teaching in schools of alcohol's evil effects. Its mental hygiene law (sec. 201) permits a judge of a court of record to commit an "alleged inebriate" to a private licensed institution for mental disorders on application of his family, a relative or friend, an officer of a charitable institution, a public welfare officer, or the inebriate himself. The physician in charge of the institution must present his consent in writing. In addition two examiners must certify that the subject is incapable of conducting himself or his affairs properly or is dangerous to himself or others by reason of frequent drunkenness, whether induced by alcohol or drugs or other intoxicating substances. The certificate must show that he is in actual need of special care and treatment and that his condition is such that his detention, care, and treatment would be likely to effect a cure. The section provides that a person so certified or a relative or friend may, within 30 days, apply for a review of the order of certification to the State supreme court. A jury then passes upon his inebriety. Private institutions have been unwilling to assume the responsibility for consenting to such commitments for fear of false-imprisonment suits. In addition only the rich could afford the cost of institutional care.

Under the present New York State law only psychotics may be retained and treated in State mental hygiene institutions. Haggard and Jellinek (5) have defined psychosis as insanity or mental disease. They report that only a small proportion of men who drink to excess develop alcoholic psychosis. Although psychosis is not a common occurrence in chronic alcoholism, certain changes in personality which cannot be called insanity do eventually occur in most chronic alcoholics. The authors state that in about 1.5 percent of chronic alcoholics the deterioration of conduct becomes complicated by uncontrolled rages, delusions, or other disturbing symptoms. The condition is then designated as chronic alcoholic deterioration with psychosis. The psychotic inebriate is segregated in mental institutions, and in that way society takes care of him. But the nonpsychotic inebriate at present gets attention from society

only when he comes into conflict with the law. It is his illness which presents us with our primary challenge.

The world has been slow to consider the chronic alcoholic as a sick person. It has been slower still to concede that the alcoholic does not voluntarily choose the road to ruin. When the problem became acute, some localities "solved" it by jailing, some by exiling to other communities, and others by closing their eyes to the existence of any problem. From time to time, public opinion became aroused over these illusionary "solutions" and demanded action. It disturbed the community that arrest and jail were so expensive in money and lives. Finally, came a realization that here was a social problem better dealt with by appropriate social agencies than by police and prison. It was the social effects of alcohol that brought about the recognition of the need for committing alcoholics to treatment clinics rather than to jail.

In December 1948, the first clinic was established at the University of Buffalo, and the Edward J. Meyer Memorial Hospital set aside 20 beds for the treatment of alcoholic patients.

Through the efforts of the Medical Jurisprudence Committee of the Association of the Bar, the New York County Medical Society, and the New York City Academy of Medicine, the Rosenblatt bill was introduced in January 1949 providing a full-scale program. It called for the establishment of a bureau of alcoholic rehabilitation in the New York State Department of Mental Hygiene to study the causes, extent, prevention, control, and treatment of alcoholism and the rehabilitation of chronic alcoholics. To be established and equipped were hospitals, clinics, and custodial institutions or farms either in connection with other facilities for the diagnosis, classification, hospitalization, confinement, and treatment of alcoholics or independently. The bill also provided for the voluntary admission of alcoholics and the civil commitment of alcoholics to approved institutions by the courts. It was not reported out of committee.

In October 1949, the same groups proposed a bill creating a New York State Commission on Alcoholism along the lines of the Connecticut State Commission, directed to establish and operate information centers and clinics and to

arrange with existing hospitals to receive alcoholics for short-term treatment. It also provided a simple procedure for voluntary admissions and court commitments of alcoholics to hospitals, to the commission itself, and to members or groups of Alcoholics Anonymous. This bill was never introduced. Some objected that extensive additional facilities for long-term commitment of alcoholics were needed. So further time was wasted.

In 1952, the same interested groups retreated to the position of requesting simply a temporary commission to study the problem and report to the legislature. This time the objection was that the subject had been investigated enough and what was needed now was action. Finally, on March 31, 1952, a first step was achieved in the enactment of the Mitchell-Ten Eyck bill, ch. 354, L. 1952. It provided that the Commission on Mental Health in cooperation with the State departments of health and mental hygiene formulate a program to provide for the diagnosis, treatment, and rehabilitation of chronic alcoholics by public and private community agencies and authorized a study of the problems relating to alcoholism in conjunction with such a program. Appropriations aggregating \$145,000 were made to carry out the purposes of the bill—\$100,000 for services and \$45,000 for research.

Under this bill the local government has primary responsibility for initiating and operating the services on a matching 50-percent basis for the cost of operation. The State supplies in addition consultant and supervisory services.

New Clinical Services

Modest progress has been made in setting up a number of outpatient clinics under the program, but these are not open to voluntary patients. The University of Buffalo Alcoholic Rehabilitation Center, opened in 1948 as previously mentioned, expanded its work under the program in association with the Meyer Memorial Hospital. Another clinic, in addition to the one opened in 1949 at the Rochester Health Bureau, was established in the Rochester City Hospital. The University of Rochester sociology department is making a penitentiary re-

search study of men committed to Monroe County jail. New clinics were set up in Syracuse, in Binghamton, at the New York State University College of Medicine on Long Island, and in the home term court of the New York City magistrates' court. Further clinics in New York have been proposed.

Under the dollar matching by local resources, New York State's expenditure for clinical services from March 1952 to March 1954 was \$42,499; an additional \$27,305 was spent for research and administration. The 1955 allocation for services is \$69,303 and for research, \$39,458. It is possible that too much of the clinical service is research-motivated, but, if so, that is in line with the purposes of the legislation.

Recommendations

In the light of this history, the New York State Bar Association's committee report, which evoked this discussion, recommends: (a) that the State's program be expanded and accelerated; (b) that hospitals be encouraged to provide treatment facilities, medical schools provide research and training, and qualified medical personnel participate in and advance the program in closer cooperation with voluntary agencies for group therapy; and (c) that a keener awareness be aroused in local governments and health institutions concerning their responsibility for establishing and operating adequate facilities for rehabilitation.

For those who seek more specific guidance, these are the recommendations offered in 1947 by the Research Council on the Problems of Alcohol:

1. Problem drinkers suffering acute physical or mental damage should be admitted to general hospitals, mental hospitals, or other institutions.
2. Mental hospitals should accept directly or by referral from general hospitals symptomatic problem drinkers, that is, the psychotic. Farms and industrial colonies should be established for seriously deteriorated problem drinkers who have physical or mental damage.
3. Custody and care of alcoholics should be transferred from the police to public health agencies.
4. Facilities for treatment should be estab-

lished in the hospitals affiliated with medical schools so as to permit research and training of personnel.

5. Thoroughgoing research should be made into the causes, mechanism, and possible cures for alcoholism.

Support is warranted especially for the following recommendations of the New York State Bar Association: arrest, treatment, or punishment where over-use of alcohol is a factor; examination of the relationship to automobile accidents of over-use of alcohol by driver and pedestrian; acceptance of insurance companies of alcoholism as an insurable risk; more public education.

The New York State Bar Association attributes a want of fulfillment in the field of alcoholic rehabilitation to lack of medical interest and a failure of localities to initiate badly needed facilities. But the legal profession shares responsibility for a solution with every other available profession, organization, or agency, State and local, government and private. The failure to move cannot be ascribed alone to the local section for "a heavy share in the snail's pace of the attack on alcoholism." If New York City must accept full responsibility for the Hart Island action, so, also, must State legislators, hospitals, and physicians acknowledge their own obligations. The State's function must be spelled out. Selden D. Bacon says (6): "That the State has a responsibility to fulfill in the control of alcoholism as an extensive public health problem is a belief which has spread widely in recent years." This should not be open to question however broad may be the disagreement on the legislation proposed.

There appears to be a broad distribution of obligations of leadership in government. In the first instance, the State may bear the duty of legislating a full-scale program, although in many States the leadership may come from a few progressive towns. Whether or not they exercise initiative and leadership, cities and counties share in building a program. When State legislation is enacted, the localities can do their part more readily. The cost may be shared but that does not relieve the State of developing leadership which is centralized and

firm rather than haphazard and dependent upon the uncertain direction in which individual localities move. In this social program, society is equated with the State. Many States have accepted such responsibility, going from simple surveys to well-established programs. Examples of well-integrated programs are found in Connecticut, Virginia, and Wisconsin.

10-Point Program

As a basis of discussion, the following 10-point program is offered with particular regard for the potentials of a rich State with broad resources.

1. Set up screening facilities in classification centers staffed by physicians, social investigators, probation officers of local departments, welfare workers, correction and police officers, and court officials. Start here. Identify. Examine. Diagnose. Give the data to the judge. Screen out the chronic alcoholics and take them off the streets and into institutions.

2. With the aid of screening material, the judge could usefully release some on probation on condition that alcoholics with a chance of rehabilitation go to the outpatient clinics such as those established under New York's Mitchell-Ten Eyck law. Make these clinics available to persons voluntarily seeking help and correlate them with the screening facilities.

3. Activate institutions such as the short-lived experiment at Hart Island.

4. Educate personnel in correctional institutions about the handling and treatment of alcoholics through inservice training programs and select more specialized personnel.

5. Set up a followup system to reduce jail repeaters. Cooperation among public health authorities, the Salvation Army, and Alcoholics Anonymous may save duplication in this respect. This system will provide case histories for screening facilities for clinics and courts.

6. Establish public farms on a self-supporting basis. They are cheaper than urban jails. Those who can afford it should go to private farms. Many States have established such farms with State and local aid. Although this point is the center of much controversy, my personal conviction is that the system is valid.

It seems to me that farms and industrial colonies are essential for seriously deteriorated problem drinkers and those needing long-term treatment. California has established a State colony. The Hart Island colony of New York City's East River was showing success. Although the Connecticut farm was closed in 1941, the report to the governor declared the idea sound (6).

Such institutions have distinct advantages. They isolate patients from congested areas; they eliminate the possibility of running down local metropolitan sections; they have a lower capital and operating cost than county or city jails or hospitals; they provide better moral and physical rehabilitation possibilities; and they afford opportunities to revive farm and other skills.

Haggard and Jellinek (5) state, "Hospitals or farms for inebriates must be equipped to classify the various types of inebriates according to the causes of their condition." Hirsh (7) says, "When we have learned to utilize our present facilities we might then go on and consider the construction of new ones, such as farms and industrial colonies for seriously deteriorated drinkers who present special and particularly severe problems of treatment and rehabilitation."

7. Empower judges to deal with persons having an alcoholic problem beyond their control under a civil rather than a criminal statute. Even rehabilitation-minded magistrates are now handcuffed to penal statutes.

8. Ultimately there must be a civil commitment procedure. When colonies or farms are set up, procedures can be established for commitment to these institutions on a voluntary and involuntary basis. Many States have commitment laws. In 1951, Georgia provided for both voluntary and involuntary commitment of alcoholics for treatment. In Connecticut, the probate court may commit a habitual drunkard or dipsomaniac or persons so addicted to the intemperate use of narcotics or stimulants that they have lost the power of self-control. California law allows commitment of alcoholics who are unable to transact ordinary business or who endanger themselves or so impoverish themselves as to require charitable aid or who are in danger of becoming degrading or detrimental

influences upon their families or others. The longest, most successful program and the best facilities for dealing with the program and treating the alcoholics are found in Sweden, where there are places for voluntary treatment and for court commitment.

For New York State, the principle of compulsory commitment of alcoholics to privately licensed institutions was affirmed under section 201 of the mental hygiene law. But principle is not practice. The principle of commitment should not depend on ability to pay the high cost of private treatment. Nor should it be thwarted by the private institution's legitimate fear of a suit for false imprisonment.

9. We know what to do. Bridge the gap between what we know and what we do. Should expense be thrown up as a blockade to action, money must be provided by imaginative budget makers. Many States have done it, some by allocating a percentage of liquor license fees to separate administrations for rehabilitation.

10. In the meantime, general hospitals must admit drunkards suffering acute physical or mental damage. Mental hospitals must accept psychotic problem drinkers.

The legal and health system of the State must be prodded into accomplishment so that it will not fail in this crucial problem. We must care to cure.

Deserving of wider recognition is the relationship between marine animal life and water conditions in harbors, bays, and estuaries into which industrial wastes and domestic sewage are discharged. A step in this direction is this study of the Los Angeles and Long Beach Harbors.

The Relation of Polychaetous Annelids to Harbor Pollution

By DONALD J. REISH, Ph.D.

NO EXTENSIVE investigations of the role of animals in areas of marine pollution have been carried out in waters of the United States, although there have been a few European studies of interest (1-3). Blegvad (3) has stated that some species of polychaetes flourish well near domestic outfall sewers in Copenhagen Harbor. Filice (4) was able to divide the bottom fauna into three zones in a polluted arm of San Francisco Bay.

The seasonal and quantitative aspects of the relationship between bottom-dwelling animals and pollution in a bay or harbor has not been studied previously. This study, which was undertaken in 1954, examines these seasonal and quantitative aspects and seeks possible indicator organisms or animal associations.

At this time only representative material is published to indicate some of the general findings about the relationship of benthic polychae-

tous annelids to zones of pollution in Los Angeles-Long Beach Harbors. Emphasis has been placed upon the polychaetous annelids since they were the bottom-dwelling animal forms most commonly encountered in the 1951 harbor pollution survey conducted by the Los Angeles Regional Water Pollution Control Board (5).

Materials and Methods

Los Angeles and Long Beach Harbors are one harbor oceanographically. For convenience of discussion in this study, the harbors have been divided into inner and outer harbors. The outer harbors are considered generally to be the area south of Terminal Island (see map).

Many types of wastes are discharged into these harbors. The sources of these discharges have been described in the report (5) of the Los Angeles Regional Water Pollution Control Board No. 4. They may be grouped into the following seven general categories: fish canneries; oil refineries; chemical plants; vegetable oil plants; creosoting and pile-treating plants; metalworking shops, repair shops, and shipbuilding yards; domestic sewage.

It is important to distinguish between the dictionary definition of the word "pollution" and the California legislative definition of pollution. The dictionary definition, which is em-

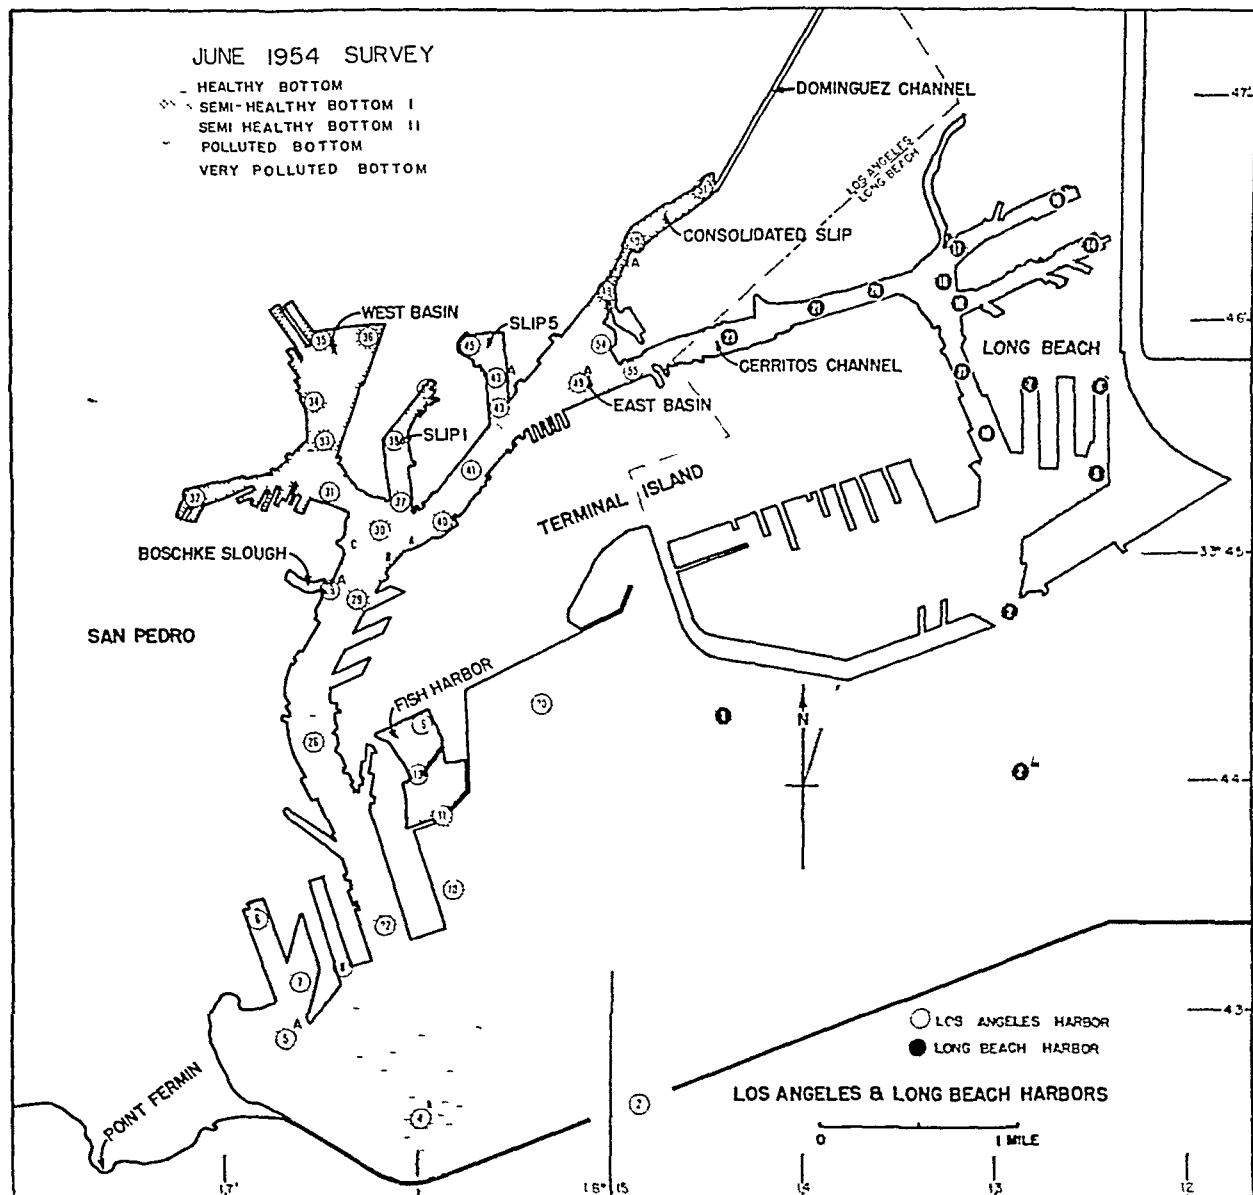

Dr. Reish, research associate, department of biology, University of Southern California, has been studying the biology of estuaries, bays, and harbors since 1950. Because the complete data of the 1954 survey of Los Angeles-Long Beach Harbors are too voluminous to be included in this general summary, they will be published in monograph form.

ployed in this study, is the act of making or rendering unclean, whereas in division 7 of the water code of the State of California, under which the State and regional water pollution control boards operate, pollution means "an impairment of the quality of the waters of the State by sewage or industrial waste to a degree which does not create an actual hazard to the public health but which does adversely and unreasonably affect such waters for domestic, agricultural, navigational, recreational or other beneficial use."

Three surveys of the harbors were made dur-

ing 1954; the first was on January 6-7, the second on June 14-15, and the third on November 18-19. In each survey the water mass and substrate at 55 stations in the harbors were sampled as to physical, chemical, and biological characteristics, with the assistance of the Los Angeles Harbor Department and the California State Department of Fish and Game. The sampling stations were in much the same location as the stations described in the 1951 survey (5). The station numbering system used in 1954 follows that of the earlier survey; however, not all of the 1951 stations were used and

The trigger (arrow) is set on this No. 1 size Hayward orange-peel bucket used in the pollution surveys of Los Angeles and Long Beach Harbors.

some new stations were added. The stations within Los Angeles Harbor are designated LA-2, LA-4A, and so on (shown as stations 2 and 4A in white circles on the map), and stations within Long Beach Harbor are LB-1, LB-2, and so on (shown as 1 and 2 in black circles).

Samples of the water mass taken at the surface and at a 20-foot depth were analyzed for dissolved oxygen concentration, chlorinity, and pH. One bottom sample was taken at each station with a Hayward orange-peel bucket (pictured). The bucket samples an area of 100 square inches and, depending on the nature of the material, holds as much as a gallon.

Part of the sample material was set aside for later determination of carbon and nitrogen content. The remainder was screened through a wire mesh with 20 openings to the inch. This size of screen was convenient to use since it re-

tains the animals and enables screening to be done in the work boats at the station. The material retained on the screen was preserved in formaldehyde. More details about methods are described in the pollution study Reish and Winter (6) made of Alamitos Bay, Calif.

Distribution of Animal Species

Insofar as possible, identification of the bottom-dwelling animals has been completed for the January and June 1954 surveys. Seventy different animal species have been identified: 45 species were polychaetes, 10 were pelecypods, and 5 were gastropods; and the remaining 10 species included coelenterates, turbellarians, nemerteans, oligochaetes, crustaceans, phoronids, and echinoderms.

The distribution of the polychaetes was plotted and correlated with bottom conditions in Los Angeles-Long Beach Harbors. On this basis the harbors can be divided into 5 ecologic areas, categorized below as healthy bottom, 2 types of semihealthy bottom, polluted bottom, and very polluted bottom. The zones of pollution, which of course varied for the three surveys, are shown on the map of the June 1954 survey. The physical, chemical, and biological characteristics of samples taken from the five areas are shown in table 1.

The white areas in the channel and harbor portions shown on the map did not fall into the categories of pollution for varying reasons:

Most of the outer harbors and that part of the channel between sampling stations LA-26 and LA-29 were not sampled.

Although the areas at stations LB-10 and LB-11 were sampled, dredging operations were recently completed.

The animals found in the sample from station LA-54 were atypical with reference to other sampling stations.

Healthy Bottom

The healthy bottom zone was characterized by the polychaete species *Tharyx parvus* Berkeley, *Cossura* sp., and *Nereis procera* Ehlers. The zone was found in both Los Angeles and Long Beach Harbors and in much of the inner harbor of Long Beach.

¹ Station LB-1, January 1954. ² Station LA-30B, June 1954. ³ Station LA-29A, June 1954. ⁴ Station LA-16, June 1954. ⁵ Station LA-49A, June 1954. ⁶ Figures within parentheses indicate number of specimens present in 1 sample.

An average of 10 animal species were present; 7 were polychaetes.

The dissolved oxygen content of the surface water and of the water at 20 feet averaged more than 6.0 p.p.m.

The substrate was typically a fine, gray-colored mud.

Semihealthy Bottom I

Two apparently distinct semihealthy zones exist principally in the main channels of Los Angeles Harbor. The main difference is in the type of animal life found: the differences in the physical and chemical characteristics of these zones were minor. The first of these semi-

healthy bottom areas was marked by the presence of *Polydora* (Carazzia) *paucibranchiata* Okuda and *Dorvillea articulata* (Hartman).

An average of 7 animal species were found; 5 were polychaetes.

The average dissolved oxygen reading of the water was 2.5 p.p.m. at the surface and 3.2 at 20 feet.

Fine mud, shell fragments, sand, fish scales, or black mud possessing a sulfide odor were among the variety of substrate types observed.

Semihealthy Bottom II

The recognition of a second semihealthy zone was occasioned by the presence of large num-

bers of the polychaete *Cirriformia luxuriosa* (Moore). This species of polychaete is particularly noticeable since it frequently attains a length of 15 centimeters, as measured in preserved condition. Otherwise, the number of animal species present, the chemical and physical characteristics, and the nature of the substrate were essentially the same in this second semihealthy zone as in the other semihealthy bottom area.

Sampling station LA-29A is given in table 1 as an example of this zone, which was found only within a portion of Los Angeles inner harbor. However, the 272 specimens of *C. luxuriosa* listed for semihealthy bottom II is unusually high. A more typical number would be around 80.

Polluted Bottom

The areas of polluted bottom were characterized by an average of 3 animal species, 2 of which were polychaetes. One of the polychaete species, *Capitella capitata* (Fabricius), was always present and frequently in large numbers. Fishery wastes or domestic sewage was being discharged near the sampling stations where the largest numbers of *C. capitata* were found. The polluted bottom zone was found usually within the slips except in the outer harbors where it was found on two occasions about the Terminal Island outfall sewer and on one occasion near the Fish Harbor outfall sewer.

Both at the surface and at 20 feet, the average dissolved oxygen content of the water was 3.5 p.p.m. This concentration was higher than that observed for the two semihealthy zones.

The substrate was a black mud with a sulfide odor.

Very Polluted Bottom

No animal life was present in the very polluted bottom areas, which are characterized by sludge beds. Sludge beds are an accumulation of toxic waste discharges to such an extent as to have killed the organisms living in the bottom and to exclude the introduction of organisms from other areas.

The inner reaches of some of the slips in the harbors had a very polluted bottom, but the areas in which no life existed were not observed in the main channels or in the outer harbors ex-

cept once during the November 1954 survey near the Terminal Island outfall sewer. The sources of pollution may be of domestic origin or of industrial origin, from oil refinery wastes for example.

The dissolved oxygen content was an average 1.6 p.p.m. at the surface and 2.2 p.p.m. at 20 feet below the surface.

The substrate consisted of black mud which had either a sulfide or petroleum odor.

Descriptive of Actual Conditions

While the general designation of the harbor bottom zones as healthy bottom, semihealthy bottom, polluted bottom, and very polluted bottom is based in part on the distribution of the different species of bottom-dwelling animals, notably the polychaetes, this terminology, adapted from Patrick (?), is employed because it is more descriptive of the actual conditions than are the scientific names of the principal species. Each type of bottom is characterized by one or more species of polychaetes, which, within limits, may serve as indicator organisms.

The division into zones may suggest well-defined demarcations, but frequently this is not the case with regard to animal distribution. Species characteristic of the healthy bottom are found in smaller numbers within the two semihealthy bottom zones but not within the polluted bottom area. *C. capitata*, the characteristic organism of the polluted bottom, may be present in the semihealthy bottom, but it has not been found in the healthy area. Animals common in the semihealthy bottom may occur in the healthy or polluted areas but again only in smaller numbers.

The most common areas of overlap occur either near the junction of two bottom types or at stations that were not well defined as to type of bottom from survey to survey. The area in slip 5 is an example of overlapping zones. The zone surrounding station LA-45 was classified "polluted" in the January and June surveys and "semihealthy I" in the November survey.

Since a relationship exists between the polychaete population and the degree of pollution in the waters they inhabit, a knowledge of the more prevalent species of polychaetes is desirable. Comparative lengths and ecologic char-

acters of the principal bottom-dwelling species of polychaetes of Long Angeles-Long Beach Harbors are given in table 2, which also includes geographic distribution and references to published material describing the species.

Seasonal Distribution

Little seasonal variation in the distribution of the animals was found during the three 1954 surveys. In general, the results of this aspect of the study are similar to the findings of the 1951 survey. Some variations are worthy of mention, however.

In 1951 the very polluted bottom zone extended into the East Basin of Los Angeles Harbor to about the level of station LA-54. The sludge beds characterizing this area in 1951 were removed in 1953 when the East Basin and a portion of the consolidated slip were dredged in order to deepen the Dominguez Channel for shipping. Although animals were found in the bottom area around stations LA-49, LA-49A, and LA-50 in the January 1954 survey, no animals were taken from these stations in the June survey. By November the sludge beds had again advanced into the East Basin to include station LA-54.

Checking upon the enroachment of sludge beds into previously productive biological beds is of particular importance to water pollution control. *C. capitata*, which was particularly

abundant near regions of pollution of biological origin in the Los Angeles-Long Beach Harbors, has been found elsewhere in southern California bay areas:

Reish and Winter (6) found the animal in two different areas of Alamitos Bay. One area is in the vicinity of a public dump, but the other is not near any known source of pollution.

Unpublished data yields the information that *C. capitata* is also present in the lower San Gabriel River, which receives waste discharges of both industrial and domestic origin, and in Newport Bay, too, where it has been found only near fish cannery outfall sewers.

Additional data relating *C. capitata* to pollution is given by Filice (4), who found the animal near industrial and waste discharges in San Pablo Bay, an arm of San Francisco Bay. The further correlation of *C. capitata* with sources of pollution, particularly of biological origin, would be of value.

Comparisons of the fauna and bottom of the Los Angeles-Long Beach Harbors with those of Alamitos Bay (6) and Newport Bay are of interest since these bays are essentially unpolluted bodies of water in southern California, except as noted. The animals in Alamitos Bay and Newport Bay are diversified and similar to those found in the outer harbors of Los Angeles and Long Beach.

Recently, Hartman (8) published the preliminary results of a quantitative survey of the

benthos of the San Pedro Basin—the area between Los Angeles-Long Beach Harbors and Santa Catalina Island. Two of the 5 stations sampled within the 2 harbors have been analyzed. These two stations were located near stations LA-4A and LB-1. A Hayward orange-peel bucket was used to sample an area of 2.8 square feet. Although the number of specimens and species was greater, as reported by Hartman, the results indicated a healthy bottom condition with *T. parvus* predominating.

Summary

A physical, chemical, and biological study of 55 sampling stations made 3 times during 1954 in Los Angeles-Long Beach Harbors, Calif., placed emphasis upon bottom organisms, particularly the polychaetous annelids. As a result of the survey, the harbors can be divided into five zones on the basis of bottom conditions and distribution of polychaetes. The zones are:

A healthy bottom area characterized by a large number of polychaete species, with *Tharyx parvus*, *Cossura* sp., and *Nereis procera* predominating.

A semihealthy bottom area, with *Polydora* (Carazzia) *paucibranchiata* and *Dorvillea articulata* predominating.

A second semihealthy bottom area in which *Cirriiformia luxuriosa* predominates.

A polluted bottom area, with *Capitella capitata* predominating.

A very polluted bottom area in which there is no animal life.

How the Public Health Worker Feels About His Job

By EDWARD M. COHART, M.D., WILLIAM R. WILLARD, M.D.,
and VIRGINIA R. MARR, M.P.H.

THE public health worker's feelings about his job—his satisfactions and his dissatisfactions—was one of several areas of study included in the Yale Public Health Personnel Research Project, which sought to provide information that would be useful in improving public health administration. For this portion of the project, 1,098 professional and semiprofessional workers in selected public health agencies were interviewed. The agencies included the State health departments of Connecticut, Maryland, and Michigan, several county health departments and visiting nurse associations in these States, and one large county health department in New York. The sampling process and the interview techniques are described in the May 1955 *Public Health Reports*, pages 447-452. Since the development of a method proved to be equally as important

in this project as the collection of data, the findings demonstrate both the use of the method and certain attitudes characteristic of public health workers.

The satisfactions and dissatisfactions expressed by the workers fell quite naturally into four categories.

First, there was a like or dislike for public health in general. Remarks such as "I enjoy public health work," "I get a feeling of accomplishment in public health," and "I find public health work satisfying," or "I dislike public health work," "I cannot use my previous training and experience in public health," and "I cannot see any results in public health" were classified in this group. The term "public health in general" defies exact definition. Obviously, the worker's concept of public health has been conditioned by his own experiences: had his experiences been other than what they were, his concept of public health might have been different.

The second major category concerned salary and job security. It included such individual items as salary, provisions for retirement and pensions, tenure, and opportunities for advancement.

Recognition and appreciation in the agency, a "feeling of belonging," and relationships with co-workers composed a third group, which was called status in the agency and interpersonal relations.

The fourth category, labeled conditions of work, related to such factors as working hours, working facilities, amount of clerical work, place of work (in the office or in the field), phys-

Dr. Cohart, formerly associate professor of public health, Yale University School of Medicine, has recently been appointed deputy commissioner of health for New York City. Dr. Willard is now dean of the College of Medicine at Syracuse, State University of New York. Miss Marr is consultant in chronic disease in the nursing division, Philadelphia Department of Public Health. Dr. Cohart and Dr. Willard were co-directors of the Yale Public Health Personnel Research Project, and Miss Marr was a research assistant with the project. The Yale project was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

ical demands of the job, and freedom and responsibility to make decisions.

In considering the data presented in the following pages, it should be remembered that the agencies studied were selected as better-than-average organizations and consequently may not be representative of all agencies. Rather detailed data are presented in the tables, but many of the findings are not discussed because the information necessary to proper evaluation is not available to the authors, inasmuch as the Yale study did not encompass case studies of individual health agencies; because many of the subgroups of workers are too small for valid generalizations; and because the need for keeping the report within a reasonable length precludes extensive discussion.

Satisfactions and Dissatisfactions

Sixty percent of the public health workers interviewed in this study said that they were happy with their work, even though some of them mentioned dissatisfaction with specific aspects of their jobs (table 1). Thirty-eight percent liked the conditions under which they worked; 32 percent found pleasure in their relations with their associates or in the recognition they received in the agency; and 22 percent expressed satisfaction with salary or job security.

Dissatisfaction was encountered most frequently in relation to the conditions of work, about which 33 percent of the workers were unhappy. Twenty-five percent were not satisfied with salary or job security, and 15 percent complained about their lack of status or their unsatisfactory relations with associates. Fourteen percent of the workers were dissatisfied with public health work generally.

The frequency of expressions of satisfaction varied somewhat with position in the administrative hierarchy and the governmental level of the agency. Notably the percentage of State health department staff workers (includes both junior and senior staffs) who expressed satisfaction with public health work was lower than the percentage of any other group. Associated with this was the fact that a lower percentage of State staff personnel than of any other group spoke of enjoying their status in the agency or

their relations with associates. Furthermore, satisfaction with working conditions was expressed less frequently by State workers, regardless of administrative level. Only with respect to salary and job security did a greater proportion of State than of local personnel express satisfaction.

With one exception, there were no important differences related to governmental or administrative level in the expression of dissatisfactions. The exception concerned salary and job security, with which relatively few high-echelon personnel (includes all personnel of supervisor and higher rank) in State health departments were dissatisfied.

Public Health in General

Varying percentages of the workers expressed no feelings, one way or the other, about public health work in general. However, between 12 and 15 percent were unhappy with public health, and about two-thirds of the high-echelon personnel in State and local jurisdictions and of staff personnel in local agencies and 43 percent of the staff personnel in State health departments expressed satisfaction with public health (table 2).

The low proportion of workers among State staff personnel expressing satisfaction can be attributed primarily to the fact that a relatively small proportion of laboratory staff personnel in State health departments appear to be happy in public health, and such personnel constitute a large segment of the State staff workers. The feelings of the staff laboratory workers in State health departments are in striking contrast to those of the staff laboratory workers in the local health departments. Medical and statistics staff personnel in State health departments also showed relatively little enthusiasm for public health.

Salary and Job Security

About half of the workers were noncommittal about salary and job security, and the remainder were almost evenly divided in expressing satisfaction and dissatisfaction with these aspects of their jobs (table 3).

Dissatisfaction centered upon salary. Staff

workers in State health departments also complained about the lack of opportunities for advancement. The expression of dissatisfaction with retirement plans and pensions and tenure was minimal.

Except for high-echelon personnel in State health departments, only 7 percent of whom considered their salary inadequate, roughly 20 percent of the workers were dissatisfied with their salaries. In the local health departments, a relatively high proportion of sanitation per-

sonnel at both administrative levels complained about salary. In the State health departments, staff nurses were most concerned.

Nineteen percent of the staff workers in State health departments, as compared to 3 percent of other public health workers, were unhappy about the lack of opportunities for advancement. Sanitation and laboratory staff personnel in State health departments were largely responsible for this high proportion.

On the positive side, almost equal percentages

expressed satisfaction with salary, retirement plans and pensions, and tenure. A relatively small number praised the opportunities for advancement.

About 10 percent of the workers felt that their salaries were good: The proportion was somewhat higher for State than for local personnel and for workers at the higher administrative levels than for staff workers. The dif-

ference between State and local personnel was particularly noticeable in the sanitation service, where more State workers at both administrative levels than their counterparts in local health departments appeared to be satisfied with their salaries. Furthermore, among high-echelon personnel in the State health departments, satisfaction with salary was more common among sanitation personnel than among

personnel of the medical and nursing services.

As with salaries, appreciation of retirement and pension plans and of tenure was expressed more often by State than by local and by high-echelon than by staff personnel. Here again, a larger proportion of State than of local sanitation personnel and, to a lesser extent, a larger proportion of State than of local laboratory personnel, appeared satisfied with these bene-

fits. The proportions among State sanitation and laboratory personnel were also greater than the proportions among State medical and nursing personnel.

Agency Status and Interpersonal Relations

Fifteen percent of the workers were dissatisfied with their status in the agency and their

relationships on the job; 32 percent were satisfied; and the remainder had no strong feelings about these aspects of their job (table 4). Although there were no significant differences on the basis of governmental or administrative level with respect to all dissatisfactions in this category, it should be noted that fewer State health department staff personnel than any other comparable group expressed satisfaction with these aspects of their jobs. The only important difference among the services was the high proportion of State sanitation personnel who expressed satisfaction.

The most frequent complaint related to lack of recognition and appreciation in the agency. Eleven percent of the workers made this complaint. It was expressed most often by staff personnel in State health departments, and among these, by sanitation, laboratory, and "other" workers. By contrast, high-echelon personnel in State health departments made this complaint relatively infrequently.

Eleven percent of the workers also expressed satisfaction with the appreciation and recognition given them in their agencies. The proportion was somewhat greater among high-echelon than among staff personnel. It is interesting to note that a relatively high percentage of sanitation personnel in State health departments expressed satisfaction with this feature of their work. The frequency with which sanitation personnel react, either favorably or unfavorably, to the recognition given them might be an indication of the importance which they attach to status.

Five percent of the workers indicated that they missed what can be called a feeling of belonging in their organization. Once again, staff personnel in State health departments were the group that seemed to be the most dissatisfied. Among the services, laboratory personnel were the most prone to make this complaint, although only 10 percent did so.

Fourteen percent of the workers commented that they felt very much a part of the agency. Sanitation personnel in State health departments stood out in this respect.

Dissatisfaction with interpersonal relations was relatively rare; only 2 percent of all personnel voiced this complaint.

On the other hand, nearly 30 percent of the

workers felt that their good relationships with co-workers were important enough to mention. Among staff personnel, nurses in local health departments and members of the sanitation service in State health departments seemed particularly appreciative of good working relationships with their colleagues. This was also true of high-echelon personnel in State health departments.

Conditions of Work

One-third of the workers were dissatisfied with one or another of the conditions of their work (table 5). State and local workers, staff and high-echelon personnel, were about equally dissatisfied. Dissatisfaction was greatest among staff laboratory personnel in local health departments and staff sanitation and health education personnel in State health departments.

On the positive side, more than one-third of the workers expressed satisfaction with some aspect of their working conditions. More local than State personnel expressed such satisfaction. The proportion of satisfied sanitation personnel ran somewhat higher than that for the other services. As pointed out previously, a high proportion of State sanitation personnel also expressed dissatisfaction with some aspect of working conditions. It would appear from these findings that sanitation personnel are more sensitive than others to the conditions under which they work.

The greatest number of complaints about working conditions concerned excessive clerical work and inadequate work facilities.

Sixteen percent of the workers were unhappy about what they considered to be excessive clerical work. Such tasks appeared to be most oppressive to high-echelon personnel in local health departments and least oppressive to staff workers in State health departments. Sanitation personnel in State health departments and high-echelon nurses in local health departments were particularly unhappy about their burden of clerical work.

Fourteen percent of the workers complained about inadequate work facilities. State and local workers, regardless of administrative level, had similar proportions. Less than 3 percent

of the workers were inclined to praise the facilities. Laboratory and statistics personnel felt the lack of facilities most keenly.

Six percent of the workers complained of lack of freedom and responsibility in their jobs. Such complaints tended to be more frequent among State staff than local staff personnel. They were voiced most frequently by staff med-

ical personnel in State and local health departments and by staff sanitation personnel in State health departments.

On the other hand, the opportunities for freedom and responsibility which their jobs afforded them were satisfying to 23 percent of the workers. As might be expected from other findings of this study, such feelings were least

Public health in general-----	45	14

frequent among staff personnel in State health departments. Relatively few of the staff laboratory personnel in State health departments or of the staff physicians in either State or local jurisdictions found their jobs satisfying in this respect. By contrast, a relatively large number of high-echelon nursing personnel in local agencies and of high-echelon sanitation personnel in State agencies found satisfaction in the freedom and responsibility for decisions and action which their jobs offered.

Four percent complained because so much of the work was indoor, office work. This objection was met with more frequently among high-echelon than staff personnel, and most frequently among high-echelon medical personnel in State health departments. On the other hand, 8 percent enjoyed their jobs because of the outdoor work involved. For all practical purposes, however, this feeling was restricted to staff and high-echelon sanitation personnel in State and local agencies and to staff nurses in local agencies. None of the workers in this study expressed a dislike of outdoor work or satisfaction with indoor work.

Three percent of the workers complained that the working day was too long. Complaints were more frequent among State than local personnel, principally because of the dissatisfaction of members of the sanitation service with this aspect of their jobs. Eighteen percent of the workers expressed satisfaction with the length of the working day. Such positive

feelings were least frequent among high-echelon personnel in State health departments.

Less than 2 percent of the workers felt that the work was too arduous. Four percent considered it important to mention that the work was not arduous.

Workers Desiring to Leave Public Health

Forty-nine of the one thousand ninety-eight workers interviewed in this study stated that they would like to leave public health for another career. In table 6 are shown the percentages of these workers and of all other workers who were dissatisfied with various aspects of their jobs. From these data, it can be seen that expressions of dissatisfaction were considerably more frequent among the workers who wished to leave public health. A much larger percentage of these workers than of all other workers were dissatisfied with low salaries, lack of responsibility and freedom of action, the absence of opportunities for advancement, and the lack of recognition and a sense of belonging in the agency, as well as with public health in general.

The relative importance of the various causes of dissatisfaction is shown in another frame of reference in table 7, which records the percentage of all dissatisfied workers in each category who desire to leave public health. These

Table 7. Percentage of dissatisfied workers who desire to leave public health

Cause of dissatisfaction	Total number dissatisfied	Workers desiring to leave public health	
		Number dissatisfied	Percent of total dissatisfied
Inadequate salary-----	240	20	8.3
Lack of freedom and responsibility-----	68	15	22.0
Lack of recognition and appreciation-----	140	14	10.0
Lack of a feeling of belonging-----	62	10	16.1

Inadequate work facilities-----	162	5	3.1
Public health in general-----	169	22	13.0

data indicate that the feeling of a lack of freedom and responsibility is the most potent factor contributing to the desire to leave public health. Almost 1 in 4 of those who feel this lack in their work want to give up public health work altogether. Lack of a feeling of belonging in the agency would seem to be another potent factor, for 1 in 6 workers who mentioned this lack wish to leave public health. These two areas of dissatisfaction are ones in which remedies may be found through improved administration, without additional funds.

Summary and Conclusions

Fourteen percent of the workers were unhappy about public health work in general. These feelings were not associated with governmental or administrative level or service. Although the general dislike for public health of some of the workers might be related to the character of current public health organization and practice, it would seem safe to say that often it is, rather, a reflection of personal incompatibility to this type of work, and that both public health and the individual concerned would be left in the long run by the withdrawal of this group from public health.

Specific causes of dissatisfaction mentioned frequently were: inadequate salary, excessive clerical work, inadequate work facilities, lack of recognition and appreciation in the agency, lack of opportunity for advancement, lack of responsibility and freedom of action, and the absence of a feeling of belonging in the agency. They were voiced, in the order given, by 20, 16, 14, 11, 8, 6, and 5 percent of the workers.

Although many of these complaints were shared by all, regardless of governmental level, administrative position, or service, these factors played an important role in a number of instances. Thus, dissatisfaction with salary appeared to be most common among sanitation personnel in local health departments and nurses in supervisory and administrative positions in State health departments. Staff sanitation and laboratory personnel in State health departments tended to be disturbed about the lack of opportunities for advancement and the meager recognition and appreciation which they received. Furthermore, State staff personnel

generally, and the laboratory workers particularly, were most apt to feel that they missed a feeling of belonging in the agency.

Dissatisfaction because of lack of responsibility and freedom of action occurred most frequently among staff medical personnel in both State and local health departments and among staff sanitation personnel in State health departments. The burden of clerical work seemed to be felt most heavily by sanitation workers and staff physicians in State health departments and by high-echelon nurses in local agencies. Laboratory and statistics personnel were most prone to complain of inadequate working facilities.

Sixty percent of the workers expressed satisfaction with their work in public health. The greatest single source of satisfaction for public health workers was not in their jobs but in their associates. Twenty-nine percent of the workers chose to emphasize the satisfying nature of relationships with their co-workers. The next most frequent source of satisfaction was the personal gratification which came with a feeling of responsibility and freedom to make decisions and take appropriate action. About one-fourth of the workers said that this characteristic of the work was particularly satisfying to them. Among the next five most frequent sources of satisfaction, each reported by at least 10 percent of the workers, were two which might be classified as meeting emotional needs. These were a feeling of belonging in the organization and recognition and appreciation of the worker's contributions. The other three were concerned with length of the working day, salary, and job security.

Although such economic considerations as salary and security are important determinants of the public health worker's feelings about his job, matters of a more personal nature, such as relationships with co-workers, a feeling of belonging, recognition and appreciation, and the sense of importance which results from having responsibility and exercising authority, are at least equally important. It should be possible, even without additional funds, to improve these aspects of the public health worker's job through proper administrative practices.

Few will care to deny that, as a general rule, burdening professional personnel with clerical

work is evidence of improper administration. Perhaps it is not equally apparent, but it is true nonetheless, that proper administrative practices can be effective in fostering good interpersonal relations on the job. They can also provide for recognition and appreciation of the worker's efforts and accomplishments. A feeling of belonging will grow in any organization that is administered in such fashion that a sense of mission is inculcated not only in the

men at the top but in every member of the team. Moreover, the proper delegation of authority and responsibility is essential to day-to-day efficiency and, perhaps even more important, to the morale and health of the organization.

Too often, the health of the organization is overlooked in our preoccupation with the health of the community. This practice will inevitably detract from the success of public health programs.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of PUBLIC HEALTH REPORTS, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Scheduled for early publication

A Child Health Program

in the

Mountains of Peru

By CRAIG BURNS, M.D.

THE MOUNTAINS of Peru rise quickly and sharply a few miles inland from the sea. The train from Lima must climb to 3 miles above sea level before it reaches a pass through which it can proceed to the Andean plateau and thence to the town of La Oroya, 137 miles to the east. It is the people of this area, which is in the region of Peru called the *sierra*, with whom this paper is concerned.

The Andean plateau of central Peru is above the tree line. Its elevation varies from 10,000 to 16,000 feet, with most of the people living at altitudes between 11,000 and 15,000 feet. A few eucalyptus trees, brought in after the conquest by Pizarro, grow in some of the sheltered valleys at the lower levels. The climate is temperate, with as much sunshine as in Reno, Nev. In summer, December through March, rainfall is moderately heavy, night temperatures rarely fall below freezing, and the daytime temperature is about the same indoors and out. During winter, June to September, almost no rain falls, the nights are cold and frosty, and the days are warm and sunny. Because the air is thin, it is difficult to start a fire, and water evaporates at an astounding rate.

Dr. Burns is chief physician of Chulec General Hospital, operated by the Cerro de Pasco Corp. at La Oroya, Peru.

The climate of the plateau is invigorating, and there are few insects, no reptiles, and no dangerous beasts. But it is no paradise. Syphilis and tuberculosis are major afflictions. Typhoid fever, typhus fever, rabies, and hydatid disease are endemic. From data obtained in La Oroya, it is estimated 1 of every 4 children dies before the age of 13 years.

It should be emphasized, however, that health conditions throughout Peru are improving at an ever-increasing tempo. The Peruvian Ministry of Public Health, which has responsibility for the health of all the people, is conducting campaigns against prevalent diseases. Municipalities are participating in the national health program in matters concerning sanitation of public buildings, urban hygiene, protection of food and water supplies, and sewage systems. The Servicio Cooperativo Interamericano de Salud Pública, an official Peruvian agency financed jointly by the United States and the Peruvian Governments, is engaged in almost all phases of preventive and curative medicine. Attention given to the problems of the hard-to-reach regions of the *sierra* is quite naturally less than that given to the more accessible coastal areas. As in other mountainous areas of the world, living conditions in the *sierra* do not attract volunteers in health work.

Particularly important in Peru is the advance in industrial hygiene. Since 1947, when a law made mandatory an industrial hygiene

program for miners and other industrial workers, the Department of Industrial Hygiene, with assistance from the Servicio, has conducted medical and engineering studies in many of Peru's industries. Already evident are improvements in control of dust, in sanitation, and in protective devices for workers.

Another significant factor in health is the effort, by both the government and the large industries, to improve housing. New houses under construction by one large mining company for its workers have two rooms, a stove, running water, and a flush toilet. Many families in the *sierra*, however, still live in one-room houses without inside water or sanitary facilities. In the mining towns, these houses have a stove or fireplace. In the outlying areas, the natives construct a low stone house, called a *chosa*, with a roof of straw or grass through which the smoke from cooking and heating fires seeps out. The floor of the *chosa* is dirt, and the bed is a bank of earth, a few feet above the level of the floor.

In the plateau area, the Peruvian Government operates two general hospitals for workers (but not for their families) and one tuberculosis hospital, and it has set up agencies for public health work. In addition, the Cerro de Pasco Corp., which has mining, smelting, and ranching operations throughout the *sierra*, maintains 10 hospitals and 8 dispensaries, employing 22 physicians. It provides medical care for its workers and their families, some 60,000 people in all.

My assignment in La Oroya began in late 1953. There had been little public health work in this area, and the number of children needing medical services was startling. Chulec General Hospital, a 130-bed, well-equipped hospital of the Cerro de Pasco Corp., cares for most of the town's 25,000 population and also receives patients needing specialized treatment from the other nine smaller company hospitals. The hospital employs 8 physicians and 3 interns, and it operates a separate outpatient clinic staffed by 2 Peruvian physicians. Because the patient load of these facilities was overwhelming, I found it necessary to abandon specific objectives of general practice and to concentrate on the sources of human ills—un-

hygienic practices, improper diet, and endemic diseases.

The fundamental need was for health education. One of the difficulties, however, was the lack of means of communication. About 95 percent of the population is Spanish speaking; the remainder converse only in Quechua, the old Inca language. Almost half of the population cannot read or write. An incident in March 1954 demonstrated that even colorful and attractive charts containing printed words could not be depended upon to deliver the desired message. We placed three such charts, on nutrition and diet, in the hospital waiting room, which was crowded with patients. Were they well received? Was everything clear to the patients? A quick survey disclosed that not one patient in the room understood the charts.

In attempting health education, one may begin with the adults and hope that the new information will be handed down to the young people. I believe, however, that major emphasis should be given to the health of the children. This is the story of the development of a child health program in La Oroya. It recounts experiences from December 1953 through November 1954, and it shows the progress of ideas, the work accomplished, and the changes in attitudes of all persons concerned.

The Pediatric Department

December 1, 1953: Pediatric department organized at Chulec General Hospital; children's bed capacity doubled, from 4 to 8! An average of 200 children seen daily in outpatient clinic; no time for immunizations, adequate records, or followup care. Few parents will accept routine immunizations for their children or allow them to be hospitalized.

Establishment of the pediatric department was the beginning of the concentrated effort to improve the health of the children in La Oroya. In past years, few children had been patients of the hospital, although there was much illness and many deaths among them. According to information obtained from the parents of children brought to the hospital or the clinic during the period of this report, 27 percent of their children had died before they reached the age

of 13 years (which is the age when many of the children begin to shift for themselves), but only 6 percent of these deaths had occurred in a hospital (table 1). It seemed that the people of La Oroya did not have much faith in medical care or that they did not understand that it was not necessary for so many children to die. We soon learned, however, that it was not that they were adverse to hospitals and modern medicine, but that they didn't know what to expect from them. This is illustrated by the following incident:

January 29, 1954: Parents brought in 3-month-old baby with six toes on left foot. Since local superstition about having six toes creates fear and anxiety, they wanted an operation right away—they would wait while we took off the unsightly toe so that they could take the baby home. Finally, they were persuaded to leave the baby for 4 days. Brother of baby also had six toes and had been successfully operated upon earlier.

By February, the bed capacity of the pediatric ward had been increased to 14, not counting bassinets for infants. By May there were 20 beds for children, 16 bassinets, and 2 incubators. Of necessity, the ward is run quite differently from such wards in the United States. For

lack of space, beds are close together; there is no possibility of isolation. Most of the children eat their meals at a table in the center of the room, where the older children assist the younger ones. All the children are helpful and cheerful. A few newcomers cry for the first 24 hours, but rarely do the children fight among themselves. Many are reluctant to leave the hospital.

Visiting days at the hospital. Wednesdays and Sundays, are a festival. In troop parents and relatives in colorful costumes, the women carrying babies in *mantas* on their backs and all carrying baskets of fruits and jars of jellies. They sit on the floor about the beds, orderly and quiet, but they have many questions to ask. At first, at least half of the visiting parents wanted to take their children home with them, but now we are rarely bothered with these requests.

Causes of Illness and Death

The hospital data presented in tables 2 and 3 give some idea of the causes of death and illness among the children in La Oroya. According to these data, pneumonia, diarrhea, and tuberculosis rank high as causes of both illness and death, and syphilis is a major cause of illness. Burns, often resulting from the use of kerosene

"... the women carrying babies in mantas on their backs"

or gasoline to start fires in this area, also are a frequent cause for admission to the hospital.

Routine chest X-rays of adults show scar tissue of healed tubercles in more than 25 percent of those examined. That the disease remains a major problem is shown by the number of patients reporting for treatment as well as by the results of tuberculin tests and X-ray surveys. In one grade school of 800 students, 34 percent had positive reactions to the Mantoux test, and 3.36 percent were found to have active pulmonary tuberculosis.

Response to treatment for tuberculosis is remarkable. Good food, a bed to sleep on, and rest produce amazing results—the antituberculosis drugs are merely a dessert. Almost every patient responds rapidly to treatment. Active pulmonary tuberculosis has been cured even with ambulatory outpatient treatment.

Syphilis is seen in many forms. Several babies with arms and legs as hard as bone have been brought into the hospital. Others have syphilitic deterioration of the nose, the lips, or the anus. X-rays of older crippled children

reveal old healed syphilitic involvement of the joints. Blindness and other eye conditions resulting from this disease are not uncommon.

Hydatid disease was diagnosed in 1.4 percent of the 437 children admitted to the hospital. In this region of Peru, there are some 200,000 sheep, one of the natural hosts of the *Echinococcus granulosa*, and a great number of dogs, one of the carriers between animals and man. We found the disease as common among town children as among those living on the sheep ranches. Usually, the cysts are in the lungs, but we have found 1 in the axilla, 2 in the liver, 2 in the abdominal cavity, and 1 in the neck. The Casoni skin test is always positive in the presence of these infestations. Not one child has died from surgical removal of the cyst or cysts.

Each month there are a few patients with typhoid fever in the hospital, although there is never an epidemic. The Cerro de Pasco Corp. filters and chlorinates its water supplies, but there is no chemical or sanitary protection for the people living outside the larger towns. The rural women wash clothes in the same streams that carry sewage, and during a few months of the year, there are many flies.

Native Customs and Health

June 28, 1954: Conference today with 50 union leaders representing the workers in the mines and smelters of the Cerro de Pasco Corp. They believed that climate, lack of money to spend on imported foods, and insufficient medical services were the three main causes of infant and child mortality. Demonstrations and discussion seemed to convince them that these were not the real causes.

The appeal to these 50 slightly antagonistic fathers with union responsibilities began with the presentation of two charts. One compared the low death rates of infants and children in the United States with the very high rates in the La Oroya area. The second showed the estimated average number of days a year a child in the United States is ill and the comparable figure for their children. Especially emphasized was the negative influence of illness on the growth of children. When asked to give what

they thought were the reasons for the differences shown in the charts, the union leaders expressed the opinions previously mentioned.

If these were the true reasons, we stated, then the children of all ages should be affected about the same. But this was not so. A chart (fig. 1) showed them that a large percentage of the deaths among children occurred before the age of 2 years. Here was a problem—what causes so many children to die during the first 2 years of life? We believe that the lack of iron-containing foods in the diet of young children—a majority of the children are anemic before they reach the age of 2 years (fig. 2)—and the use of *fajas* are contributing significantly to this

situation. We proceeded to try to convince the union leaders of the importance of these factors.

The men laughed when shown a picture of themselves at night—a man and a woman lying on a bed with a child between them breast-feeding throughout the night. We explained that allowing the child to breast-feed all night (a practice that may continue until the child is 2 to 4 years old) spoils his appetite for health-giving foods in the daytime. A child needs iron, and there is practically no iron in milk. To illustrate the last point, we used the following demonstration:

Two 2-liter beakers were placed on the table, along with a 1½-liter bottle of basic fuchsin solution (which is the color of blood), and a quart bottle of milk. The first beaker was filled one-third full of fuchsin solution, to represent the amount of blood in a newborn baby. The second beaker was filled almost full with the fuchsin solution, to represent the amount of blood in a 1-year-old child. During the first year of life, the baby's body has to make the quantity of blood shown by the difference in the amount of liquid in the two beakers. If the baby gets only milk (containing no iron), the blood looks like this—and the quart of milk was emptied into the first beaker, bringing the level of the liquid up to the level in the second beaker. What a difference in color! The blood fortified with milk was a sickly pink shade.

By now the men began to appear interested. Appetite for iron-containing foods, as well as other nutritional foods, we continued, is also

Table 3. Causes of death among children under 13 years of age in Chulec General Hospital, December 1953–November 1954

dulled as a result of the practice of adding sugar to all liquid given a child—1 to 3 teaspoonfuls to every cup of water or milk or coffee. Sugar does not contain iron, and we demonstrated this point as follows:

Sugar, like wood, burns and gives energy, with only ashes left—no minerals, no iron to form blood. Had they ever obtained iron by burning wood? A stick of wood was produced and burned—the men smiled when the ashes were passed around for their inspection. Did they know that sugar would burn too? A volunteer was called for, a man smoking a cigarette. A pile of sugar was placed on a plate on the table. Cigarette ashes were mixed with the sugar, the ashes representing the chemicals in the body. Then the sugar was ignited with a match, and the men saw that it burned like wood. They could find no iron in the ashes.

After these demonstrations, we emphasized

that there were plenty of iron-containing foods available locally, but that they were not being used. We urged the men to send their wives to the clinic so that we could instruct them in proper diet for children.

Next, the subject of *fajas* was discussed. *Faja* is the name of the woven cotton or wool band which is wrapped around a baby from the time he is born until he is 2 or 3 years old. Three *fajas* are usually used. One is placed next to the skin around the chest. The second is wrapped around the body and arms at the level of the elbows to keep the baby from using his arms to climb out of the *manta* in which he is carried on his mother's back. The third *faja* is placed at the level of the knees to keep the baby's legs quiet.

When asked about the *fajas*, every woman gives the same answer: If the baby does not begin life with the *fajas*, *se recalca*. But get-

Figure 2. Hemoglobin values for 365 children tested in La Oroya, December 1953–November 1954.

ting to the meaning of *se recalca* is another matter. It means that the ribs will not stay where they should. It means that the baby will have stomach pains. It means that the baby will have "much cough" when he grows up and that he must then be held upside down and shaken so that the bones will go to the proper places. But the *fajas*, we attempted to explain, prevent full expansion of the lungs and hinder blood circulation and normal body movements in the rapidly growing baby, and thus they may contribute to many of the ills and deformities of the population. We have seen deformed ribs and concave thoraxes produced by this constriction.

Child Health Clinics

May 31, 1954: The first child health clinic was held in La Oroya today, from 3 to 4 p. m.

Number of patients was overwhelming. Managed to see 14 mothers with 18 children. Gave 17 injections of DTP vaccine; instructed the mothers on diet and cleanliness; and distributed fifteen 1-cc. dropper bottles of ferrous sulfate solution.

The need for a children's clinic in La Oroya had been recognized early, and plans for the operation were under way by April. The clinic was envisaged as a means not only of providing medical care but of increasing the efforts to prevent illness. Hence, immunizations against such diseases as whooping cough, diphtheria, smallpox, and typhoid fever, as well as education in matters of diet, cleanliness, and the like, have been as important a part of the clinic program as the treatment of ill children.

At the conference with the union leaders previously mentioned, the final subject of discussion

was immunizations. A show of hands revealed that 13 of the men present were unable to sleep well the night before because of coughing children. We guaranteed them that if they saw to it that their workers brought their children to the clinic for whooping cough immunizations, there would be no epidemic of that disease the next year.

Originally scheduled for 2 hours a week, the clinic was soon being held 10 hours a week. Always, there were more patients than could be seen in the allotted time. By August, although most of the mothers still brought their children because of cough, fever, or diarrhea, a few were coming only to receive the immunizations.

School Health Program

August 26, 1954: Our first visit to a school—76 students aged 4 through 12 years. Set up table and chairs in the playground and administered smallpox and DTP vaccine to each child. Placed inkmark on child's right hand to show that he had received the immunizations—his badge of bravery.

This visit represented another major step in the child health program, for it was the beginning of our school health activities. Two more visits were made to this school to complete the DTP immunizations, and during these visits many of the children's mothers appeared in the schoolyard and asked us to vaccinate their children who were too young to attend school. One mother even brought a small dog, figuring that what was good enough for her baby was good enough for her puppy.

On September 8, 1954, we held our first conference on health with the teachers of one of the larger schools in the town (800 students). The teachers unanimously agreed that nutrition was the major health problem, and we discussed a powdered-milk program as a first step in meeting it. (The powdered-milk program finally got under way in mid-1955.) We also presented a filmstrip lecture on how disease is transmitted, and the following week we gave the same lecture to each class as an introduction to a typhoid immunization program. Subsequently, the typhoid immunization pro-

gram was carried out, with full cooperation from both students and teachers. Interest ran particularly high because one schoolboy, the son of one of the teachers, became ill with typhoid fever 2 days before the program was begun.

In November, BCG immunizations were begun. The vaccine is made in Lima and furnished free by the Peruvian Government, which also supplies free the typhoid, DTP (from UNICEF), and smallpox vaccines. Every baby born in the hospital and every schoolchild who reacts negatively to the tuberculin skin test now receive the BCG vaccine.

Recent Developments

A review of the child health clinics after the first 6 months of operation indicated that we were not making the best possible use of our time. The following changes have been made in recent months:

1. A Peruvian physician specializing in pediatrics sees all children brought into the outpatient clinic in La Oroya. He has a staff of three auxiliary nurses trained in pediatrics (Peruvian women who have received training at Chulec General Hospital), who interview each mother and give her instructions as to diet, cleanliness, and when to return to the clinic.
2. Every child brought to the outpatient clinic is given DTP and typhoid immunizations.
3. A child health nurse has been employed to supervise the child health program in the clinics, the schools, and the outlying areas.
4. A visual education program has been started in each of the schools to teach the importance of cleanliness and immunizations.
5. A well-baby clinic has been established.
6. Every mother delivering a baby at Chulec General Hospital is given a course of instruction in infant care while she is in the hospital.

Summary and Conclusions

In line with the increasing efforts to improve health conditions throughout Peru, an intensive child health program was begun in La Oroya in December 1953. The first action was

the establishment of a pediatric department at the Chulec General Hospital. Within the next year, child health clinics were started and a school health program was initiated. These latter activities, with their emphasis on immunizations and health education, were directed toward the prevention of illness, rather than its treatment.

The tempo of progress in the betterment of health in Peru has been accelerating rapidly during the past 5 years. This can be attributed largely to the following factors:

1. Efforts of the Peruvian Government and assistance from the bilateral programs of the United States and from international health agencies.

2. Change for the better in the attitude of foreign companies toward their workers.

3. The antibiotics. (It would be almost im-

possible to attempt a program against syphilis without penicillin, for example.)

4. The provision of better housing by both the Government and the foreign corporations.

My work in La Oroya for the past 2 years leads me to the conclusion that the following items are among those most needed for further advancement:

1. Better equipped schools and more years of instruction—to raise the level of general education, as well as health education, and to make it possible for more Peruvians to meet the requirements for advanced education so that the supply of trained local people can be increased.

2. A 300-bed tuberculosis hospital to serve the people of the central Andean plateau.

3. Improvement of the public roads.

4. Incorporation of a utilizable form of iron in canned milk to help combat anemia.

Vending Stands for the Blind

A report from the Office of Vocational Rehabilitation issued at the end of October 1955 showed that 1,721 blind vending stand operators (602 on Federal property) were employed in 1954 as against 1,659 during 1953, the previous high. Operators and their employees (310 blind and 746 sighted assistants) earned \$5.3 million in the year ending June 30, 1955, an increase of \$500,000 over the preceding year. The net earnings of the operators totaled approximately \$4 million and those of the assistants, \$1.3 million.

An act initially passed in 1936 provided for the establishment of vending stands in federally owned or leased buildings. Amendments in 1954 authorized the establishment of such stands on other property, such as national parks and grounds of Federal buildings. They require each Federal agency in control of property to issue regulations designed to assure preference for blind persons in the operation of vending stands on that property.

The great majority of the blind persons employed in the vending stand program have been trained through the State-Federal vocational rehabilitation program. Only about 8 percent of the estimated 320,000 blind persons in the United States are employed although experience has indicated that about 25 percent of those disabled by blindness can be trained for gainful employment.

Classifying the Tuberculous for Isolation in California Mental Institutions

By WALDO R. OECHSLI, M.D., EDWARD KUPKA, M.D., M.P.H., and CHESLEY BUSH, M.D.

TUBERCULOSIS is a well-known scourge among the mentally ill. When a patient with active tuberculosis is admitted to a mental hospital, because of the nature of his mental illness, he may cough or expectorate only infrequently or not at all. He may be afebrile. He is not X-rayed and not diagnosed and thus becomes a focus of infection in the large confined population. Overcrowding in the past has sometimes been so severe that a patient often had to climb over another patient's bed to reach his own.

Such circumstances are ideal for transmittal of the disease; in time, the secondary cases infect others, and the vicious circle continues. This situation is due to a number of factors: lack of knowledge of who are the actively tuberculous individuals being admitted to a greatly overcrowded hospital population; the absence of an easy, practical method of discovering tuberculosis; incomplete segregation; absence of treatment for unrecognized cases; and the tendency of tuberculosis to become reactivated (1). The key underlying factor in the problem is the communicability of the disease.

Procedures for Control

Periodic X-ray surveys of the entire hospital population, including personnel, segregation of

Dr. Oechsli is roentgenologist, bureau of tuberculosis control, California State Department of Public Health. Dr. Kupka is chief of the bureau, and Dr. Bush was formerly assistant chief.

the tuberculous thus discovered, and instituting an X-ray program at admission have become the basis for the solution of this, one of the most serious remaining problems in the tuberculosis control field. In many States there is increasing evidence that this approach is successful in reducing the number of new cases discovered by annual X-ray surveys and in decreasing the intramural tuberculosis death rate.

A death rate of over 1,000 per 100,000 population among hospitalized mentally ill was not uncommon 20 years ago as compared with a rate of 56.6 per 100,000 among the general population in the United States in 1934. As more diagnosis, segregation, and treatment are effected, the rate in mental institutions is dropping. In 1948, Anderson (2) reported that the tuberculosis death rate for 682,251 patients in the mental institutions of this country was 535 per 100,000. Weber (3), in Toronto, reported a drop in the intramural death rate from 414 in 1938 to 182 in 1952. Katz and his co-workers (4, 5) in New York reported a decrease in death rate from 623.6 per 100,000 in 1935 to 252.4 in 1951, and they attributed this decrease to environmental factors, chiefly early diagnosis and segregation.

In the California hospitals for the mentally ill, the death rate rose substantially until 1946, to a peak of 800 per 100,000 resident population (table 1, fig. 1). Since 1946, when a continuing X-ray survey and segregation program started, the death rate among the mentally ill has dropped 65 percent—to 283 per 100,000. Among the mentally deficient, the death rate, which had generally been lower than among the mentally ill, has dropped to 29 per 100,000.

Tuberculosis Classification for Isolation

Type A. Active and probably active; communicable.

Type B. Probably inactive; greater than minimal extent; potentially communicable; more likely to undergo reactivation than type C.

Type C. Strictly minimal in extent; inactive; presumably not communicable; reactivation considered unlikely.

Type D. Calcified primary lesions, parenchymal or hilar or both. Considered essentially negative.

Type E. Formerly suspected tuberculosis, now negative on film; probable nontuberculous pathology; calcified or thickened pleura only.

This favorable result is due largely to the aggressive case-finding and isolation program in effect.

Satisfactory as this decline may appear, much remains to be accomplished. Continuing persistent effort will be necessary. Instituting an X-ray program at admission and surveying a mental hospital once are not sufficient. Wherever repeated annual X-ray surveys have been carried out, it has been found that a certain number of new cases develop within the institution each year even among the apparently un-

exposed. In California, the first survey (6) revealed a prevalence of a tremendous number of unsuspected cases of tuberculosis. Later an annual survey incidence rate of about 11½ new active cases per 1,000 patients X-rayed was found (7). The true incidence rate is unquestionably higher than the survey incidence rate.

Deficiencies in Control

Granting the theoretical possibility of endogenous reinfection as a factor, in our opinion these new cases arise chiefly because of deficiencies in the control system. These deficiencies may be many, depending on the stress laid on the tuberculosis control program and the zeal with which control measures are applied. They include failure to take admission films on all patients; failure to include patients on parole; and the very ill, infirm, or disturbed patients in annual X-ray surveys; delay in discovering reactivation of tuberculosis through failure to X-ray periodically those with supposedly inactive disease; missing the diagnosis of active tuberculosis which is occasionally atypical in its manifestation; and too great dependence on demonstration of tubercle bacilli as a criterion for segregation.

Probably most important among these deficiencies is the occurrence of reactivation of

Table 1. Tuberculosis death rates per 100,000 in California mental institutions and in the State, 1938-53

Year	Mentally ill			Mentally deficient			State death rate
	Average daily population	Number of tuberculosis deaths	Death rate	Average daily population	Number of tuberculosis deaths	Death rate

1952	32,808	147	448	6,600	1	15	15.5
1953	34,588	98	283	6,828	2	29	11.4

Tuberculosis death rate per 100,000 for mentally ill and mentally deficient in California institutions and for the State, 1938-53

disease in the unsegregated, supposedly inactive tuberculous patients (8, 9). Despite the estimate that the tuberculosis in these patients had been considered as inactive, routine X-rays on 14" x 17" films made at the time of annual X-ray surveys showed that unsuspected reactivation had taken place in a certain proportion of such patients. Reactivation was judged by one or more of the following criteria: (a) cavitation where none had existed; (b) infiltration in a new area; or (c) definite increase in density of certain areas of infiltration. Since laboratory aids were often unavailable, it was necessary to make careful comparison of chest X-rays of comparable technical quality before this conclusion was felt to be justified, recognizing that the securing of comparable films on mentally ill persons requires care and patience.

Laboratory confirmation of activity is, of course, more dependable and a more definitive proof of pathological activity. However, such proof was not always available, and conditions had to be dealt with as they were.

It has been said that dealing with the mentally ill, in diagnosis at least, has some of the characteristics of pediatric or veterinary medi-

cine. Often, the patient will not be able to give reliable information regarding his symptoms or cooperate in producing sputum. Add to this the shortage of personnel, especially laboratory technicians, and it becomes necessary to depend heavily upon X-ray findings, even when only a single chest film is available. However, when one has a series of chest X-rays of comparable technical quality, activity of the disease process can often be inferred by changes inter-

Table 2. Reactivation or progression of known tuberculosis among unsegregated mentally ill patients as observed by annual X-ray surveys in California mental institutions, 1947-54

Survey year	Number of patients X-rayed (14" x 17" films)	Tuberculosis reactivation or progression	
		Number	Percent
1947-48-----	261	32	12.3
1948-49-----	221	19	8.6
1949-50-----	370	24	6.9
1950-51-----	410	35	8.5
1951-52-----	516	26	5.0
1952-53-----	608	27	4.4
1953-54-----	597	33	5.5

preted as evidence of progression of disease, as noted above.

As part of the second of the California surveys in 1947-48, 261 unsegregated patients with presumably inactive tuberculosis were X-rayed (table 2). Of these, 32 (12.3 percent) presented X-ray evidence of progression of disease. In subsequent surveys, the percentage of those showing progression dropped to less than half of this ratio. Nevertheless, a ratio of 1 in 20 unsegregated, apparently safe, tuberculosis patients suffering reactivation each year is surprisingly large, dangerous to nontuberculous patients and personnel, and calls for corrective action.

Resolving the Problem

The most nearly complete solution of the problem would seem to be the segregation of all patients diagnosed as tuberculous, regardless of extent of disease or its activity status. This alternative is open to objections. It is too restrictive for the patients who have had arrestment of their disease for many years, and neither isolation space nor additional personnel are available. Other than a laissez-faire policy, the alternative was to appraise the criteria for segregation.

Two solutions presented themselves. Since the crucial factor in communicability of tuberculosis is the presence of tubercle bacilli, it appears logical to base a decision for segregation on the demonstrated presence of the organism in the sputum or in gastric or tracheal washings. Laboratory investigation certainly should be made regularly and frequently. However, it appeared unwise always to await bacteriological proof before segregating a patient with tuberculosis, since a given patient's findings might be negative today and positive tomorrow. Since examination by culture and guinea pigs takes weeks, the hazard of exposure exists for that period of time. Furthermore, laboratory technicians and other needed personnel were not available, and it often was not possible to carry out even a minimum laboratory investigation. Also, it was difficult, and at times impossible, to intubate some of the patients, and dependence on such clinical findings and symptoms as fever, loss of weight, and cough is no-

toriously unreliable. In some cases tuberculin testing ruled out tuberculosis; however, the small percentage of the mentally ill who are negative to tuberculin minimizes the value of this test.

For these reasons, the other possible solution was utilized—serial chest X-ray examinations. As a starting point we again examined the X-rays of every mental institution patient who had ever had a diagnosis of tuberculosis or suspected tuberculosis. Some patients had only one film, most patients had several, and quite a few of long residence had dozens of films each. The serial films were supplemented by any available sputum studies, skin tests, or clinical evidence. On the basis of this film reappraisal, an arbitrary decision was reached in each instance. If the patient was still considered tuberculous, a further decision on segregation had to be made.

Some type of classification was needed to designate those who should or need not be segregated. The requirements were to categorize patients not by extent or activity of disease alone but by actual or potential communicability. The classification of the National Tuberculosis Association was not suitable for this study for two reasons: "Arrested" under certain circumstances permits a positive sputum by the more delicate tests, and "inactive" includes cases which still have a potential of reactivation high enough to be of great importance in mental hospital populations. Hence, a new classification was created to designate three groups—currently communicable, potentially communicable, and probably not communicable (types A, B, C).

Type A. The finding of tubercle bacilli by any method automatically places a patient in this category regardless of the X-ray appearance. In the absence of positive sputum findings, the chest X-rays must present the findings characteristic of recent, active tuberculosis: soft, exudative, caseous pneumonic or soft, miliary infiltration, or cavitation. Reactivation or extension of infiltration or the appearance of cavity in a recent film also calls for a type A classification. All these patients are presumed to have communicable disease and are strictly segregated. They also are as vigorously treated as their cooperation permits.

Type B. Chest X-rays of patients in this

group give an impression of relative or definite inactivity. Cavity must not be present or suspected. Bullous blebs, of course, must be differentiated. The sputum must be negative by any type of investigation; if it has been positive in the past, it must have been negative for at least 1 year. The infiltration is more or less discrete and fibrotic and may be calcific. There may be sharply circumscribed, dense areas usually associated with encapsulated, caseous lesions. If the disease has been active in the fairly recent past or if of longer standing it is more extensive than minimal, these patients are presumed to present a potential communicability hazard. Segregation, however, need not be quite as strict as for type A patients. They may leave the ward, if attended and supervised, for treatments, motion pictures, beauty parlor, or barber shop. Nevertheless, they should be X-rayed every 3 months and, if possible, sputum examinations or gastric lavage performed periodically every 3 months. Their diet should be adequate. They receive whatever psychiatric treatment is indicated, but they need no treatment for tuberculosis.

Type C. This group includes only those in whom reactivation of tuberculosis is considered quite unlikely. The infiltration must be stable, very discrete and fibrotic or fibrocalcific and of small extent, with no evidence of activity for several years. A sharply circumscribed tuberculoma less than 2 cm. in diameter may be present, if not of recent origin. The laboratory findings, of course, must be negative. These patients are not segregated, but care is taken that they are not lost to observation and they are X-rayed every 6 months. Their psychotherapeutic needs are cared for in the same way as the hospital population generally. If they are to be allowed to work, medical permission is required.

Type D. Calcified primary lesions, which are often hard to differentiate from fibrocalcific minimal reinfection tuberculosis, are placed in this category. Although some of these patients had in the past been included in the tuberculosis register in some hospitals, they are considered here as essentially negative and removed from the register. During the annual X-ray surveys, they are filmed along with the rest of the presumably negative patient population.

Type E. Various miscellaneous patients who sometime in the past were put on the tuberculosis register, but who in all probability were not tuberculous, were also reviewed and placed in this category. They included:

1. Those in whom tuberculosis had been tentatively diagnosed, or in whom infiltration of the lung fields had been observed, but in whom current chest films show completely clear lung fields.

2. Those with infiltration of the lungs once tentatively believed tuberculous. By location or progress, the infiltration seems more characteristic of some nontuberculous condition, particularly suppuration of the lung or bronchiectasis, or coccidioidomycosis.

3. Those with infiltration of the lungs which do not seem typical of tuberculosis, though this cause has not been absolutely ruled out. Great caution should be used in evaluating this group.

4. Those with thickening or calcification of the pleura of undetermined origin, in whom no parenchymal lesions are demonstrable.

Those in categories E-1 and E-4 require no further attention other than inclusion in annual X-ray surveys. Those in categories E-2 and E-3 require continuing clinical and laboratory study until a diagnosis is reached.

Using the Classification Scheme

In the course of this review, we studied over 3,000 sets of chest X-ray films in 11 California State mental institutions in collaboration with the staff physicians in the hospitals. Each case was reviewed; the chest X-rays were carefully studied; and clinical data and available laboratory data were weighed. Decision as to classification rested largely on the serial X-ray films, however, because of the sparseness of clinical and laboratory data.

In 2,915 (85 percent of the 3,443 cases studied) the original diagnosis of tuberculosis seemed valid (table 3). Of the 2,915, 32 percent, or 923, were classified as type A. These constituted the most important group of patients needing strict segregation and active treatment. An additional 832, 28 percent, were classified as type B. This group of patients is considered almost as important as the type A patients. Be-

Total removed from register.....							110	21	418	79	528	100

cause they have fewer symptoms, negative sputum, and an unchanging X-ray appearance, there is a strong tendency to consider these patients as inactive and, therefore, innocuous. The danger lies in the fact that reactivation (table 2), often unnoticed in the mentally ill, occurs distressingly often in this group of patients. If reactivation does take place, it is usually not discovered until the patient is X-rayed again. If he is not segregated during this period, many nontuberculous patients are exposed to infection. It is important, therefore, that the patients classified as type B should be segregated. Psychiatric treatment is given, of course, as needed.

The remaining 1,160, 40 percent, were classified as type C. This group was restricted, by definition, to those whose tuberculosis appeared very unlikely to reactivate because of its slight extent and fibrotic-appearing character over a long period of time. These patients were not segregated. However, since the estimate of the stability of disease could be in error, these patients should be X-rayed every 6 months instead of annually. Laboratory check is not needed unless the character of the disease changes.

Three percent, 110, of the 3,443 patients studied had findings which were judged as probably due to calcified primary lesions, hilar or parenchymal, or both (type D). Little or no skin

testing was done on these patients. The lesions may have been due to coccidioidomycosis or histoplasmosis. These patients were considered as essentially negative and were, therefore, removed from the register.

Twelve percent, 418, of the 3,443 were placed in one or another of the categories under type E. Some of these cases still presented diagnostic problems; others could be considered as non-tuberculous.

During and after this review of all tuberculosis patients in the mental institutions, the centralization of tuberculosis patients into a few institutions went on as rapidly as possible. A 500-bed tuberculosis hospital was completed at Patton State Hospital to care for tuberculosis patients from the southern part of California. At Napa State Hospital, a tuberculosis unit houses 240 patients. A 460-bed addition is being constructed there for tuberculosis patients from the central and northern part of the State. Until this addition is completed, tuberculous patients are being cared for at DeWitt State Hospital also. The tuberculous mentally deficient patients have been centralized at Sonoma State Hospital where a 120-bed tuberculosis hospital was built 3 years ago. The numbers of mental patients from which these tuberculous are drawn, in the above regional and type categories, were: mentally ill patients, southern California—13,000; mentally ill pa-

tients, central and northern California—22,000; mentally deficient patients, 7,400.

All patients classified as type A or type B were segregated and transferred to these tuberculosis centers. Type C or type D patients were not segregated nor moved from their wards or institutions. Patients classified as type E were studied further if a diagnostic problem existed. Otherwise, they remained in the general mental hospital population.

Summary and Conclusions

Tuberculosis is still a serious problem of frequent occurrence among the mentally ill and mentally deficient. A program of X-ray of all admissions and periodic X-ray surveys plus segregation are the first requirements in control. However, segregation of patients with active tuberculosis does not entirely meet the problem. Tuberculosis often undergoes reactivation, and, in the mentally ill patient, this fact often goes unnoticed until revealed by X-ray. Segregation of all patients diagnosed as tuberculous, regardless of extent or status of disease, appears impracticable.

The classification of the National Tuberculosis Association is not suited to the needs of mental hospital populations. A new classification has been created, based on the appearance of X-rays plus available laboratory or clinical data. This classification designates three groups, currently communicable (type A), potentially communicable (type B), and unlikely to reactivate (type C). Two additional groups were designated: those with only calcified "primary" lesions (type D) and those once designated as suspects with probable nontuberculous pulmonary disease (type E).

In a review of the case histories and films of 3,443 mentally ill and mentally deficient patients with tuberculosis or suspected tuberculosis in California mental institutions, 27 percent were considered as communicable and were classed as type A; these patients were segregated and treated. Another 25 percent of the

patients were considered as potentially communicable and were classed as type B; these patients were segregated but not treated. Thirty-three percent were considered as noncommunicable and not likely to suffer reactivation and were classed as type C; these patients were neither segregated nor treated. A few patients (3 percent) were diagnosed as having only calcified "primary" lesions, and were considered, in effect, as nontuberculous and were classed as type D; these patients were removed from the tuberculosis register and were handled as other nontuberculous mentally ill patients. Eleven percent of the patients reviewed had X-ray evidence of pulmonary pathology which was considered as probably nontuberculous; these were classed as type E and only a few undiagnosed problem cases in this group are still being segregated.

How One Health Department Helps the Handicapped

By MURRAY GRANT, M.D., D.P.H.

FOR several years, the Cattaraugus County Health Department has participated in the New York State medical rehabilitation program, which arranges for the diagnosis and treatment of physically handicapped children under the age of 21 and of persons of any age with poliomyelitis.

However, participation was not without its obstacles. Chief of these was the local lack of recognized specialists in rehabilitation. As a result, almost all patients eligible for rehabilitation service had to be transported from Cattaraugus County to Buffalo, approximately 70 miles away. Moreover, the expense was imposing an additional tax burden on the people of Cattaraugus County, a rural county of 80,000 with a median income below the median for the United States, where the tax burden was already increasing every year.

During 1953, a survey by the author found that a considerable proportion of the total expenditures for rehabilitation went for treatment of cerebral palsy and poliomyelitis cases and that most of these funds were expended for physical, occupational, and speech therapy. Most patients remained in Buffalo or at a treatment center near New York City for months. During their absence from home, particularly in the case of cerebral palsy patients, the initial

zeal with which parents accepted treatment for their children was often transformed into lack of interest and even fear of the burden to be reassumed when the children returned home.

The staff of the county health department felt that, if there were a sufficient number of patients in the county to warrant it, an outpatient clinic staffed by full-time, physical, occupational, and speech therapists and operated by the health department might offer certain advantages:

1. The health department could initiate a rehabilitation program for both children and adults. Many children are not seen under the State rehabilitation program, and therapy is not available to all adults.

2. Patients could be seen 2 or 3 times a week and could continue to live at home instead of being separated from their families for weeks and months.

3. Parents of handicapped children could accompany them to the treatment center, where the parents could not only see what was being done for their children but also could learn how to continue the treatment at home.

4. The initial interest with which parents seek and accept treatment for their cerebral palsied children could be capitalized upon, because the parents would be able to share in planning the treatment.

5. The family physician could participate more actively in the program. Because children had been sent to specialists in Buffalo, away from the private physician, there had been some antagonism to the State medical re-

Dr. Grant, director of the Clay County Health Department, Liberty, Mo., was formerly commissioner, Cattaraugus County Health Department, Olean, N. Y.

habilitation program on the part of local physicians.

6. The new program would result in considerably less expenditure of funds, and yet service could be given to many more persons.

Organization

Specialists in rehabilitation felt that an outpatient clinic in the county would be worth trying. However, although the clinic team could be administratively responsible to the county commissioner of health, a qualified person would have to be responsible for medical supervision. Therefore, an orthopedist with special experience in cerebral palsy was recruited. He resides in Buffalo and visits the county four times a year to see patients, ascertain their progress, and recommend therapy.

The orthopedist remains at the clinic from 9 a. m. to noon. He examines the patients, evaluates their progress, and, if necessary, recommends continued treatment or surgery. He also sees new cases or cases in which there is a question of the value of rehabilitation clinic service—for example, a cerebral palsy patient with a low I. Q. For these children, he will usually recommend psychological examination, which is usually done at the county mental health clinic. For all patients coming directly to the clinic, the orthopedist dictates a progress report, which is sent to the family physician; if the patient is referred by a physician, the orthopedist telephones him to discuss the case and the findings and recommendations.

Investigation revealed that the number of known handicapped persons in the county warranted the establishment of a clinic staffed by full-time personnel, and the county health department included in its 1954 budget an item of approximately \$12,000 for a rehabilitation clinic. The county board of health approved the item, and the board of supervisors, the appropriating body, included it in the budget. A most influential factor in their decision was the statement that expenditures would be reduced and services increased.

Recruitment of qualified personnel was difficult but was accomplished in time for the clinic to commence limited operations in March 1954. Clinic headquarters were established in the

county health department in Olean, and an additional treatment center was set up in another area having a considerable population.

Transportation of patients to the treatment centers was expected to be a major difficulty. However, there has been surprisingly little difficulty and, on the 1 or 2 occasions when transportation has been an obstacle, arrangements have been made with volunteer workers to bring patients to the treatment center.

A nominal charge of \$1 is made each time a patient visits the clinic or treatment center because we believe that it helps give to the families the feeling that they, too, are contributing to the patient's rehabilitation. No extra charge is made when patients are seen by more than one therapist. The fee system is flexible, and the charge is waived when the patient or his family is unable to pay. Only once has a parent declined further treatment for a child because of the fee, and she brought the child back to the clinic when the fee was waived.

So far, most of the clinic patients are children, who have visited the treatment center twice a week for several months. The policy is not to accept children unless they are accompanied by a parent, primarily to insure parent participation in the treatment program—by watching how the child is treated and by being shown what can be done for him at home. Practice at home is strongly encouraged, and the importance of not assuming that treatment at the clinic is sufficient is stressed. Each therapy session usually lasts half an hour; if a patient receives all three types of therapy—physical, occupational, and speech—he remains at the clinic for approximately an hour and a half.

Publicity

A program was arranged at a hospital staff meeting at which all three therapists described their services. To acquaint the public—particularly those who are possible sources of referral of patients, such as physicians, schools, and social agencies—with the clinic and what it is trying to do, the county medical society was kept informed of developments. Several newspaper articles were published, with pictures. Two local service clubs donated equipment, and pictures were taken of the presentation and

published in the local newspapers. The clinic was discussed at community meetings and, in the near future, a meeting will be held with all school authorities in the county to describe the clinic services. However, informing the public about the rehabilitation services is a slow process, which must continue indefinitely.

Convincing local physicians of the value of the rehabilitation clinic and persuading them to refer patients to it also must be a continuing educational process. Most physicians recognize that a patient with a speech defect can be helped, but the concept of occupational therapy or even of physical therapy is more difficult to appreciate. Physicians will be convinced of the clinic's value if they know that patients have been definitely benefited by the treatment received there. For example, after a patient with multiple sclerosis of many years' standing was helped, his physician referred another patient to the clinic.

Coordination of Services

Fitting the county rehabilitation clinic into other programs—the State medical rehabilitation program; a recently established county medical social service; a county mental health clinic; and the county public health nursing service—required special attention.

Coordinating the new clinic with the State medical rehabilitation program was comparatively simple because many children who re-

ceive surgery under this program are referred to the rehabilitation clinic. For example, a patient with a cleft palate will be referred for speech therapy following completion of the reparative operation. On the other hand, a person attending the rehabilitation clinic may require braces, which can be purchased under the State rehabilitation program.

Since the county medical social worker is familiar with the State rehabilitation program, she knows many of the patients attending the county rehabilitation clinic, knows their problems, and can help them or assist the clinic therapists in working with them. She can also serve as a liaison between the rehabilitation clinic and the mental health clinic. All recommendations for surgery, braces, or psychological tests are transmitted to her.

Many of the children attending the rehabilitation clinic require psychological testing to determine how much benefit can be expected from rehabilitation therapy. Adult patients who find it difficult to accept their physical handicaps present emotional problems which the mental health clinic team can sometimes treat. Also, when patients attending the mental health clinic are found to have physical handicaps, they are referred to the rehabilitation clinic.

Making maximum use of the public health

nurses in the rehabilitation clinic services, however, called for more deliberation. For several months, mainly because many of the patients attending the clinic were not known to the public health nurses, we pondered the part the nurses would take in the work of the clinic. It was finally decided that they would fit into the program:

1. By referring patients to the clinic and by making the service known to those in need of it.

2. By contributing to the clinic information about factors in the patient's history and background which might affect the treatment plan.

3. By becoming familiar with the needs of patients who require considerable home treatments.

The public health nurse observes treatment in the clinic and becomes acquainted with the patient and, if the patient is a child, with the parent. Then she visits the patient in his home and helps him or the parent learn to carry out treatment in the home situation. In addition, periodic conferences are arranged at which the clinic therapists, the medical social worker, and the public health nurse discuss the progress of the patient and any problems in the home or in the environment which may have a bearing upon the treatment plan and upon the prognosis. The public health nurse develops special skills accessory to the rehabilitation clinic through inservice training.

The rehabilitation clinic team has discussed the services offered by the clinic with the vocational counselor of the State department of education. He plans to meet with the clinic team at regular intervals to discuss cases and to determine whether rehabilitation clinic service would be more practical than to have services paid for under the vocational rehabilitation program.

Results

Since the clinic commenced operation, the following types of cases have been seen: poliomyelitis, cleft palate, delayed speech, arthritis, cerebral palsy, postural difficulties, multiple

sclerosis, hemiplegia, tongue-tie, clubfeet, tight heel cords, old fractures, orthodontic defects with speech impairments, lisp, hearing loss, knee injury, encephalitis, stuttering, birth injury, stroke, and paraplegia.

The following cases reviewed indicate the results that can be achieved.

CASE 1. A little girl, now 4 years old, contracted poliomyelitis in 1953, when she was 2 years old. She was left with a weak and contracted right arm, which she could not use. Physical and occupational therapy were started at the clinic on September 22, 1954, and were continued twice a week until December 1954, when sufficient function had returned to the arm to allow her to use it in feeding herself and in play.

CASE 2. A 43-year-old man was diagnosed as having multiple sclerosis. When he was first seen at the clinic, on November 10, 1954, he could not walk except with a cane and by clinging to his wife. At the clinic he was taught crutch balance, coordination, and stair climbing, and within 6 weeks he was walking alone with crutches. Occupational therapy was then started to give him confidence and to train him to make a living.

The patient is now undergoing processing by the New York State Vocational Rehabilitation Bureau, with a view to possible placement in a job. In the meantime, he operates a neighborhood store, selling light lunches, groceries, and articles of leather which he has made at the rehabilitation clinic. His personality has changed completely; self-pity has turned to determination and hope. He is independent to a large degree and is again the head of his family.

By the end of 1954, patients had made 1,130 visits to the rehabilitation clinic; 78 patients had actually been treated, and many of these were still under treatment.

The 1955 health department budget for rehabilitation has been reduced by 36 percent, and this alone is a strong point in selling the program to those responsible for appropriating tax funds for health purposes.

Although much remains to be done, particularly in coordinating the clinic services with services offered by schools and vocational rehabilitation agencies, we feel that the rehabilitation clinic is the nucleus of a workable program aimed at helping the many handicapped persons, both children and adults, in Cattaraugus County.

Clinical Laboratory Aspects of Leprosy

By LAWRENCE L. SWAN, M.D., and SISTER HILARY ROSS

ALTHOUGH the origins of leprosy probably are rooted in antiquity and the disease has been a dreaded affliction since the beginning of historic time, the etiological agent has been neither successfully cultivated in vitro nor propagated in experimental animals. As a consequence, unequivocal confirmatory laboratory tests are not available in leprosy as they are in other bacterial diseases of man. Nevertheless, numerous observations concerning the results of laboratory studies in leprosy may be found in the world literature.

In this paper, these observations, as well as our own observations based on work done at the Public Health Service Hospital in Carville, La. (the National Leprosarium), and the Public Health Service Hospital in New Orleans, will be presented and discussed in the light of present-day knowledge. It will be seen that the diagnostic laboratory procedures are limited to examination of tissues and that the abnormal clinical laboratory findings reflect, in actuality, the widespread systemic complications and sequelae of leprosy.

Dr. Swan, a pathologist, is now with the Lafayette Medical Laboratory, Lafayette, La. From September 1948 through June 1955, he was chief of pathology, Public Health Service Hospital, New Orleans. He was also chief consultant pathologist for the New Orleans Histopathological and Reference Center and for the Public Health Service Hospital in Carville, La. (the National Leprosarium). Sister Hilary Ross is a biochemist in charge of the laboratory at the National Leprosarium. She has been with this hospital for the past 32 years.

Bacteriology

The human leprosy bacillus, *Mycobacterium leprae*, was the first organism reported as the etiological agent of a specific disease in man. Despite this fact, it is the only pathogenic bacterium that has not been cultured on artificial media, transmitted to animals, or even transmitted experimentally within the natural host. Attempts to cultivate the leprosy bacillus on artificial media have been innumerable, and positive, as well as negative, results have been reported. The claims of successful cultivation, however, have never been substantiated by other investigators.

Although chick embryos are susceptible to a remarkable variety of bacteria, viruses, and rickettsiae, attempts to infect chick embryos and chick tissue cultures with leprosy bacilli have also met with failure (1).

In 1947 Hanks studied the effect of adding *Myco. leprae* to actively growing fibrocytes obtained from the skin of patients with tubercloid (2) and with lepromatous (3) leprosy. He observed rapid reduction of the organisms to acid-fast debris in the tissue cultures of fibroblasts from the patients with tubercloid leprosy; the degeneration of the *Myco. leprae* was less rapid with fibroblasts derived from lepromatous lesions. Cultivation from 2 to 7 months did not result in growth of the leprosy bacillus within the fibrocytes.

Chemistry

Serum Proteins

Most investigators agree that there are profound changes in the serum proteins in leprosy. For the determination of protein values, many

workers have used chemical methods (4-6). The quantitative and qualitative aspects of these methods compare favorably with the more recent electrophoretic methods of fractionating the complex mixture of serum proteins, but the latter methods are more sensitive and may detect abnormal constituents of the protein mixture.

The majority of the workers who have studied leprosy serums by electrophoretic methods have used the moving-boundary type apparatus (7-12). Miguel and his co-workers (13) made use of the Kern apparatus and paper electrophoresis. No specific references were found in the literature pertaining to the examination of serum from leprosy patients by paper chromatography, column chromatography, or ultracentrifugation.

According to most of the references cited, the total proteins are normal or increased in the great majority of leprosy serums. The quantity of albumin is usually moderately reduced, and, in our experience, in one case complicated by amyloidosis, albumin was undetectable by ordinary chemical methods and only poorly demonstrated by paper electrophoresis. There is a moderate to marked hyperglobulinemia in the majority of cases, and, obviously, reversal of the albumin-globulin ratio occurs frequently in leprosy.

There is less unanimity of opinion in regard to the quantity of the various globulin fractions in leprosy. However, it seems that α_2 is the most frequently elevated fraction. Miguel and his associates reported that this fraction was above normal in 69.76 percent of the patients studied (13). α_1 and beta globulin are elevated less frequently, although a majority of the reports specify an increase. All observers noted an abnormal increase of gamma globulin, and in Miguel's study the gamma globulin was above normal in 68.82 percent of the patients.

C-Reactive Protein

Serum from 100 patients at the National Leprosarium was tested recently for C-reactive protein. This abnormal protein was found in 79 percent of the patients with clinically active lepromatous leprosy and in 30 percent with clinically inactive lepromatous leprosy. It is believed that serial determinations of C-reactive

protein may have some value in following the progress of the inflammatory response to *Mycobacter leprae* infection.

Liver Function Tests

Many of the reports of liver function studies in leprosy are based on methods now considered obsolescent or are no longer significant in the light of our better, though still imperfect, understanding of the mechanism of the reactions involved in these procedures (14). As should be expected, the incidence of abnormally high cephalin flocculation and thymol turbidity tests closely parallels the number of serums in which the proteins deviate from normal (15).

Normal values for urobilin and bilirubin in blood and urine were reported by Molinelli and Royer (16). It is important to note that the bilirubin test employing Ehrlich's diazo reagent diazotizes the two amino groups of the sulfone drugs. A positive test for bilirubin, therefore, would be indistinguishable from the reaction produced by the sulfones, a fact which makes this procedure as unreliable in leprosy as other liver function tests.

In our review of the literature, no reports regarding the results of the bromsulfalein excretion test in leprosy were found. Probably, bromsulfalein is excreted by the parenchymal cells in a manner similar to that in which bilirubin is excreted. Therefore, in the absence of jaundice and with normal renal excretion, this test should be one of the more useful procedures in leprosy.

Hopkins and others (17) reported that cholesterol was high in 14 and normal in 27 leprosy patients and that cholesterol esters were increased in the majority. Gomes and his colleagues (18) observed that reduction of serum cholesterol levels was proportional to the gravity of the disease, especially in febrile reactions. Lippi (19) noted that the serum cholesterol fell in patients with the lepromatous type and in those in serious condition. Ross (20) found serum alkaline phosphatase to be within normal limits in 87 percent of 102 patients. There is little information regarding the zinc sulfate turbidity test or the hippuric acid test in leprosy.

At the National Leprosarium laboratory, we have studied a small number of liver biopsy

specimens obtained percutaneously by the Vim-Silverman needle method from patients with active lepromatous leprosy. Hepatic miliary lepromata were easily identified, and *Mycobacterium leprae* organisms were demonstrated by acid-fast staining. Hepatic amyloidosis was demonstrable histologically by crystal-violet stain in the instances in which there was 100-percent absorption of congo red. Our experience with needle biopsies of the liver has been too limited to draw definite conclusions, but the technique seems to be a very promising one for evaluation of hepatic involvement by leprosy and by amyloid. The procedure is not without hazards, however, and all established safeguards should be observed.

Calcium and Phosphorus

There is disagreement in the observations of investigators regarding serum calcium levels in leprosy. Reports of normal levels (21-23), of hypocalcemia (24) and of hypercalcemia (25) may be found. Wooley and Ross (26) found diffusible calcium to be lower than normal in leprosy patients and that it increased with clinical improvement of the disease. They reported that inorganic phosphorus was normal in uncomplicated leprosy.

Lemann and others (27) found no relation between serum calcium levels and the bone absorption in leprosy; however, Wooley and Ross reported that in the aforementioned series bone atrophy was shown by radiography in 44 of 53 patients whose serum was studied.

Glucose

Very little has been reported on carbohydrate metabolism in leprosy since Villela's review in 1938 (24). Certain of the older reports, such as those of Lai (28) and Otsuka (29), mentioned lowering of glucose tolerance. Wayson, Badger, and Dewar (30) stressed the high frequency of disturbance of carbohydrate metabolism in Hawaiian patients. Glycosuria was noted in 23.0 percent of 175 patients, and 80 percent had abnormal glucose tolerance curves.

More recently, Lancepleine (31) reported the frequency of hypoglycemia to be greater in patients with neural leprosy than in those

with lepromatous leprosy, but the number of patients studied was too small to give significance to the observation. Tanioku (32) found some increase in blood sugar in both macular and lepromatous leprosy, but he did not consider it to be specific for leprosy. Sakakibara (33), however, could detect no consistency in occurrence of either hyperglycemia or hypoglycemia.

The sugar content of the blood is determined routinely on admission of patients at the National Leprosarium, and, if it is above normal, a glucose tolerance test is performed. A urinalysis is made at 3-month intervals on every patient. There are usually 20 to 30 patients in the hospital, or about 5.0 to 7.5 percent of the total, who have glycosuria.

Hematology

In 1949 Kiang and Choa (34) reported the results of the hemograms for 36 leprosy patients and reviewed a few pertinent references dealing with the blood picture in leprosy. Anemia was found to be frequent but never severe, and no morphologic abnormalities of the erythrocytes were noted. The reticulocytes were low, averaging 0.2 percent. For all except 4 patients, the erythrocyte sedimentation rate was increased. Leukocytosis was inconstant, and when present it was only of moderate degree and only in patients with lepromatous leprosy. The differential counts indicated that leukocytosis was due to increased numbers of mononuclear cells; however, in the untreated cases there was a definite neutrophilic shift to the left. Eosinophilia was observed in 36.1 percent of the patients, and the condition was believed not to be due to parasitism.

From the literature and from our own observations it can be stated that anemia in leprosy is seen mainly in the lepromatous type, especially in patients in whom the disease is advanced, is in a reactional crisis, or is complicated by nephrosis. The majority of workers emphasize leukopenia, but at the Carville hospital leukocytosis has been maintained occasionally over a period of years even in uncomplicated cases. Eosinophilia has been mentioned frequently; however, findings at Carville do not substantiate the opinion that leprosy

per se causes an increase in the number of eosinophils.

The erythrocyte sedimentation rate is accelerated in leprosy, especially in the lepromatous type and in mixed types (35). In our experience, there are no characteristic alterations in the bleeding time, coagulation time, or clot retraction.

In bone marrow from patients with leprosy, *Myco. leprae* bacilli are occasionally demonstrated in the smears as well as in the marrow particles. In a series of 32 bone marrows obtained at autopsy, we found bone marrow involvement in 6. Although there is a relatively high incidence of amyloidosis among patients at the National Leprosarium, amyloid has not been convincingly demonstrated in aspiration material from the sternal or iliac crest marrow or from autopsy material. Cytologically, the marrow usually is not remarkable.

The demonstration of *Myco. leprae* in the cytoplasm of leukocytes has been reported. Namba (36) observed the presence of bacilli in both neutrophils and monocytes removed from the buffy layer of sedimented citrated blood. Montel (37) also found bacilli by this method. He nearly always obtained positive results in generalized lepromatous cases, especially during febrile reactions, but never in tuberculoid cases.

Myco. leprae bacilli have been observed in dehemoglobinized blood. By examining thick drops of blood dehemoglobinized with water, Clouston (38) obtained 77.7 percent positive results in nodular leprosy. The results were negative in 21 early cases, however, and he concluded that the procedure was of no practical use in detecting early or latent leprosy. Baru (39) laked and centrifuged venous blood and found bacilli concentrated in the sediment. At the National Leprosarium, a similar technique revealed the presence of bacilli in approximately 50 percent of the newly admitted patients with lepromatous leprosy.

Immunology

Serologic Tests for Syphilis

It is generally agreed that there is a high incidence of biologically false positive serologic tests for syphilis in leprosy patients (40). A

clinico-serologic study of 224 patients at the National Leprosarium was made in 1952 (41). The serologic tests for syphilis used were (a) the Kahn standard quantitative; (b) the Kolmer (cardiolipin) quantitative; (c) the VDRL slide flocculation quantitative; (d) the Rein-Bossak slide flocculation quantitative; and (e) the *Treponema pallidum* immobilization (TPI). The reactivity rates were as follows:

	Reactivity rate (percent)
Kolmer-----	63.4
Kahn-----	52.7
VDRL-----	46.9
Rein-Bossak-----	31.8
TPI-----	11.2

It was concluded that the reactivity rate for the *Treponema pallidum* immobilization test appeared to be consistent with the syphilis rate that might be expected in a comparable population group without leprosy.

The majority of the patients considered to have false positive tests for syphilis had lepromatous leprosy. This seroreactivity seemed to diminish with the prolongation of the disease, but there did not appear to be any correlation with the age of the patients. There was no significant relation to seroreactivity in amyloidosis of leprosy, diabetes, or carcinoma.

Universal Serologic Reaction

In his discussion of the universal serologic reaction with lipid antigen, Kahn (42) states that the reaction between tissue lipids and serum upon which serodiagnostic tests for syphilis are based is not primarily a syphilitic reaction but a biologically universal reaction. A special method known as the universal serologic technique seemed to distinguish specific serologic patterns in all human beings and animals. Concerning such patterns, Kahn states, "In lepromatous leprosy, the serologic pattern of the universal reaction is also apparently distinctive; yet, it is entirely different from the serologic patterns noted in either syphilis or yaws." In addition, he indicates that this test should assist in differentiation of the various clinical forms of leprosy.

Ross and Gemar (43) investigated the universal serologic reaction in 130 leprosy patients, 20 of whom had tuberculoid leprosy and 110

of whom had lepromatous leprosy. From analysis of the data, they concluded that there was no indication of any distinctive serologic pattern in lepromatous leprosy. In addition, the data suggested that treatment may alter the type of pattern in this form of the disease. Pinto and Zeo (44) also were unable to confirm a distinctive universal serologic reaction in lepromatous leprosy, and their conclusions were in agreement with those of Ross and Gemar.

Human Leprosy Antigen

Microflocculation tests employing antigens made from human leprosy material, according to the method of Castro (45), have been investigated recently at the National Leprosarium. Serums from 144 normal persons were all negative. Serums from 50 patients with tuberculosis were negative except for one doubtful and one positive test, and serums from 32 patients with syphilis were all negative. The overall results of the microflocculation tests on serums from 219 leprosy patients were as follows:

Tuberculoid, inactive..... 13 negative; 0 positive.
Lepromatous, inactive..... 4 negative; 2 positive.
Lepromatous, active..... 23 negative; 177 positive.

These results, which are in close agreement with the original investigations by Castro, indicate that the use of antigens made from human leprosy material may be a worthwhile laboratory procedure in leprosy.

Middlebrook-Dubos Hemagglutination Test

The erythrocyte agglutination test of Middlebrook and Dubos has also been studied at the National Leprosarium (46). In a study of 261 cases of leprosy, it was found that the proportion of high titers was significantly higher in clinically active lepromatous cases with large numbers of bacilli than in quiescent lepromatous or tuberculoid cases. Results in a small number of cases studied repeatedly over a 1-year period suggest that there may be some correlation between the clinical course of the disease and alterations in titer.

Spinal Fluid

In 32 National Leprosarium patients, no characteristic changes were observed in the spinal fluid. This study included cell count; sugar,

chloride, protein, and colloidal gold tests; and a Wassermann complement fixation test. The negative finding is in agreement with the results of other studies (47, 48).

Tissue Diagnosis

From the preceding discussion, it is obvious that the reviewed clinical laboratory procedures offer no pathognomonic diagnostic information in leprosy. At this time, the laboratory procedures which are most likely to be diagnostic of leprosy are limited to (a) microscopic examination of biopsy material and (b) microscopic examination of smears from skin and nasal mucous membrane scrapings (49).

Examination Techniques

It is of considerable importance to select the site of biopsy or smear specimen with care. The margins of macules and areas of infiltration offer the best material.

We prefer that the biopsy specimen be obtained with a sharp scalpel and that it be sufficiently deep to include subcutaneous tissue. In this country, 10 percent formalin solution is preferred as the fixative, and the sections are stained with hematoxylin and eosin. We have found that the Fite-Cambre-Turner modification of the Ziehl-Neelsen stain to be the most satisfactory acid-fast stain for tissue sections.

In obtaining material for a smear, the skin is compressed between the fingers until it blanches, and a very small incision is made with a single edge razor or a scalpel blade. The blade is scraped through the incision at right angles to collect tissue fragments, which are spread on a glass slide. The slide is stained by the Ziehl-Neelsen acid-fast method.

Demonstration of *Myc. leprae* in leproma is not difficult; however, it is usually a laborious task to obtain bacilli in acceptable numbers from the macules of tuberculoid leprosy. Recent reports from India describe simple methods of concentrating the bacilli by tissue homogenization which are superior to the usual skin smears in such cases (51, 52). These methods are being studied at the Carville hospital, and the results thus far tend to confirm the observations of the Indian researchers.

Characteristics of Three Leprosy Types

Lepromatous leprosy, one of the two polar types, is the one usually illustrated in textbooks and found in class slide sets. Except for a characteristic uninvolved zone immediately beneath the basal layer of the epidermis, the dermis is infiltrated by large, pale, mononuclear phagocytes with a slightly granular cytoplasm, the so-called lepra or Virchow cell. In the early stages of the disease, collections of these cells are oriented around capillaries and lymphatics, and, in later stages, they coalesce into homogeneous masses of lepra cells. Acid-fast stains reveal astounding numbers of leprosy bacilli in the cytoplasm and in cystlike structures called globi. Bacilli are also present in walls of vessels. No caseation necrosis or giant cells are seen unless complicating factors have altered the picture. On rare occasions, foreign-body type giant cells are present around the globi.

Tuberculoid leprosy is the other of the two polar types. Its most obvious feature is the presence of epithelioid tubercles with Langhan's type giant cells. No uninvolved sub-basal zone is present, and the picture is closely mimicked by some cases of sarcoid of the skin, tuberculosis, beryllium granulomas, and other granulomatous cutaneous lesions. In a study of the histological differentiation of nonleprous and leprous cutaneous tuberculoid granulomas at the Armed Forces Institute of Pathology, one of the authors (Swan) and Dr. Chapman H. Binford concluded that nerve involvement is seen almost exclusively in the leprosy cases. *Mycob. leprae* bacilli are infrequently seen in tuberculoid leprosy, although a few may be found in most cases if a determined and vigorous search is made.

What is known as the indeterminate type of leprosy is histologically nonspecific. In this type the presence of acid-fast bacilli is rather infrequent. The dermal reaction consists of perivascular and perineural lymphocytic infiltration.

Summary and Conclusions

The cultivation of *Mycobacterium leprae* is probably the one most important goal sought by leprologists. Conclusive proof of the pres-

ence of leprosy, exact determination of activity, precise evaluation of therapeutic agents, and development of specific diagnostic tests await the cultivation of this organism. The leprosy bacillus appears to be an intracellular parasite, and it is possible that with present-day tissue culture techniques the organism will be successfully grown in vitro.

The abnormal values of serum proteins generally are considered to be due to the response of the reticuloendothelial system to leprosy bacilli. It is important to evaluate the protein values in leprosy according to (a) the type of leprosy from which the serum is obtained and (b) the activity of the disease and complicating conditions, such as amyloidosis and renal disease. It is apparent that in almost all cases of lepromatous leprosy there are abnormalities of serum proteins. The globulins are increased during acute lepra reactions and erythema nodosum leprosum, and they subside as the erythema disappears. Abnormalities of the serum proteins are rare in tuberculoid leprosy. In view of the frequency of complicating amyloidosis in leprosy, the evaluations of serum proteins are significant, especially in the light of recent evidence suggesting that amyloidosis seems to be related to the appearance of beta and alpha₂ globulins in the blood of experimental animals (53).

The cephalin flocculation and thymol turbidity tests are abnormal in leprosy because of the quantitative, and possibly the qualitative, variations in the serum proteins. The reduction of serum cholesterol levels, as reported by most observers, is more in keeping with what is known concerning cholesterol metabolism and excretion. The relationship between free and esterified cholesterol seems not to have been adequately studied in leprosy. The low serum cholesterol levels in active lepromatous leprosy suggest that there is hepatic involvement, a condition which the finding of lepromata and organisms in needle biopsies of the liver seems to confirm.

Other clinical chemistry tests reviewed do not appear to be altered by leprosy per se.

Hematology offers little in the diagnosis of leprosy. The presence of organisms in the cytoplasm of circulating leukocytes or in smears from laked blood is usually seen only in cases

in which organisms can be demonstrated more easily from smears of cutaneous lesions. Bone marrow examination likewise contributes little to the diagnosis of the disease.

False serologic tests for syphilis in leprosy are well known and have made the diagnosis of concurrent syphilis difficult unless spirochetes are demonstrated. The recent results of the *Treponema pallidum* immobilization test in patients with leprosy suggest that the false biological positive reactions have been eliminated.

The Middlebrook-Dubos hemagglutination test reveals that leprosy probably produces antibodies which cause agglutination of red blood cells that have been sensitized with tuberculin. The microflocculation test of Castro, from the serologic point of view, may be assumed to be a diagnostic test for leprosy. We believe that this test may be of value as a routine laboratory procedure in the detection of overlooked cases of lepromatous leprosy in endemic areas.

It is our opinion that at the present time examination of tissues is the best method of making a laboratory diagnosis of leprosy and of classifying the disease as to type. The concentration of organisms by homogenization of tissue is perhaps the method most likely to demonstrate organisms in all types of leprosy. Meticulous technique and cautious interpretation of results are essential for proper utilization of this procedure.

Conference Report

SIX BRIEFS of papers presented at the 13th annual meeting, May 6-9, 1955, Mexico City, appear on the following pages. The official publication of the association is the *Boletín de la Oficina Sanitaria Panamericana*, in which one may expect to find Spanish versions of the conference papers.

Good Health at the Border

PHR Unsolved public health problems exist at practically every point where communities meet at the boundary line between the United States and the Republic of Mexico. But none are of greater magnitude than the public health conditions along the Rio Grande, which separates Texas and Mexico.

Morbidity statistics per 100,000 population for 1953 illustrate the lack of good health in the 11 border counties of Texas. The tuberculosis morbidity rate is 128.8; for the entire State it is approximately 56.8.

Gonorrhea and syphilis rates for the entire State are 267.2 and 89.4; for the 11 border counties they are, respectively, 397.3 and 199.5.

Bacillary dysentery and amebic dysentery rates for the entire State are 197 and 6.5; for the 11 border counties they are 923.6 and 30.2.

The infant mortality rate, one of the most sensitive indicators of the state of public health in any population was 48.7 per 1,000 live births in these 11 counties; for the entire State it was 34.3.

One border county annually reports 3 times the number of shigellosis cases that are reported by all the other 253 counties of Texas.

The flow of migratory labor into Texas has increased the scope of public health problems in the border counties. Little has been done, however, to meet the health needs of incoming legal "braceros." Frequently, labor contractors neglect making arrangements for the health, safety, and comfort of the migratory workers they transport.

Rest stations have not been provided at strategic points for these people in transit. Little in the way of proper housing and basic sanitary facilities has been provided for these laborers at their employment destinations.

Standard Health Units

What can be done to help us reach our mutual goal of good health at the border? Most prob-

lems of public importance can be solved by the community when people understand the necessity of finding a solution to their problems.

The satisfactory solution of community health problems can best be approached through the services of a standard full-time health unit. Local health units or their counterparts along each side of the boundary line would eventually achieve our mutual goal.

I hope to be able to report at some future meeting of the United States-Mexico Border Public Health Association that every county on the Rio Grande is served by an accredited full-time health unit and that all other Texas counties are also covered by such a service.

The basic professional team needed for the local health unit consists of—

- One or more licensed physicians who have had graduate training in public health administration.
- At least one dentist with training in public health dentistry.
- A corps of nurses who are qualified through training, experience, and skill to give communitywide public health nursing.
- A sanitary engineer and a sufficient number of properly trained sanitarians to assure the environmental safety of the local community.
- Skilled laboratory personnel to verify and support the technical efforts of other staff members.
- A trained and skilled health educator to correlate the educational effort of the unit.
- Sufficient nonprofessional personnel to carry out the routine work of the unit.

Functioning on a county or multicounty basis, the standard health unit—

- Collects and analyzes morbidity and mortality statistics, for use in planning and carrying out programs aimed at raising local health standards.
- Makes epidemiological studies and, in cooperation with the local medical profession, institutes appropriate measures in the control of communicable or preventable diseases.
- Supervises and administers a continuing program of environmental sanitation, which will assure the community a safe water supply, proper disposal of industrial and human waste, protection of all food sources, control of insects

By Henry A. Holle, M.D., State health officer, Texas.

Setting the Pattern

The United States-Mexico Border Public Health Association has demonstrated that our two countries can live peacefully side by side and solve our problems at the council table in a democratic fashion. Learning to live peacefully with one's neighbor is one of the highest attainments yet to be reached in the public health field.

—Victor M. Ehlers, director, division of sanitary engineering, Texas State Department of Health, Austin, Tex.

and rodents, and the elimination of health hazards and nuisances.

- Conducts projects to promote better health for mothers and children, through maternal and child health clinics.
- Promotes dental health, through clinical demonstrations, education in dental hygiene, and corrective services provided by local dentists.
- Provides those laboratory services which are prerequisite and directly related to the successful administration of the overall public health effort in the community.
- Carries out consistent programs of community education through available channels, to guide individuals and groups toward better individual and community health.

Border Health Units

In developing local health units along the border, we shall give special attention to staffing with persons who speak English and Spanish fluently, and who are best qualified to cope with the health problems common to all communities along the Rio Grande. These communities will cooperate with Mexican health authorities in every possible way.

Much has been gained by public health personnel who participated in the environmental sanitation training seminar at Laredo, Tex., sponsored by the Pan American Sanitary Bureau, the Ministry of Health and Welfare for Mexico, the United States Public Health Service, and the Texas State Department of Health.

The success of the seminar points to the great need for a special training agency to reach all types of health workers on both sides of the in-

ternational boundary. In the event the establishment of a special agency is not immediately possible, we can all work toward expanding in-service training programs along the border to include all categories of health personnel from both countries. It is desirable that we also work out a program for the exchange of public health personnel working on each side of the border.

Even with the very best international and intranational cooperation, we still face an uphill fight. I venture to say that it was best we did not adopt a plan considered in the 1930's, which would have turned over to an international commission the matter of public health administration in the border counties and municipalities. It would have destroyed local initiative in developing adequate community public health resources. Properly staffed and equipped local health departments, encouraged and assisted by state and federal governments, can ultimately attain our goal.

A Natural Resource

PHR Under construction in Mexico City and soon to be completed is the sewage treatment plant of Chapultepec. From the sewage the plant will produce liquid activated sludge and humus for agricultural purposes.

The new plant will be used as an experimental laboratory for the Sanitary Engineering School of the National University of Mexico. This school is sponsored by the Ministry of Health and Welfare through its division of experimental studies in public health. Other research will be conducted at the several installations of the sewage treatment plant.

Soon to be in operation is a pilot plant to treat the sewage of the Grand Canal, Mexico City. Over a year's time, a daily chemical analysis has been made of 24-hour composite samples. The outcome of this study will de-

By Raúl Enrique Ochoa Elizondo, engineer. Departamento de Obras Hidráulicas del Distrito Federal. México, D. F.

termine the design of corresponding subsidiary installations.

For more than 10 years the problem of treating sewage in Mexico City has been a cause for public concern. During this period the problem was aggravated by a diminishing water supply.

The falling level of Xochimilco Lake, one of the main tourist attractions of Mexico City, led the Departamento del Distrito Federal to endeavor to preserve the lake and by so doing to improve its actual sanitary condition. The department has recommended that treated sewage be used to supplement the rainwater that normally flows into the lake in order to maintain the water level.

The water in some of the wells formerly used for watering public gardens has been exhausted. This is true particularly of the Bosque de Chapultepec, which is the main public park in the city.

As part of the general attempt to solve the problems of sewage and water supply, it is planned to establish a closed cycle in the rational use of the waters in the Mexico Valley basin. It is economically desirable to take part of the city water supply from the deep ground water in the valley, which at present is used for irrigation purposes, and to use the treated sewage for irrigation. The sludge is also used for fertilizer to replace the nutrients removed from the soil.

Wildlife Rabies Control

PHR

Rabies is as much, or more, a problem of agricultural economics as it is of public health. During 40 years' experience in controlling animals harmful to man, the Fish and Wildlife Service of the United States Department of the Interior

By Clifford C. Presnall, assistant chief, Branch of Predator and Rodent Control, Fish and Wildlife Service, United States Department of the Interior, Washington, D. C.

Exchange of Rabies Reports

We recognize the importance of mutual cooperation in solving the problems of rabies along the United States-Mexico border. The Texas-Mexico border is long, and the Rio Grande River is not an effective barrier against the rabies virus.

Let us attempt to share reports on the laboratory findings of rabies along the border. The Texas State Health Department will be pleased to send its monthly report on rabies and other animal diseases to interested persons in Mexico. In exchange we would appreciate having copies of similar reports and other significant information regarding rabies along the border.

—J. V. Irons, M.D., director of laboratories, and R. B. Eads, Ph.D., principal entomologist, Texas State Department of Health, Austin, Tex.

has learned two basic truths about rabies in wildlife.

The disease can often be stopped, or greatly limited, by reducing without actually exterminating the population of wolves, coyotes, and foxes. Rabies epidemics seldom start where these animals are kept from becoming too numerous.

The numbers of these animals can be kept low without great expense and without danger to beneficial animals, domestic stock, or mankind. An incidental benefit is a reduction in the number of livestock killed and eaten by predators.

Applied with success for many years in the United States, these principles have been used with good results along the border between Mexico and the United States. Since the informal Nogales agreement was made on April 26, 1949, a joint program of rabies control demonstrations has operated in a 150-kilometer zone on both sides of the boundary.

Regular Predator Control

All of the work north of the border has been part of the regular predator control program which the Fish and Wildlife Service operates in cooperation with State and county agencies and local livestock associations. This work has

kept predators from becoming abundant along much of the border with the result that there has been little rabies among either wild or domestic animals.

During the past 6 years there have been only two outbreaks of rabies among wildlife in the control zone: one among coyotes and foxes in San Diego County, Calif., and the other in Santa Cruz County, Ariz. A few other cases of rabies have been known among domestic animals in Arizona also.

In the New Mexico portion of the zone there has been no wildlife rabies reported during this time. Texas reported only one rabid coyote along the border.

South of the border the amount of rabies reported among wildlife has been equally small. Within the zone, however, few animal heads have been available for examination because there has been little trapping of foxes and coyotes.

Public interest in coyote and wolf control has been most active in border areas of Chihuahua, Sonora, and Baja California. Six small demonstrations of control methods have been held in these Mexican states since the agreement for joint action—all with the joint aid of the Pan American Sanitary Bureau, the United States Fish and Wildlife Service, federal or state agencies, and local livestock associations.

In Chihuahua, and to some extent in Sonora, the local livestock associations have carried on the work during the intervals between demonstrations. In all demonstrations, the work has been hampered by movement of wolves and coyotes from large uncontrolled areas into the small controlled areas. Results of the demonstrations show that similar work all along the border would be desirable. These results are best shown west of Nueva Casas Grandes, Chihuahua, where control has been effective during the past 5 years in an area which varied from 1,000 to 4,000 square kilometers.

A recent survey of the Casas Grandes area revealed a low population of wolves and coyotes, similar to many parts of the United States where no rabies outbreaks have occurred since the excess numbers of predators were first reduced some 35 years ago. The wolf and coyote population is now low enough to make it unlikely that rabies could spread rapidly. There

has also been a great reduction in loss of livestock since predators were controlled.

Ranchers report that the number of sheep, calves, and other livestock killed by predators is now only a small fraction of the number killed before 1950. One herd of cows produced twice as many calves in the year after predator control as in the year before. Thus, the work directly benefits both the health and economics of the area.

Economic Benefits

Economic benefits are more easily seen by cattlemen than are health benefits. It is logical for them to support measures which help raise and sell two calves rather than one. Most people give little thought to benefits to health until they become sick. Then it may be too late.

The same applies to rabies control, which is seldom given any attention until the outbreak occurs. By controlling the domestic and wild carriers of rabies before an epidemic starts and by removing the excess numbers of wolves and coyotes, continuously and on a wide scale, we can decrease the danger and expense of repeated local outbreaks.

The small rabies control areas along the United States-Mexico border have demonstrated the suitability of methods for preventing spread of the disease among wildlife and of reducing livestock losses. The time now seems ripe for action which will aid broad-scale application of the idea throughout the entire border zone.

Mosquitoes and Encephalitis

PHR An epidemic of St. Louis encephalitis in August 1951 affected 600 people in Hidalgo County, Tex., causing at least 2 deaths. Local physicians, baffled by the nature of the disease, called it poliomyelitis. Naturally, alarm re-

*By Sam L. Warrington, B.S.C.E., sanitary engineer.
Hidalgo County Health Unit, Edinburg, Tex.*

sulted from reports of 92 cases of "poliomyelitis" in 1 week.

Countywide Control

Hidalgo County has a population of 180,000, with 12 cities ranging in size from 5,000 to 25,000. The county lies on a flat delta on the Rio Grande across from Tamaulipas, Mexico. A vast irrigation and drainage system affords many ideal mosquito-breeding potentials.

No mosquitoes in the area had been known to transmit encephalitis. *Culex quinquefasciatus*, the most numerous species, proved to be the vector responsible for carrying the encephalitis virus from wild birds to man.

Working on the assumption that the Hidalgo County epidemic was mosquito-borne, insect control specialists began a mass mosquito-killing campaign. The county health unit furnished the supervision, equipment, and crews for larviciding all breeding places within each city and for about a mile around the fringe areas. The cities paid for the chemicals used for spraying and for the gasoline for the trucks.

At first we thought that we could control the mosquitoes by finding and larviciding all the water holes. It didn't take long to discover that we were missing too many breeding places on private premises for this measure to be effective. To kill the larvae, 5 percent DDT and diesel oil were applied on all standing water. To kill adult mosquitoes, a 3 percent gamma isomer benzene hexachloride (BHC) dust and 5 percent DDT and water were used in turbine sprayer-dusters in all of the cities.

The epidemic began to subside before the mosquito control activities had been completed in all the cities. Continuous collections of mosquitoes are being made and studied by the laboratories, however. As late as January 1955, the virus was still present in the mosquitoes. Since then, two cases of encephalitis have been reported, although one patient later was found to be suffering from a blood clot.

In the likelihood of another epidemic, unless mosquito control continues, it is planned that the county and cities will share the expenses of control operations. For adult mosquito control, the cities which have fogging machines or dusting equipment will continue to fog with them. For the cities which do not have space-

spraying equipment, the county health unit has purchased a jeep-mounted turbine sprayer-duster. Space spraying will be done for the cities on a fee basis.

From our mosquito control efforts we have learned that larviciding plus fogging with 5 percent DDT and diesel oil in a dynafog gave good control for about a week. Larviciding plus space dusting with 3 percent gamma BHC and space spraying with 5 percent DDT and water gave good control for a longer period than with the fogging machine.

El Paso-Juarez Area

PHR El Paso and Juarez are the two largest cities in their respective countries on the United States-Mexico border. They are contiguous, being separated only by the Rio Grande, a narrow sandy stream which can be waded most of the year round. The northbound traffic amounts to 18 million people a year. Southbound traffic is only slightly less. Thus, there are many joint sanitation problems.

Joint Insect Control

Mosquitoes, more of a nuisance than a public health problem, breed in thousands of ditches, irrigation boxes, and culverts—all close to thickly settled suburban developments. Most of these breeding areas can be reached only by foot. The breeding is enhanced by the fact that much of the Mexican irrigation water contains a high percentage of sewage, which tends to seal the ground, preventing the water from drying away between irrigations. The sewage also furnishes abundant organic matter to feed the larval stage.

For control, we use 5-gallon knapsack sprayers containing stove oil of 40 gravity with 2 percent benzene hexachloride (BHC) in solution. The oil is sprayed on the mosquito-breeding water surfaces and effects a suitable kill. The

By J. Harold Tillman, B.S.C.E., sanitary engineer,
El Paso (Tex.) City-County Health Unit.

El Paso Health Department furnishes the equipment, insecticide, and some supervision, and the Juarez Health Department furnishes the labor and some supervision.

The housefly does not recognize international boundaries either. In addition to the usual fly sanitation control, we have a supplementary program which consists of spraying garbage cans and pit privies along public streets and alleys with a residual type of insecticide. This is a concurrent program with Juarez rather than a joint program.

Because flies rapidly become resistant to various residual chemicals, we change insecticides each year. We plan to change to malathion, DDT, and a new product called Die-Fly. Sugar is added to attract the flies.

A few years ago the Texas State Department of Health conducted a 4-day course for training health department personnel and people in industry responsible for fly control. Six inspectors from the Juarez Health Department attended the course, held in El Paso.

Voluntary Cooperation

As a result of the efforts of the first international committee on diarrhea and enteritis, in El Paso the infant death rate per 100,000 has dropped from 54.6 in 1951 to 13.6 in 1954, and Juarez has had a similar improvement. Representatives from the two cities form the committee which was organized several years ago.

Theirs is a completely voluntary program, sponsored by the two local health departments and the Central Council of Social Agencies. Volunteers armed with demonstration equipment and pamphlets have visited each home in areas having the most cases of diarrhea and enteritis. Mothers were told how to protect their child's food and what to do when the child first shows signs of illness.

El Paso has oil refining, smelting, brickmaking, woodworking industries, packinghouses, railroads, quarries, and a fertilizer plant. For several years we have had a voluntary program of air pollution abatement. Our mayor set up a smoke control committee to work with the industries on a voluntary abatement program. When we had made every improvement possible by this means, we recommended a smoke control ordinance, but industry promptly proposed

that it set up its own policing committee to handle individual complaints and to strive for further air pollution abatement. This is the program now in effect.

The Rio Grande flow has been decreasing for years. At the same time, the waste load has been rising. Stream pollution is heavy with discharges from sewage plants and industries. Only a small part of this pollution comes from Mexico.

El Paso is building a secondary sewage treatment plant to treat an effluent of about 12 million gallons daily. The El Paso County water improvement district is building two other secondary treatment plants. A large packinghouse has built a plant to treat its waste discharges. These latter treated discharges, now used for irrigation on Mexican soil, no longer enter the Rio Grande directly except in winter.

By mixing sewage with irrigation water and well water and using the mixture for land irrigation, Juarez has corrected an odor nuisance caused by the discharge of sewage into a drainage ditch parallel to the river.

Ways of Cooperating

When El Paso and Juarez conducted a joint rat-typhus survey in 1946, sampling points were set up in both cities. Men from both health departments worked side by side in the program. Although neither city had any human cases of typhus, 25 percent of the rats caught were infected. In the 1951 survey 5 percent of the rats were infected.

The sanitary landfill in El Paso was located adjacent to Cordova Island, a portion of Mexico north of the river. A wire fence is the international boundary at that point. The health officer of Juarez protested the location of the fill, stating that he had an almost impossible police problem to keep citizens from crossing the fence to rummage in the fill for salvage, which he felt was a health menace. Locating another site for the fill away from the boundary solved the international phase of this problem.

Vegetables, pineapples, strawberries, bananas, and shrimp are part of the international food traffic from Mexico to the United States. The United States sends corn, beans, and rice into Mexico. All foods are inspected on both

sides of the river. One El Paso company proposes to import grade A milk from a Juarez dairy. Another proposes to import ice if our local requirement that ice be manufactured from distilled water can be met.

Many of the sanitarians in the Juarez Health Department have earned certificates from our food-handlers school. Juarez has initiated a similar school.

There is no "iron curtain" here. The only curtain between our two cities is an occasional curtain of dust, not man-made. Cooperative, friendly relations exist between us and our esteemed Mexican neighbors.

Mosquito Source Reduction

PHR

It is understandable why mosquitoes have become and bid to be even more of a formidable problem to the State of California. The water resources of the State are now developed to approximately one-half of that planned. The State will have approximately 17 million irrigated acres when all the irrigable land is developed. The present irrigated acreage is about one-fourth of all the irrigated land in the United States.

California's mosquito abatement problem is dealt with by more than 50 local control programs. The control technology utilizes preventive and corrective environmental measures, augmented chiefly by insecticides. Scientific studies are seeking improved methods of control, of mosquito measurement, of neutralizing the vector of encephalitis.

A Changing Problem

Organized mosquito abatement has been in existence in California for more than 40 years. During this time four distinct periods have characterized control effort. They might be classed as follows:

Reclamation period—This period utilized the

engineering approach in obtaining control since the principle of drainage was the foremost control measure employed. Extensive land reclamation was the result.

Petroleum period—To a great extent petroleum oils served as a partner to drainage during the reclamation period, being relied on increasingly from the beginning of organized mosquito control in California through World War II.

Chlorinated hydrocarbon period—The movement leading from DDT's dramatic initiation by the military forces during the war to its almost unrealistic use for civilian purposes later served to the detriment of the environmental sanitation approach toward mosquito abatement and fly prevention. Nature soon responded, and after several years domestic flies and certain mosquitoes became clearly resistant to DDT, lindane, toxaphene, chlordane, heptachlor, aldrin, and dieldrin.

Mosquito source reduction period—Partly in response to insecticide resistance, there has been a return to progressive elimination of mosquito sources through engineering methods.

The primary reason for this shifting emphasis has been in response to a changing mosquito problem, arising to a great degree from the accelerated program of water resources development. The increase in irrigation practices, the rapid growth in population, and the rapid industrialization of the State are also contributing factors.

The Present Program

Our State and local program is of necessity hinged on preventing mosquitoes from developing at their source. Provision of adequate drainage or for re-use of excess water in new irrigation developments, effective land preparation, and judicious land and water management practices are our means for prevention of new mosquito problems.

Efforts are being made to get cooperation from other public agencies. Close working relationships have been developed between the farm advisers and the mosquito abatement districts and with irrigation districts, soil conservation agencies, and wildlife interests. Insecticides are relied on as supplemental measures. Wherever mosquito resistance to chlorinated hydrocarbon insecticides has devel-

By Richard F. Peters, B.S., chief, bureau of vector control, and Frank M. Stead, M.S., chief, division of environmental sanitation, California State Department of Public Health.

oped, phosphate-type insecticides have been substituted.

The bureau of vector control of the California State Department of Public Health is studying the ecology of the important mosquito species in the State as a basis for determining the most efficient control measures.

Every aspect of irrigation practice and mosquito production on irrigated pastures is being investigated with the aim of trying to break the mosquito life cycle at its most vulnerable point. The belief exists that the most probable gains in control can be made in positively or negatively influencing egg hatching.

A companion study of mosquitoes in rice fields is likewise receiving attention. Both *Culex tarsalis*, the vector of encephalitis and the most common mosquito in the State, and *Anopheles freeborni*, the vector of malaria, flourish in a ricefield habitat. The most promising lead is related to the influence of blue-green algae upon mosquito larvae.

An ecologic study of mosquitoes in row crops, particularly in cotton fields, is now under way. California has approximately 1 million acres of cotton. The full importance of this crop to mosquito production is only vaguely understood.

Encephalitis Studies

The two important types of encephalitis in California, the western equine and St. Louis

strains, are transmitted principally by *C. tarsalis*. The disease is endemic in the Central Valley, but infection has also been recorded in other areas.

In an effort to seek more information about encephalitis and its relationship to humans, horses, mosquitoes, and other intermediate animals, several bureaus of the State health department, as well as the Hooper Foundation for Medical Research, the University of California School of Public Health, and the Public Health Service, are engaged in intensive research.

The department is making annual collections of *C. tarsalis* on a weekly basis from May 1 until October 31. Fifty pools a week are processed for the presence of the encephalitis virus by the State viral and rickettsial disease laboratory.

Attempts are being made to interpret the significance of mosquito infection as it relates to occurrence of the disease. This involves careful measurement of the mosquito density and of animal and bird populations in the vicinity of mosquitoes known to possess the virus. One obvious inadequacy in accomplishing this study, which will take a number of years to make more meaningful, pertains to existing methods of mosquito population sampling. The State bureau of vector control will determine whether a more sensitive method of objective sampling is obtainable.

A survey of sanitarian education, experience, and training, such as the questionnaire study described here, accents the administrative need for inventories of sanitation personnel.

A Pilot Survey of Sanitarians and Their Background

By HENRY R. O'BRIEN, M.D., M.P.H., and
ARTHUR H. NEILL, C.E., M.P.H.

YESTERDAY, environmental health services were performed chiefly by the sanitary inspector on the one hand and the sanitary or public health engineer on the other. Today, there appears between them the modern sanitarian. While the exact duties of the modern sanitarian and his qualifications are subjects of debate, we know that since he handles complex situations he requires a broad educational background. At the same time, he does not have the training of the sanitary engineer, who is prepared to deal with the design, construction, and operation of water or disposal plants.

Dr. O'Brien, recently retired from the Public Health Service, is with the Pennsylvania State Department of Health as director of professional training. After 4 years of service in Region III, Mr. Neill is now acting chief, Technical Services Section, General Engineering Program, Division of Sanitary Engineering Services, Public Health Service.

Arthur P. Miller, sanitary engineer director, Division of Sanitary Engineering Services, acted as consultant in planning the study described in this paper, which was originally presented at the 23d annual meeting of the Southern Branch of the American Public Health Association, May 11-13, 1955, New Orleans. Other papers presented at the Southern Branch meeting appear in brief in the September 1955 issue of Public Health Reports, p. 914.

All three, the engineer, the sanitarian, and the inspector, are concerned with matters of environmental sanitation. The dividing line between the sanitarian and the sanitary inspector is not always drawn clearly, but a distinct line is becoming visible in places. The future may see fewer of the latter and more of the former. This survey and other studies may help define our goals and shape our definitions.

This paper uses the term "sanitarian" in its broadest sense, to include the great number of those doing field work in the sanitation of the environment. We include staff members and their supervisors and omit those who hold engineering degrees, as well as laboratory workers and laborers.

The people we are considering are the second most numerous group in public health. Only public health nurses outnumber them. The contribution of sanitarians to public health progress is significant and important, for these men are in intimate and daily contact with the community's environmental needs. They may deal with only one phase of environmental health, such as milk or plumbing sanitation, or they may handle more generalized programs. They may enforce regulations or use more educational processes.

How sanitarians are being trained is therefore important even beyond the need for training all of us share in public health. Sanitarians come to the health department with

widely varied educational background and job experience. Most of them have to be trained from the beginning. It is accepted practice that in planning any inservice program of education we study such items as the trainee's age, schooling, experience, and previous practical training.

Because information on these points was lacking in the States included in Region III of the Public Health Service (Washington, D. C.), a questionnaire was prepared to secure this information for selected areas. Copies of the questionnaire were distributed to the individual sanitarians in May and June 1954, through the health department of a State (Maryland), a city (Baltimore), a large island (Puerto Rico), and a small island group (the Virgin Islands), which are all within Region III and offer some contrast with each other. If the pilot study proved worth while, it was planned to extend it to other States in Region III, and perhaps elsewhere.

In all, 491 replies were returned as follows:

Maryland:	
State health department.....	5
County health departments.....	68
Private industry (milk plants).....	11
Total	84
Baltimore:	
City health department:	
Industrial hygiene.....	6
Food sanitation.....	12
Housing sanitation.....	19
Meat inspection.....	18
Milk sanitation.....	12
Rodent control.....	12
General community sanitation.....	13
Plumbing inspection.....	7
Health department total.....	99
Sanitary corps (police department).....	24
Private industry:	
Grocery chains or railroad dining cars....	22
Milk plants.....	19
Total	164
Virgin Islands	10
Puerto Rico:	
Vector control.....	10
General sanitation:	
Supervisors	22
General community sanitarians.....	201
Total	233

The returns from official health departments apparently include all the sanitary staff. The number of sanitary workers (52) paid by private industry in the State of Maryland, including Baltimore, is probably not complete. Doubtless, there are still others in industry whose work is broadly like that of a health department sanitarian. Those of us who are in Government service might be more alert to searching them out, for we are all working in community sanitation together, and the advantages of training should be extended to sanitation personnel wherever possible.

Analysis of the Tables

Some of the findings of the questionnaire are included in various tables and are touched on in this discussion. The samples of information included in the tables and the groupings in which they are presented illustrate some of the ways in which the returns of similar questionnaires can be studied. We caution that the data reported here are limited in scope. However, from such types of information in our own area we should be able to determine what kind of sanitary workers we are getting. Are they the kind we want? How are we training them? How do we compare with our neighbors, with ourselves some years ago? Are we moving in ways we want to go?

Population Ratio

Our first interest might well be the number of sanitarians employed by health departments in relation to population. Baltimore City and Puerto Rico are much alike in this respect. In Baltimore, 1 sanitarian is employed for each 10,060 persons in the population. In Puerto Rico, the ratio is 1 to each 9,532. Maryland outside of Baltimore shows 1 sanitarian for each 20,904 persons. The Virgin Islands ratio is 1 to 2,200, but there the population is scattered over 3 islands.

Age, Education, and Salary

The relation of age and level of education attained before employment is an appropriate study. Figures for Maryland appear in table 1. The table might be interpreted in this fashion: Most of the men with less than average

Table 1. Relationship of age and education attained by Maryland sanitarians,¹ 1954

¹ The 3 sanitarians who had not finished the 8th grade were not in the health department.

schooling are in the older age groups. When these workers were in their boyhood, fewer children went on to finish high school, or even grade school. It might be that the 5 who attended only grade school and the 11 others who did not finish high school would raise problems in inservice education, though their maturity and experience will aid them.

Another grouping summarizes the educational background of sanitarians in the four areas studied (table 2). About three-fourths of the sanitarians in each area—more in Puerto Rico, fewer in Baltimore and the Virgin Islands—finished high school. Half of the Maryland workers, a third of those in Baltimore City, and a tenth of those in Puerto Rico had college degrees. None in the Virgin Islands had college degrees. And in no area had every sanitarian finished grade school.

The figures change greatly when we consider only the 172 sanitarians with less than 4 years in the present sanitation service. All health department appointees have finished the eighth grade. More than 90 percent of the new sanitarians are high school graduates, and 40 percent have college degrees. This trend is distinctly encouraging. The knowledge helps in

of sanitarians with major work in biology, chemistry, science, and mathematics is expected. The large number in agriculture might surprise some. But certainly law, education, English, philosophy, and history are not conventionally listed among the expected basic requirements for a sanitarian. It would be worth while for the competent administrator to ponder on the work of the individuals on his staff, as reflecting their college training, and come to his own conclusions. He may reach the opinion that nonscientific courses are better preparation for dealing with the public than scientific training or that the course itself does not matter so much as the candidate's personality, or he may return to a preference for the biological sciences.

Three tables (tables 4-6) express in various groupings the relationship of salary and education level in State, local, and private industry sanitarians. In general a greater degree of education is recognized with a higher salary. Yet other influences are at work also. The level of salaries in Puerto Rico and the Virgin Is-

¹ Information from private industry on salaries was incomplete.

lands is lower than in the mainland areas studied. That 14 Maryland sanitarians without a degree (table 5) are in a higher salary bracket than 20 holders of a degree is usually because the college graduates have been at work a shorter time.

Service and Training

Tables 7 and 8 deal with length of service with the present employer. In this field, as a rule, the length of service is identical with the years in sanitation; very few sanitarians have had previous experience in sanitation before coming to the present job.

The information in these two tables gives us some idea of turnover. It appears that one-third of the sanitarians in Maryland counties and one-fourth of those in the other areas have served their present employers less than 3 years. We can also see that the period of service in

Baltimore City varies also according to the activity—plumbing inspection has been long established in the health department, whereas housing is new. We can interpret the tables as pointing a need and opportunity for early training in order to make the workers effective as soon as possible and to prevent undesirable work habits from forming and becoming fixed.

The most detailed account of on-the-job training is available in Puerto Rico's replies to the questionnaire. Almost one-third of the sanitarian staff attends one or more short courses each year. Twenty-two sanitarians took 1-day short courses in 1951; altogether, 31 took short courses that year. Forty-two sanitarians took short courses in 1952, and 74 in 1953. Several persons attended from 3 to 6 institutes each in the years 1951 to 1953. The health department usually arranges the programs for these short courses, sometimes with outside help.

For years, a feature of training sanitarians in Puerto Rico has been a general sanitation course lasting some 90 days. A similar course is offered in many States. The training in Puerto Rico was intended for the nonsupervisory personnel but was not taken by the workers in vector control, a group of older men, or by those studying for a master's degree in sanitary science at the University of Puerto Rico. Of the 201 general sanitarians, 143 (71 percent) took the 90-day course in the years from 1937 to 1954—a remarkably good record

for this 17-year period. The ages of the 58 who have not taken such a course vary as follows:

Age group	Number	Age group	Number
25-29-----	5	50-54-----	7
30-34-----	7	55-59-----	13
35-39-----	3	60-64-----	12
40-44-----	4	65-69-----	3
45-49-----	4		

The health department might well consider which of these individuals could profitably take the 3 months' general course.

Uses for a Sanitarian Study

For some 14 years the public health nurses concerned with staff preparation have used a questionnaire on college education and formal training in public health nursing to point out problems, to plan programs, and to measure progress from year to year.

We offer this analysis of a pilot study in an effort to spur a similar evaluation for sanitarians. All concerned—sanitarians, sanitary engineers, training officers, and health officers—need to discuss the subject and move toward some agreement on standards.

That an inventory of sanitarians is seriously needed is evident. It is important to know much more than we do about our sanitarians, who they are, where they are, whether they are employed by the community or privately. They will all be needed in a public emergency.

Some such inventory procedure would seem indispensable for any administrator responsible for the services of a group of sanitarians. Whether a questionnaire, as used in this study or after some revision, should be used or whether a personnel card containing similar data would suffice is a fair subject for consideration. The questionnaire used in this study frequently aroused staff interest, a desirable reaction. It seems evident that the information should be collected in every State and in such a uniform fashion as to permit comparison.

. . .

Samples of the questionnaire on sanitarian training are available from Region III, Public Health Service, Department of Health, Education, and Welfare, Washington 25, D. C.

Ratio of Old-Age Assistance to Old-Age Insurance

Proportionately, 20 percent fewer people were receiving old-age assistance payments in June 1955 than in June 1950, Commissioner of Social Security Charles I. Schottland reported in November.

There were 14,244,500 persons aged 65 or older in June 1955. Old-age assistance was received by 2,544,496, or 179 of each 1,000. In June 1950, 2,786,690 of the aged population of 12,399,100, or 225 of each 1,000, were receiving old-age assistance.

One reason for this decline in the number of assistance recipients is the increase in the number of aged who now receive old-age and survivors insurance benefits. In June 1950, only 169 of each 1,000 aged persons received insurance benefits. In June 1955, 423 of each 1,000 aged received insurance benefits.

Although the caseload of aged persons drawing public assistance has dropped during the past 5 years, the cost of the program has increased because payments to individuals in most States are larger.

Canine Leptospirosis and Public Health

By ROBERT J. BYRNE, D.V.M.

SINCE the first report of canine leptospirosis in the United States in 1937 (1), the disease has been found with increasing frequency. Today, the effective detection and treatment of canine leptospirosis must be regarded as one of the most important problems challenging the veterinary profession.

Leptospira canicola, the organism responsible for the canine disease, can be transmitted to man by various methods. The resultant illness is a serious one and should be considered as a public health problem of importance. The various aspects of *Lept. canicola* infections necessary to an understanding of the problem will be considered here.

History

The first detailed description of the disease now believed to be human leptospirosis dates back to 1886 when Weil described the clinical disease syndrome which still bears his name. The disease was characterized by icterus, fever, hemorrhagic tendency, and a high mortality resulting from renal, hepatic, and vascular failure.

The search for the etiological agent of this so-called "Weil's disease" ended when Japanese

(2) and European (3) workers independently isolated a spirochete, later designated as a *Leptospira* by Noguchi (4).

The first evidence of an animal-host carrier was obtained by Miyajima in Japan, who demonstrated that spirochetes were present in the tissues of field mice (5). The significance of such leptospiral carriers was dramatically illustrated in the rat infested trenches of World War I where over a hundred cases of human leptospirosis occurred (6). Since those early reports, new leptospiral hosts have been found, including almost every type of domestic animal, most rodents, and many wild animals. In addition to *Leptospira icterohemorrhagiae*, numerous other leptospiral serotypes pathogenic for animals and man have been identified and differentiated from each other by serologic techniques.

In 1931, Klarenbeek and Schuffner, in the Netherlands, isolated leptospires from the urine of a dog affected with nephritis (7). The leptospiral strain was found to differ, serologically, from *Lept. icterohemorrhagiae* and was designated as *Lept. canicola*. Shortly thereafter the first human infection with *Lept. canicola* was reported in that country (8). This leptospiral serotype was isolated from dogs in the United States by Meyer and associates in 1937 (9), and the first human case in this country was reported in 1938 (10).

Etiology

Members of the genus *Leptospira* are delicate filamentous organisms, tightly coiled, and usu-

Dr. Byrne is with the Grayson Research Laboratory, University of Maryland, at College Park. This address was delivered at Pennsylvania's Third Annual Health Conference in August 1954. At that time, Dr. Byrne was with the Army Medical Service Graduate School, Washington, D. C.

ally hooked at both ends. They are generally 6 to 14 microns in length, but individual organisms measuring up to 40 microns have been observed in laboratory cultures. They are difficult to stain and cannot be observed in the living state except by darkfield or phase-contrast microscopy. These spirochetes can be propagated in special laboratory media in which they may remain viable for a year or longer. Viability, as well as pathogenicity for certain animal hosts, may be maintained by serial passage in hamsters of infective blood or tissues. Since one leptospiral species cannot be differentiated from another by morphologic, cultural, or biochemical methods, classification is based on serologic methods involving cross-agglutination and absorption techniques.

Epidemiology

The widespread distribution of canine leptospirosis in the United States has been substantiated by numerous epidemiological surveys. The reported incidence has varied from 3 to 38 percent depending on the diagnostic technique used and the age of the dogs surveyed (11-13). Man and other susceptible hosts can become infected by direct contact with contaminated urine from infected dogs, by consumption of food or water so contaminated, or by close contact with surface water in which pathogenic leptospires are present. Infection can occur by entry of these organisms through a skin abrasion or cut, or through the unbroken mucosal surfaces of the conjunctiva, pharynx, or nasal passages.

Pathogenic leptospires are harbored in the kidneys of rodents and other mammalian hosts. These organisms display a characteristic affinity for the renal cortex where they may be found nesting in the lumina of the convoluted tubules. From these foci they may be excreted in the urine for long periods of time. Should such organisms find their way into a favorable environment—such as damp soil or a small body of fresh water—they may survive for as long as 22 days (14). Dr. D. W. Johnson of Australia in a personal communication reports survival of the organisms for as long as 7 weeks.

The possibility of transmitting this disease from dog to man is readily apparent. Dog

handlers, kennelmen, and veterinarians are most subject to infection from exposure to contaminated urine. Cuts, abrasions, or scratches of the hands provide suitable routes of entry for these organisms. The fact that in many instances a dog's urine may be acidic is no assurance that infections cannot be acquired in this manner. Despite the preference of leptospires for an environment having pH values ranging from 6.8 to 8.6, these organisms are able to survive for short intervals in acidic urine, and upon invading a new susceptible host could multiply and produce disease.

Human *Lept. canicola* infections associated with swimming or wading in surface waters contaminated with dog urine have been reported (15). Of possibly greater epidemiological significance is the transmission of *Lept. canicola* infections from dogs to larger domestic animals and subsequent development of leptospirosis in these new hosts. The relatively large volume of infected urine excreted by these animals, cows and swine, for example, poses a far greater threat in the contamination of surface water than that excreted from dogs (16).

A constant reservoir of infection is maintained in the kidneys of the many urinary shedders among the canine population. This factor, coupled with the characteristic greeting behavior of dogs, insures the sustenance of *Lept. canicola*. Presumably, *Lept. icterohemorrhagiae* infections in dogs are contracted in this manner or when dogs kill and eat infected rats or other rodents.

The dog has been proved a host to several distinct leptospiral strains, some of which have yet to be reported in the United States. *Lept. canicola* has been universally incriminated as the most frequent leptospiral parasite of dogs, although occasional cases of *Lept. icterohemorrhagiae* infections have been reported. In the United States, serologic evidence indicates that about 90 percent of all canine leptospirosis involves *Lept. canicola* and 10 percent are probably due to *Lept. icterohemorrhagiae* (17).

Other leptospiral strains which have been reported in dogs are *Lept. pomona*, the principal causative agent of bovine and porcine leptospirosis in the United States; *Lept. hebdomadis* and *Lept. autumnalis*, the latter two serotypes being found most frequently throughout the Far

East. *Lept. australis* A, *Lept. medanesis*, *Lept. bataviae*, *Lept. grippotyphosa*, and *Lept. sejroe* have all either been isolated from dogs or there is serologic evidence suggesting their existence in this host. The importation of dogs from many parts of the world carries with it the possibility that new leptospiral strains may be introduced in the United States, thus presenting new disease problems among both animals and man.

Clinical Aspects in Animals

Added to the other pathogenically unique effects which characterize leptospirosis are the particular syndromata produced by this disease in dogs. Based on experimental evidence and field observations, it is impossible to predict consistently the precise clinical response to leptospiral infection. Reactions following inoculations with living leptospires are variable—a dog may remain completely asymptomatic, or become jaundiced, develop a renal syndrome, or suffer a peracute fulminating disease resulting in death.

Acute canine leptospirosis resulting in either a severe icteric or hemorrhagic disease has been

reported in epizootic proportions (9). The disease may appear in kennels and result in a high fatality rate, particularly among young dogs. These outbreaks are characterized by the high incidence of jaundice in affected animals from which the common designation, "canine yellows," has been derived.

An animal surviving the acute disease or experiencing a mild subclinical infection almost invariably becomes a urinary carrier. The apparent effect of the extended nesting of leptospires in the kidney tubules of dogs is a tissue response manifested finally by the development of interstitial nephritis. Should this process continue over a prolonged period of time, severe renal dysfunction may result with the development of a uremic syndrome known as "canine typhus" or "Stuttgart disease."

Numerous attempts have been made to outline the symptomatology of canine leptospirosis and to define and describe various forms in which the disease may manifest itself. These descriptions usually include a hemorrhagic type and a uremic type. Bloom (18) comments: "The clinical manifestations of canine leptospirosis are extremely variable and may be absent, latent, subclinical, atypical, mild or

Leptospira canicola
magnified about
27,000X.

Photograph by Dr. Edgar Ribi, PHS,
Rocky Mountain Laboratory, Hamil-
ton, Mont.

Transmission of canine leptospirosis to animals and man.

severe. The clinically obvious disease may be peracute, acute, subacute, or chronic."

It would be equally accurate to describe the clinical disease from the bacteriological and pathological standpoint. This has been done by Stuart (19), who mentions three stages:

Invasive. After gaining entry, the leptospires multiply and find their way to all organs of the body. Direct isolations from the blood may be made at this time. This is the period of febrile illness and is generally accompanied by lethargy and anorexia. Jaundice, if it occurs at all, usually appears immediately at the end of this period. Serum titers do not usually reach significant levels at this stage.

Primary renal. The invasive stage may be followed a week later by a primary nephritic stage, which may be the first stage to be clinically detected. During this period leptospires have found their way to the kidney tubules, whereupon the spirochetes may be isolated from the urine. A diffuse or focal round-cell infiltration characterizes the interstitial nephritis that results from the kidney infection. The

uremia which commonly occurs from this stage may result from nephron obstruction or other pathological changes, not clearly understood. Apathy, stomatitis, and thirst are the chief clinical symptoms manifested by affected animals. The blood-urea nitrogen level is generally elevated, and the leptospiral agglutination titers of the serum reach a high level.

Secondary renal. The primary nephritic stage may proceed, after a lapse of several months or years, into a secondary nephritic stage. This stage is characterized pathologically by chronic interstitial nephritis accompanied by fibrosis and clinically by uremia. Leptospiuria is rarely found, and it must be concluded that the kidney damage is not associated with a continuing infection. The serum agglutination titers tend to be of a low order during this stage.

Clinical Aspects in Humans

The basis for naming the human leptospirosis diseases has included such considerations as g

graphic location or epidemiological and clinical similarities associated with infections by specific leptospiral strains or serotypes. For example, Weil's disease is associated with *Lept. icterohemorrhagiae* infections, and *Lept. grippotyphosa* is the etiological agent of mud fever. In Japan, akiyami, or autumn sickness, is caused by *Lept. autumnalis*. *Lept. canicola* infections in man have been described as canicola fever. Within some of these groupings extreme variations in the clinical manifestations are frequently found. The protean nature of the human leptospires is exemplified by the various symptoms of *Lept. canicola* infections.

As with other leptospiral infections, the onset of canicola fever is quite sudden and characterized by chills and fever, severe headache, stiff neck, and intense muscular pains.

In general, it is a relatively mild disease, but on occasions it may simulate classical Weil's disease and result in death. A grippelike form of canicola fever has been described in which such respiratory symptoms as cough and bronchitis are observed. Ocular manifestations in the form of uveitis may occur long after the febrile stage of this disease has passed (20).

The ease with which leptospiral infections can mimic other diseases was demonstrated in an outbreak affecting 25 children in Georgia (16). These children went swimming in a small stream which was polluted with the urine of cows and pigs upstream and developed a disease initially diagnosed as dengue. It was not until the epidemiological and laboratory aspects of the outbreak were completed that *Lept. canicola* was established as the etiological agent.

Rosenberg (21), in his review article, states that approximately 50 percent of all cases of canicola fever are accompanied by meningeal symptoms. A study by Beeson and Hankey (22) indicated that 8 to 10 percent of all cases of aseptic meningitis are leptospiral in origin, and half of that number were canicola infections. This figure agrees closely with data obtained by other American and European investigators. Reference has been made to the resemblance of leptospiral meningitis to early poliomyelitis (23). Woodward (24) points out that leptospirosis must be considered in the differential diagnosis in any disease in which lymphocytes are found in the spinal fluid—

such as lymphocytic choriomeningitis, mumps, herpes, poliomyelitis, Cocksackie disease and the various neurotropic encephalitides.

Laboratory Diagnosis

The reported incidence of leptospirosis often varies with the awareness of the disease. To confirm a diagnosis of leptospirosis in either man or animals, adequate laboratory support is essential. At present, this type of support is not always available. There are relatively few laboratories in the United States which have the necessary equipment and trained personnel essential to carry out this task. The laboratory diagnosis of leptospirosis is based either on the demonstration of the organism in the blood, cerebrospinal fluid, or urine during the course of disease, or by a rise in antibody titer between serum specimens taken during acute and convalescent phases, or by pathological findings at autopsy.

Leptospires appear regularly in the circulating blood during the first week of disease and may be isolated at this time by directly inoculating a few drops of blood into appropriate laboratory media. These cultures are subsequently examined at 2-week intervals by dark-field microscopy. If no leptospires can be demonstrated in the media after 28 days, cultures may be discarded as negative. Such techniques may also be employed in isolating leptospires from cerebrospinal fluid during the early stages of infection. It is difficult and often dangerous to base a diagnosis of leptospirosis on the direct darkfield examination of blood. The presence of artifacts in the form of fibrin shreds or other blood constituents may lead to a false diagnosis. Conversely, leptospires are ordinarily present in such small numbers as to be missed by direct examination.

The leptospiruric phase of the disease usually commences about 12 to 14 days after the onset of symptoms. The same precautions must be applied to the direct darkfield examination of urine as were cited regarding blood, although on occasions, large numbers of leptospires have been directly observed in the urine of dogs and other animals.

Attempts to isolate these spirochetes from urine are best made by inoculating freshly

voided or catheterized urine samples intraperitoneally into young guinea pigs or hamsters, bleeding these animals by cardiac puncture 4 to 6 days after inoculation and culturing media with their blood. These cultures are then handled in the same manner as those initiated directly from the patient's blood. Cultivation of leptospires directly from urine is usually not feasible, because of bacterial contaminants.

Serologic diagnosis is based on the demonstration of a rise in antibody titer between serum specimens drawn during the acute phase of disease and during convalescence. In the laboratory at the Army Medical Service Graduate School, a modification of the Schuffner-Mochtar agglutination-lysis test employing a battery of viable leptospiral type strains is used (25). In making a serologic diagnosis of leptospirosis, the value of paired serum specimens cannot be stressed too strongly. Single serum specimens, particularly those with a low antibody titer, are often of little value unless accompanied by a complete clinical history. A low serum titer may indicate a past leptospiral infection or a new infection in the early stage of antibody development.

Complement fixation has been employed in the diagnosis of human leptospirosis infection (26). Although it has proved of value in the diagnosis of leptospirosis per se, it is not sufficiently specific to give any clue as to the infecting strain or serotype. To date at our laboratory, this test has been of little value in the diagnosis of canine leptospirosis due to the occurrence of nonspecific reactions between antigens and the majority of canine serums.

The use of various types of macroscopic agglutination antigens in the serologic diagnosis of leptospirosis has been cited on numerous occasions. Although tests employing such antigens have had advantages in the ease and rapidity of performance, they are generally less sensitive than microscopic tests, and often the antigens have been found to be unstable. Recently a capillary-tube test for the diagnosis of leptospirosis was described by Stoenner (27).

Therapy

An effective course of treating human leptospirosis still remains a conspicuously unsolved

problem. Hall and associates (28), in a study of 67 laboratory confirmed cases, concluded that none of the antibiotics employed in their study altered the course of disease or affected the duration of leptospiremia. Other workers (29) obtained similar results in dogs, hamsters, and guinea pigs when evaluating chloramphenicol, subtilin, and penicillin G. Gsell (30), however, reports favorable response in human leptospirosis to either aureomycin or terramycin if initiated on the first or second day of disease. Brunner and Meyer have reported that streptomycin (31) or aureomycin (32) given in adequate dosage will eliminate the carrier state in dogs and hamsters. These investigators suggest the administration of either of these antibiotics to dogs whenever there is a question of an animal being a carrier and transmitting the disease to other animals or man.

Control

The ultimate control of human canicola fever is based on the control of the animal leptospires. To achieve this end and to break the chain of infection that perpetuates the disease, it is essential that a vaccine for the prevention of canine leptospirosis be developed and made available for widespread distribution and use. Such a vaccine, of necessity, should meet the following requirements:

1. Elicit the production in the recipient of protective antibodies which will persist over a reasonable period of time, while at the same time insure that the vaccinated animals will not develop either clinical symptoms or leptospiruria subsequent to challenge. Bacteriological studies on both vaccinated animals and controls must be carried out to determine the degree of protection attained.

2. Exhibit minimal toxicity following administration.

3. Be polyvalent and give adequate protection against both *Lept. icterohemorrhagiae* and *Lept. canicola* in the United States. In certain other countries, additional leptospiral strains would have to be incorporated in such a vaccine.

Until canine leptospirosis is controlled, a large reservoir of infection remains among the dog population. The owners of these animals must be educated to this fact and to the danger

of acquiring canicola fever from close association with dogs.

Conclusions

Canine leptospirosis is widespread, and its control is a growing problem to the veterinary profession. Certain fundamental questions regarding epidemiological, clinical, pathological, and immunological characteristics of canine leptospirosis remain unanswered. Practicing veterinarians can do much to alleviate this situation by recording and reporting clinical cases of canine leptospirosis, particularly in those instances in which laboratory support has been made available.

Research activities must be directed toward the development of improved diagnostic techniques, further evaluation of therapeutic agents in the treatment of clinical leptospirosis, and development of adequate vaccines for the protection of man and animals.

The extent of human leptospirosis acquired from dogs remains undetermined. Education of the public to the danger of acquiring the disease, the development of adequate diagnostic laboratory facilities, and a constant awareness of the protean nature of the disease are the best means of bringing the problem into proper perspective.

Warning on Salicylate Drug Labels

The Food and Drug Administration has asked drug manufacturers to label aspirin and other salicylate drugs with a warning to keep these products out of reach of children.

Accidental misuse of salicylate preparations prompted the new ruling. Although salicylates ordinarily are not toxic in amounts required for producing analgesic action, they can cause injury or death when taken in excessive quantities. Poisoning by salicylate preparations are responsible for about 100 deaths a year, mainly in children under 5 years of age.

Recommended statements on the labels are: "Warning—Keep out of reach of children" or "Warning—Keep this and all medications out of the reach of children."

In lieu of specific dose recommendations for children under 3 years of age, FDA recommends the statement: "For children under 3 years of age, consult your physician."

The ruling does not apply to oil of wintergreen (methyl salicylate), which already bears a warning statement; effervescent salicylate preparations (those that "fizz" when placed in water); or preparations of para-aminosalicylic acid and its salts, which are used only in the treatment of tuberculosis.

The advisory ruling, published in the *Federal Register* on October 15, 1955, is based on the recommendation of the FDA medical advisory panel consisting of pediatric experts and drug industry representatives. Six months are allowed for modifying present labeling.

Location of Dentists in Relation to Dental School Attended

By WALTER J. PELTON, D.D.S., M.S.P.H., ELLIOTT H. PENNELL, B.S.,
and MARYLAND Y. PENNELL, M.Sc.Hyg.

DENTISTS in the United States tend to establish their practice within the area where they received their training. Data from the 1953 American Dental Directory (1) have been used to analyze the relationship between each dentist's location in 1952 and the location of the dental school in which he received his training. The directory listing usually identifies the city or town where the dentist is located, the year he was graduated, and the name of the dental school under the title which applied at the time he was in attendance.

In mid-1952 there were 84,214 dentists located in the 48 States and the District of Columbia, excluding the 7,423 dentists in the Federal services. As would be expected, most of the dentists were trained in schools located within the continental United States. A total of 78,025 dentists were graduates of active or formerly active schools located in 25 States and the District of Columbia; 490 were graduated from foreign dental schools, and 5,699 were listed in the directory without specifying the dental school from which they received their degree.

Each geographic division of the country draws the majority of its dentists from graduates of schools located within its borders, with the exception of the Mountain States (table 1).

Dr. Pelton is chief of the Division of Dental Resources, Public Health Service, and Mr. Pennell is public health analyst in that division. Mrs. Pennell is a statistician in the Division of Public Health Methods.

The most striking examples of this pattern are represented by the East and West North Central groups of States where nearly 9 out of 10 of the dentists attended school in the geographic division in which they were located in 1952 (fig. 1). In four other divisions—Middle Atlantic, South Atlantic, East South Central, and West South Central—where the proportion of dentists trained within the area was not quite so high, the rest of the dentists were drawn from schools located in one or another of the adjoining geographic divisions.

A wider spread, however, is found in two other divisions. In New England, for example, where 56 percent of the dentists were trained locally, 18 percent had attended a dental school in one of the South Atlantic States, and 16 percent came from a school in the Middle Atlantic area. While 76 percent of the dentists in the Pacific area were trained there, the others were mainly drawn from schools in the North Central States.

The pattern for the Mountain States is exceptional because they have lacked dental training facilities for the past 20 years or more. Only 18 percent of the dentists in this area were trained locally; another 18 percent came from States in the Pacific division. Approximately 32 and 25 percent, respectively, were drawn from schools in the West and East North Central States.

Dentists Trained Within State

Missouri and Pennsylvania each had more than 90 percent of their dentists trained within

their borders. In 13 other States and the District of Columbia, three-fourths or more of the non-Federal dentists received their training in the State where they were located in 1952. In 6 additional States, local schools supplied between one-half and three-fourths of all the dentists, while in 4 other States the proportion varied from 1 to 46 percent. None of the dentists practicing in the remaining 23 States were graduates of dental schools within the State. More detailed information on where the dentists practicing in each State received their training and the reverse of the picture—the location in 1952 of the dentists trained in each of the 26 States with dental schools—is given in the Health Manpower Source Book series (2).

In New England, Massachusetts is the only State with a dental school. More than half of the dentists in Maine and New Hampshire as well as three-fourths of those in Massachusetts were trained in the latter State. Vermont, Rhode Island, and Connecticut were less dependent upon the Massachusetts schools; they also drew sizable proportions of their dentist manpower from the training facilities in Maryland and Pennsylvania.

The Middle Atlantic division has 6 active dental schools, 3 each in New York and Pennsylvania. A former dental school in New Jersey has been closed for 30 years. Two-thirds

or more of the dentists in New York and Pennsylvania were supplied from the schools within their respective boundaries. Almost the same proportion of the New Jersey dentists received their training in these same two States.

All 5 East North Central States have active dental schools. For Ohio, active dental schools at Ohio State and Western Reserve Universities and schools which are now extinct have trained more than three-fourths of the dentists located in that State. In like manner, Indiana University is the principal source of the Indiana dentists. Loyola, Northwestern, and the University of Illinois trained 81 percent of the Illinois dentists; Detroit and Michigan Universities were the source of 77 percent of the Michigan dentists; and Marquette University supplied 74 percent of the Wisconsin dentists.

Active dental schools in 4 of the 7 West North Central States supplied from 78 to 91 percent of the dentists in their respective States—Minnesota, Iowa, Missouri, and Nebraska. North Dakota drew its dentists largely from schools in Minnesota and Illinois in the East North Central division; South Dakota's dentists came mainly from schools in Nebraska and Illinois. Missouri schools trained 83 percent of the dentists in Kansas.

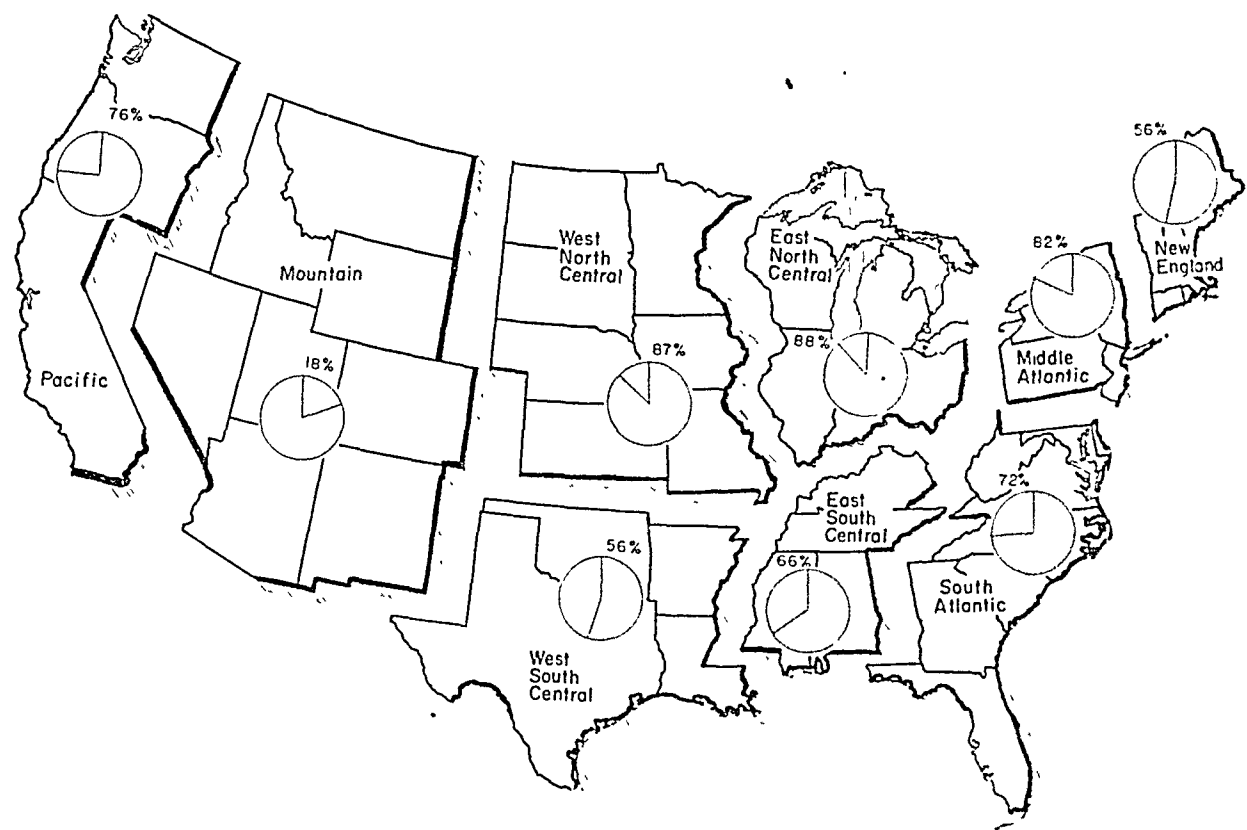

In the South Atlantic division, Maryland, Virginia, Georgia, and the District of Columbia have dental schools that graduated a class in 1952. These schools supplied from 62 to 86 percent of the dentists in their respective States, as well as the majority of the dentists in North and South Carolina. (The University of North Carolina graduated its first class in 1954, and hence is not included in this study.) Delaware drew nearly two-thirds of its dentists from schools in Pennsylvania. West Virginia had almost equal numbers from dental schools in Maryland, Ohio, and Pennsylvania. Florida had one-third of its dentists from Georgia, with sizable numbers of graduates from schools in Illinois, Pennsylvania, and Tennessee.

In the East South Central area, both Kentucky and Tennessee had 78 percent of their dentists graduated from schools in their own States. Alabama, with a school that graduated its first class in 1952, drew about two-thirds of its dentists from dental schools in Georgia and Tennessee. Mississippi depends upon

Table 1. Non-Federal dentists located in 1952 in the same geographic division in which they attended dental school

Figure 1. Dentists in the nine geographic divisions who were graduated from a dental school in that same division.

schools in these same two States to supply its dentist manpower.

The West South Central States have active dental schools in Louisiana and Texas that supplied 73 and 67 percent of their dentists, respectively. Oklahoma is largely dependent on graduates from dental schools in Missouri; Arkansas mainly depends on schools in Missouri and Tennessee.

The Mountain States have no currently active school, although nearly half of the dentists in Colorado were trained at the Denver schools closed many years ago. The Illinois schools led in supplying the largest number of dental school graduates to Montana and Utah. Missouri graduates ranked first in Wyoming and New Mexico; California graduates, in Arizona and Nevada.

All Pacific States now have active dental schools, since the University of Washington graduated its first class in 1950. The three California schools trained three-fourths of the local dentists. The University of Oregon, in

addition to supplying its own State, furnished more than half of the dentists in neighboring Washington.

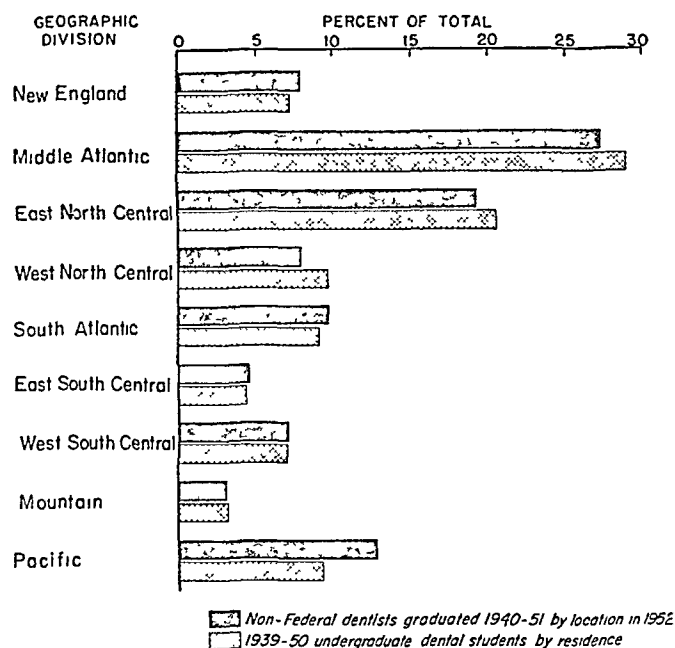

Residence of Dental Students

It has been shown that 1 out of 4 dentists listed in the 1953 directory received his professional training at a dental school located outside of the geographic area in which he later established his practice. Doubtless many of these dentists left their home State to attend dental school with the intention of returning home to set up practice. While data are not available for direct comparisons that would reveal the extent of this return, some deductions can be drawn from the distribution of undergraduate dental students published annually in the Dental Students' Register (3).

The proportion of undergraduate dental students in each geographic area is closely related to the proportion of graduates who subsequently established dental practice within the

same geographic area. In figure 2 the distribution by location in 1952 of the non-Federal dentists who were graduated in recent years

Figure 2. Distribution of dentists and dental students.

(1940-51) is contrasted with the distribution by residence of students attending dental school in the 12 academic years 1939-40 to 1950-51.

Among the nine geographic divisions, the Pacific States show the greatest relative difference in the length of the two bars. Nearly 1 dentist in 8 who established practice in the United States in recent years was located in 1 of these 3 States in 1952. On the other hand, only 1 in 10 students trained during the 12-year period was drawn from that area. In other words this area acquired a share of recent graduates that was more than one-third in excess of that expected on the basis of its contribution to the pool of students.

In terms of actual numbers, the Pacific States gained about 700 dentists over and above their share of students (table 2). The influx was chiefly into California. Since 1940 the population growth in the Pacific States has been so great that even this gain in dentists was insufficient to maintain the 1940 dentist-population ratio.

The migration to the west coast was largely among former residents of the Middle Atlantic

Table 2. Distribution in 1952 of dentists graduated during 1940-51 from United States dental schools and distribution of undergraduate dental students, 1939-50, according to residence at time of entering dental school

Geographic division	Non-Federal dentists graduated 1940-51 by location in 1952		1939-50 dental students according to residence		Prorated share of students	Gain or loss between number of new dentists and share of students

¹ Excludes 6,558 graduates in the classes of 1940-51, of whom 4,787 were in the Federal service in 1952 and the remainder were located outside the United States or were dead.

² Total of the undergraduate students in United States dental schools in the fall of 1939, 1943, and 1947, excluding 788 students with residence outside the continental United States (3). This figure corresponds to the 1910-51 graduates after allowance is made for those who were not graduated. However, it may not include all students under accelerated programs—those not listed in the three issues of the Dental Students' Register.

³ Non-Federal dentists represent 80.73 percent of the students. This rate has been applied to the number in the preceding column on the assumption that Federal dentists are drawn in the same proportion from each geographic division.

and North Central States. Each of these areas retained somewhat fewer recent graduates than might have been anticipated on the basis of the number of dental students trained during 1940-51 in these areas. Among the 15 States in these three geographic divisions only Michigan showed an excess of new dental practitioners over its share of students. In Minnesota, Iowa, North Dakota, South Dakota, and Nebraska about 1 in 4 students apparently failed to return to his home State to establish practice. New York, Pennsylvania, Illinois, and Minnesota each lost more than 100.

New England and the South Atlantic area showed a slight gain between the number of dentists who located there and their share of the students trained. About half of the States in these two divisions had gains; about half, losses. The largest gain, both percentagewise and in numbers, was in Florida, as would be expected from its tremendous population increase since 1940.

The South Central and Mountain States showed equal percentages of new dentists and of students. Thus, in these sections of the country, the degree to which new dentists have established practice closely paralleled the area's share in the pool of dental students maintained while these new dentists were being trained.

States With Dental Schools

The presence or absence of a dental school in a State does not greatly influence the relationship between the number of recent graduates choosing the State for practice and the State's share of dental students at the time these dentists were being trained. During the period from 1940 to 1952, 21 States and the District of Columbia had active dental schools. As a group these States accounted for 71.9 percent of the

1952 civilian population and 76.6 percent of all the non-Federal dentists. Located in these States in 1952 were 77.3 percent of the non-Federal dentists graduated in 1940-51. They had the same proportion (77.1 percent) of the students in dental schools during the period from 1939-40 to 1950-51. Within this group, however, California gained new dental graduates at the expense of the Middle Atlantic and North Central States.

On the other hand, the 23 States without dental schools supplied 15.9 percent of the students and in return received 15.1 percent of the recent graduates. (Excluded from this comparison are New Jersey and Colorado, whose only dental schools have been closed, and Alabama and Washington, whose training facilities were established for the first time during the period.)

This close correspondence between students trained and new dentists establishing practice, regardless of whether resources for professional training are primarily centered in within-State or in out-of-State dental schools, suggests that the majority of the dentists locating in an area are the same individuals who made up the undergraduates from that area.

Venereal Disease Among Puerto Ricans in New York City

By JULES E. VANDOW, M.D.

FOLLOWING World War II, thousands of Puerto Ricans migrated to the continental United States seeking better economic conditions than were available to them in Puerto Rico. The greatest number of these migrants settled in New York City. About 246,000, or approximately 82 percent of all the Puerto Ricans in the continental United States and 3.1 percent of the city's total population, were located there, according to the 1950 census. As a result of further in-migration and births, these figures have increased to an estimated 500,000—6.2 percent of the total population of New York City. Estimates recently published by the department of city planning indicate that by 1970 Puerto Ricans in New York City may number 1,160,000, or about 13.5 percent of the city's population (1, 2). However, this estimate may have to be revised downward if the 1953 decrease in migration, resulting from increased industrialization in Puerto Rico, is maintained.

From the point of view of the division of social hygiene of the New York City Health Department, it seemed worth while to examine

whatever data were available which could give information regarding the prevalence of syphilis in this large and growing group. This paper is based upon the following reports:

1. Results of the 1953 mass blood testing survey in New York City.
2. Results of blood testing in the Puerto Rican project of the division of social hygiene, New York City Department of Health.
3. A sample study of the statistics of the New York City Health Department social hygiene clinics for the last quarter of 1954.
4. The total venereal disease case reports for the city as a whole for the period January 1–December 31, 1954.

Puerto Ricans are defined as those individuals who were born in Puerto Rico or whose mothers were born there. By this definition, all persons at the Puerto Rican blood testing project of the health department were Puerto Ricans. In the mass blood testing survey, each person was asked where he was born and where his mother was born. In both studies, the race of each person was recorded as white, Negro, or "other." The term "other" refers to dark-complexioned Puerto Ricans who could not be classified as either white or Negro.

The data obtained from the records of the social hygiene clinics and from the venereal disease case reports are far less specific or accurate than data from the records of the Puerto Rican blood testing project and the mass blood testing survey, and conclusions drawn from clinic or morbidity records are of questionable accuracy. Information on the birthplace of the patient or his parents is not requested by

Dr. Vandow is chief, division of social hygiene, New York City Department of Health, New York, N. Y., and a special consultant to the Public Health Service. This report of a study conducted with Public Health Service assistance was read as part of a symposium on selective blood testing programs at the Venereal Disease Control Seminar, Regions I and II, Department of Health, Education, and Welfare, Atlantic City, N. J., March 24, 1955.

the social hygiene clinics or on the health department venereal disease report form, lest the erroneous impression be given that such information would have a bearing on the type of treatment received. In this connection, it cannot be stressed too strongly that at all health department installations the same treatment is given to all persons, regardless of race or national origin. Studies dealing with such mixed groups reveal information necessary for health authorities to prepare their programs.

Mass Blood Testing Survey

From May 4 through June 26, 1953, the New York City Health Department conducted a mass blood testing survey. A detailed report of the survey was presented by Dr. Samuel S. Frank at the 1954 Venereal Disease Control Seminar of the Department of Health, Education, and Welfare.

Only Puerto Ricans living in Manhattan will be considered in this report since over 60 percent of the Puerto Ricans in New York City and 89.3 percent of the Puerto Ricans tested live in the Borough of Manhattan. In the mass blood testing survey, 4,885 Puerto Rican born residents of Manhattan—3,870 white and 1,015 nonwhite—were tested for syphilis. The overall positivity rate was 9.6 percent for the 3,870 whites and 11.8 percent for the nonwhites. Using data from the 1950 census and from a study made by the research bureau of the Welfare and Health Council of New York City (3), it was concluded that about 6,238 Puerto Ricans over age 10 residing in three Manhattan health districts, namely, Central Harlem, East Har-

lem, and Riverside, had positive blood tests. Two-thirds (64.8 percent) of the Puerto Ricans in Manhattan live in these three districts. Since slightly more than 58 percent of the positive cases required antisyphilitic treatment, it was further concluded that, as of the time of the survey in 1953, about 3,600 Puerto Ricans over age 10 in these three health districts of Manhattan were in need of treatment.

No conclusions can be drawn about the 40 percent of the Puerto Ricans in New York City who lived outside of Manhattan since most of the persons tested in the survey lived in that borough. Likewise, no conclusions can be drawn for the 38,000 Puerto Ricans living in the four other health districts of Manhattan since too few persons in these health districts were tested.

Puerto Rican Project

In 1952, a selective blood testing project was set up by the New York City Health Department at the office of the migration division of the Puerto Rico Department of Labor. This office was opened in 1948 to help the new immigrants from Puerto Rico to adjust to a new environment, and it has been extremely helpful in finding jobs, in settling the many problems which result from language difficulties, and in cooperating with all Government and private agencies to promote the general welfare of the Puerto Rican in-migrant.

With the cooperation of the migration division, a clinic was set up in the local office of the Puerto Rican Department of Labor, where several hundred Puerto Ricans gather daily.

Table 1. Results of serologic examinations for syphilis at the Puerto Rican project of the division of social hygiene, New York City Department of Health

Results of examination	1952 ¹		1953		1954	
	Number	Percent	Number	Percent	Number	Percent
Total examined.....	1, 575	100. 0	2, 016	100. 0	1, 760	100. 0
Positive.....	115	7. 3	137	6. 8	113	6. 4
Previously unknown.....	104	6. 6	124	6. 2	95	5. 4
Doubtful.....	(?)	(?)	(?)	(?)	6	. 35

¹ June-December. ² No data available.

The clinic is staffed by a Spanish-speaking clerk and a health department physician. At intervals during the morning, the clerk speaks to the group in Spanish over a public address system on general health matters and mentions the fact that a health department physician is available to provide examination and advice. Those requesting a consultation are given a physical examination. At the same time, a blood specimen is drawn and sent to the serologic laboratory. Each patient is then referred to a district health center for a chest X-ray. When a blood test is positive or doubtful, the patient is referred to the nearest health department social hygiene clinic for a repeat blood test and evaluation. Treatment is given in the clinic if it is indicated.

Table 1 summarizes the results of blood testing this group of individuals from June 1952, when the project was started, through December 1954. During this period, 5,351 individuals were tested. Of these, 365 had positive blood tests—a positivity rate of 6.8 percent. Most of the group—323, or 6.0 percent of the total tested—were new cases, not previously known to the division of social hygiene. Over 50 percent had received treatment in Puerto Rico, but the type and adequacy of therapy is not known.

Table 2 summarizes, by age group, race, and sex, 111 cases of syphilis found through the Puerto Rican project during the period July 1954–January 1955. In this table, “other” refers to those patients who cannot be classified as either white or Negro. The race determination is, of course, quite arbitrary, and undoubtedly

the classifications vary greatly, depending on the judgment of the individual clerk. The number of individuals classified as “other” in this study, 38 percent of the entire group, is considerably higher than the 7.6 percent given by the Bureau of the Census.

The preponderance of males over females (81 to 30) probably reflects the fact that more males than females come to the United States from Puerto Rico and that more males than females seek employment at the migration office, so that a higher percentage of males were examined. The greatest number of cases of syphilis—63, or 56.7 percent, was found in the 20-year age period 15–34, reemphasizing the fact that syphilis is a disease of youth. Of course, it is true that the majority of Puerto Ricans who migrate to the continent are the younger people, so that most of the testing is done in this group.

As for the stage of syphilis, 111 of 910 patients examined during the period May 1954–January 1955 were diagnosed as syphilitic; 23 (20.7 percent) had early latent syphilis and 88 (79.3 percent) had late latent syphilis. No cases of primary or secondary syphilis were found.

Social Hygiene Clinics

A study was made of the total number of patients examined at the social hygiene clinics of the New York City Department of Health during the period October–December 1954 (table 3).

Altogether, 8,736 individuals were examined

Table 2. Cases of syphilis among Puerto Ricans examined in the Puerto Rican project, New York City Health Department, July 1954–January 1955, by age, sex, and race

Age group	All races			White			Nonwhite			Other

Other venereal disease.....	404	4. 6	120	5. 4	242	4. 5	42	3. 6

during this period. Of these, 2,210 were recorded as white, 5,360 as Negro, and 1,166 as Puerto Rican. The race breakdown in the latter group was not recorded. As the table indicates, 1,181, or 13.5 percent of the total number examined, had syphilis. Sixty-one percent of this group were Negroes; the remainder were divided about equally between white (17 percent) and Puerto Ricans (22 percent). In the white group, 200 (9.0 percent) had syphilis, and in the Negro group, 721 (13.4 percent). In the Puerto Rican group, 260 were found to have syphilis. This was 22.3 percent of all the Puerto Ricans examined, almost 9 percent more than was found in the Negro group, a most surprising finding. This high percentage seems to be quite out of proportion to figures obtained from most sources.

There may be several explanations for this high rate of syphilis among Puerto Ricans. First of all, our clinic population is composed of persons with a high venereal disease rate. Over 60 percent of the total number examined sought consultation as a result of either contact investigation or the actual presence of symptoms of venereal infection. It is quite clear that we are not dealing here with the casual groups examined during blood testing surveys. Therefore, it is not surprising to find higher rates of infection among those applying for treatment in our clinics.

Another explanation of the high rate of infection with syphilis in the Puerto Rican group is that there were probably more Puerto Ricans examined than is indicated by the 1,166 figure.

In many instances, Puerto Ricans were not identified as such on the history charts. A sample of several hundred charts bore this out. A number of individuals with typical Puerto Rican names were recorded—quite correctly—as white or Negro, with no indication of their Puerto Rican origin. The number of such individuals in this study is not known. However, if even 500 noninfected individuals listed as white or Negro were Puerto Ricans, the syphilis rate in the Puerto Rican group would drop to about 16 percent. Suffice it to say, this 22.3 percent figure is probably too high.

Venereal Disease Case Reports

During 1954, 19,412 new cases of syphilis were reported in New York City, 6,363 in white patients, 9,726 in Negro patients, and 3,323 in "others." The exact character of the latter group is not known. Undoubtedly, many Puerto Ricans are so classified. As has already been pointed out, many Puerto Ricans may be classified as either white or Negro without any indication of their ethnic origin. It is clear, therefore, that no satisfactory conclusions can be drawn from morbidity statistics. Information from surveys is unquestionably more reliable.

Summary

1. Data on syphilis infection among Puerto Ricans in New York City taken from the 1953 mass blood testing survey, the Puerto Rican

project, the social hygiene clinics of the New York City Health Department, and the New York City venereal disease morbidity reports for 1954 are presented.

2. The percentages of syphilis infections in Puerto Ricans residing in New York City as recorded in these studies varied considerably and are as follows:

<i>Study</i>	<i>Percent infected</i>
Mass blood testing survey, 1953:	
White.....	9.6
Negro.....	11.8
Puerto Rican project, July.....	6.8
Social hygiene clinics, October-December 1954..	22.3

3. Some of the possible reasons for the differences in these rates are indicated. The most important appears to be that not all Puerto Ricans are designated as such in the venereal

disease case reports and on the records of the social hygiene clinics. Many are classified by race only and are not included in vital statistics for Puerto Ricans.

4. The data considered most reliable were derived from the Puerto Rican project, in which the syphilis infection rate was 6.8 percent.

Vaccination Certificates

Complete information and proper authentication are the two requisites for validating certificates of vaccination. The former is the province of the physician; the latter that of the health officer, State or local.

The vaccinating physician can help speed up processing persons for travel abroad by using the International Certificate of Vaccination form on which to record complete immunization data and by instructing the prospective traveler to have the certificate authenticated by the health officer. This form is given with the passport application. If the person is traveling on a tourist card, he may obtain his certificate from the local health department or purchase it from the Superintendent of Documents, Government Printing Office, Washington 25, D. C., at 5 cents a copy. Most travel agencies and automobile clubs also have the certificate.

A health officer's stamp on the certificate is required by international agreement for the purpose of attesting to the fact that the immunizing physician is a practicing physician within the area. This simple expedient reduces the possibility of fraudulent certificates being used.

If the health officer does not have an official stamp or seal, the Public Health Service suggests that he have a stamp made. The stamp should include the term "health officer" and the name and address of the health department.

Enforcement of Housing Laws and Housing Rehabilitation

The rehabilitation of existing substandard housing is an important facet of the prospect for a decent home and a suitable living environment for every American family. Along with the production of new housing, the prevention of blight, and the redevelopment of slum areas, housing rehabilitation can contribute toward a healthful and safe living environment. Much has been learned in the past few years about the specific effects of municipal programs for improving substandard housing. Far more is unknown. This study was undertaken to determine the changes in housing quality relating to health, safety, and livability of dwellings, as a result of compliance with the standards in housing and related ordinances.

The quality of approximately 1,000 dwelling units and their environment in 25 adjacent blocks in a pilot area in East Baltimore was measured by the American Public Health Association Housing Appraisal Method before and after the enforcement of the Baltimore City housing code and related ordinances and regulations in that area. The "before" and "after" conditions were compared. All scores are penalty scores, which means that as the score decreases, the quality improves. As a result of this "before" and "after" comparison, the following results are apparent:

1. The average dwelling penalty score decreased from 93.75 to 60.51, or 35.5 percent.
2. The average subtotal score for facilities decreased from 51.47 to 44.56, or 13.4 percent.
3. The average subtotal score for occupancy decreased from 7.52 to 6.98, or 7.2 percent.
4. The average subtotal score for maintenance decreased from 34.76 to 8.97, or 74.2 percent.
5. The percent of owner occupancy remained at 41.5 percent.
6. The average shelter rent increased \$6.40, from \$36.40 to \$42.80 per dwelling unit per month. The average gross rent increased \$5.70,

from \$48.20 to \$53.90 per dwelling unit per month.

7. The median family income increased from \$239 per month to \$259 per month.

8. The median environmental block penalty

Public Health

MONOGRAPH

No. 34

The accompanying summary covers the principal findings presented in Public Health Monograph No. 34, published concurrently with this issue of Public Health Reports. Mr. Johnson is director of the Research Institute and Construction Department, National Association of Home Builders; Mr. McCaldin is with the Division of Sanitary Engineering Services, Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

...

Johnson, Ralph J., and McCaldin, Roy O.: Housing rehabilitation and enforcement of housing laws. Public Health Monograph No. 34 (Public Health Service Publication No. 451). 34 pages. Illustrated. U. S. Government Printing Office, Washington D. C., 1955. Price 30 cents.

score was 57.5. This is due primarily to penalty points assigned for "land crowding" and "non-residential land use." The environmental survey was not repeated because it was evident that no significant changes occurred in items that would affect the environmental score. An important exception to this was the demolition of two blocks of deteriorated dwellings for the purpose of building a school. However, the dwellings in these two blocks had to be excluded from the "before" universe, since they were demolished before the time of the "after" survey.

9. The results of the examinations of rent and housing quality appear to show that, in the

pilot area during the enforcement period, rent and housing quality bear little or no direct relationship to each other, either before or after enforcement of the housing code.

10. The data indicate that the enforcement effort resulted in significant improvement of the quality of housing in the pilot area, without untoward effect on the residents. As a consequence, the improved dwellings are healthier and safer places to live. Furthermore, the improvement in maintenance scores alone should insure that the useful life of these dwellings will be significantly extended.

Federal-State Rehabilitation Program

Marion B. Folsom, Secretary of Health, Education, and Welfare, has invited the "full support" of State governors for the Federal-State program of restoring disabled persons to useful lives.

Congress has increased Federal appropriations from \$23,000,000 in fiscal 1954 to \$27,000,000 in fiscal 1955 and \$33,750,000 for 1956. Legislation passed in 1954 is designed to increase the number of disabled persons restored to employment each year from the current level of 58,000 to 200,000.

The major portion of the appropriations was designated for State programs of vocational rehabilitation and the remainder was made available for training personnel, expanding public and private non-profit rehabilitation facilities, and for research and demonstrations of ways of dealing with disability.

The Office of Vocational Rehabilitation reports that available State funds apparently will permit the States to use all of the appropriated Federal funds during the current fiscal year. With uneven expansion and improvement in rehabilitation activities, however, some States are exceeding the required appropriations and others only partially meeting the expected goals.

Each year some 250,000 persons reach the point of disability at which they require rehabilitation services. Even if the public program can annually achieve 200,000 rehabilitations, a sizable number will continue to rely on private services for help.

Organized Home Care Programs

Sick persons have been cared for at home from time immemorial. Care usually has been limited to physicians' services and, when it has been available, to nursing care. Rarely has it included the full range of services and the special supplies and equipment so often necessary to meet the total needs of patients.

The current concept of a home care program is one in which selected patients are provided with a full range of services in their homes. These services are planned for and coordinated through one administrative agency or institution.

Comprehensive services to patients at home include:

Physician's services	Housekeeping services
Medical specialist consultation	Laboratory examinations
Nursing service	X-rays
Social service	Drugs and medical supplies
Physical therapy	Prosthetic appliances
Occupational therapy	Hospital and sickroom equipment
Speech therapy	Transportation
Nutrition consultation	

During the past two decades, organized home care programs have been established to make available a range of services to patients at home and to provide a field work experience in a home setting for professional personnel. Comparable information on these programs has been lacking. To meet the need for such information, the Public Health Service and the Commission on Chronic Illness undertook a joint study of 11 home care programs, selected to represent various auspices, different administrative patterns, and broad geographic distribution.

For the purposes of the study, organized home care programs were defined as those having centralized responsibility for the administration and coordination of services to patients and providing at least the minimum of medical, nursing, and social services, and essential drugs

MONOGRAPH

No. 35

The accompanying summary covers the principal findings presented in Public Health Monograph No. 35, published concurrently with this issue of Public Health Reports. The study upon which the report is based was a joint project of the Public Health Service and the Commission on Chronic Illness.

The study was conducted and the monograph was prepared by a study staff from the Public Health Service. The director is a physician on the staff of the Division of Public Health Methods. The nursing, medical, social, and statistical consultants on the study staff were in the Chronic Disease Program, Division of Special Health Services. They have since been assigned to other units of the Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of major universities and in selected public libraries.

Waterhouse, Alice M., Bailey, Eleanor C., Gillis, Mary C., and Palmer, Jeanne T.: A study of selected home care programs. Public Health Monograph No. 35 (Public Health Service Publication No. 447). 128 pages. U. S. Government Printing Office, Washington, D. C., 1955. Price 65 cents.

and supplies. Part I of the monograph summarizes the findings, presents conclusions, and suggests guidelines for the establishment of home care programs.

Programs in the study show that they range in size from an annual patient load of less than 100 up to several thousand. Patients of all ages with virtually all types and severity of illness are given care at home. Some programs serve patients with either acute or chronic illness; others provide care to patients with chronic illness only; one serves exclusively patients with tuberculosis. All of the programs make available medical, nursing, and social services; drugs and medical supplies; X-rays and laboratory tests; hospital equipment and sickroom supplies; and transportation. The availability of the other services listed above varied. In all programs, patients could be hospitalized without delay when the need arose.

Of the programs studied, the eight based in hospitals and health departments are administered by physicians. Social workers administer the two programs that are under the auspices of social agencies; and the program sponsored by a nursing agency is administered by a public health nurse.

Wide variation was found in the extent to which the central administrative agency itself provides services or assumes responsibility for arranging for services through other community agencies. In some programs, the major portion of the services are supplied by a home care staff, while in others, services are

provided through community agencies, with the home care staff functioning primarily as the coordinating agent.

Indigent and medically indigent patients only are eligible for services in 10 of the programs. The one exception offers service to patients regardless of financial status through their private physicians, although patients are charged according to their ability to pay.

It was impossible to obtain comparative data on costs of the programs since the items included in the home care budgets varied greatly from one program to another. Moreover, no records were kept of the costs borne by the family or of expenditures by the community for services provided without charge.

A number of the programs are used to provide educational fieldwork experience for graduate and undergraduate medical students, professional and practical nurse students, and graduate students in social work. Teaching methods are still experimental in the home setting and show wide variation in the programs studied.

Part II of the monograph describes each program studied with regard to its origin and development, objectives, organization, administration and operation, and use of home care in professional education. It gives cost and statistical data on types of patients and services.

The appendix presents the types of information collected in the schedules used for the study.

Noise Health Hazards in the Air Force

By LT. COL. JACK C. CARMICHAEL, USAF, MSC

DURING the past 10 years the public has become concerned with the effects of noise. Noise is an unavoidable byproduct of modern power producing machinery. It is a byproduct of force, energy converted to sound. Production of power in prodigious amounts is necessary to effective military aircraft. Inevitably, such power generates noise at extremely high levels.

Industry, too, has encountered noise problems. Within the plant a noisy environment possibly affects efficiency and may damage hearing. Imperfect hearing and nervous strain also reduce the normal margin of safety. Noisy mixers, washers, or vacuum cleaners encounter sales resistance. Noisy products or operations raise acute objections in residential areas. Noise is disparaged as a nuisance, for interference with communications, for damage to hearing, and for other possible effects on health, efficiency, or safety.

The problem is indeed broad. It directly affects the daily lives of the majority. Many excellent papers have covered technical aspects of noise and its control. In this short paper, I shall not attempt to repeat more than the minimum necessary for dealing with my subject,

which is only presented as an introduction to the topic.

For this purpose "noise health hazard" is defined as those aspects of noise for which the Medical Service of the United States Air Force has a responsibility. Noise is defined as any undesirable sound, a sound that interferes with a desirable activity. However, such interference has to be specified. A given sound is not equally effective in masking speech, in interfering with sleep, or in producing permanent hearing loss.

The medical service's responsibilities cover seven major areas:

- Establishment of engineering criteria for noise control.
- Environmental noise surveys.
- Advice on control procedures.
- Evaluations on effectiveness of control programs.
- Personnel protective measures.
- Audiometric examinations.
- Education programs, both on and off the Air Force base.

The engineering aspects of the noise health hazard can best be described by a brief discussion of these responsibilities.

Establishment of Engineering Criteria

Engineering criteria for noise control are basic to any discussion of the noise problem. The establishment of a single criterion to cover all conditions is not possible. Therefore, a separate criterion must be considered for at least three areas, namely, (a) damage risk, (b) speech communication, and (c) residential living.

Colonel Carmichael is chief of the engineering branch, Office of the Surgeon, Headquarters Air Materiel Command, Wright-Patterson Air Force Base, Ohio. From 1950 to 1954 he was senior sanitary engineer, Office of the Surgeon General, Headquarters, United States Air Force, Washington, D. C., and from 1947 to 1950, district sanitary engineer, United States Armed Forces in Europe.

In each area there are unknown factors which complicate the establishment of these criteria. Notwithstanding these unknowns, decisions that involve the interaction of noise and man must be made. The following criteria are based primarily on the Wright Air Development Center (WADC) Technical Report (1).

Establishment of Damage-Risk Criteria

Personnel exposed to noise at damage-risk levels may suffer hearing losses (2). Safe levels would permit personnel to work regularly 8 hours a day for years without serious probability of such damage. Factors to be considered include a wide variation in susceptibility among individuals, duration of exposure, and, especially, the noise spectrum. The damage-risk criteria utilized, it is felt, will assure safety for the majority of exposed personnel. The criteria are given as the maximum permissible noise levels in specific frequency bands. There are eight octave bands used in the frequency range 20–10,000 cycles per second. The maximum allowable sound pressure in each of these bands is shown in the accompanying chart. These values apply to exposure with no ear protection and to continuous daily exposure. An overall sound level is not adequate as a criterion because the damaging action of noise is related to the frequent distribution of the pressure and not to the overall level.

Notwithstanding this, there are overall levels which are of such intensity as to produce known effects. For example, 150 and 160 decibels, regardless of how short the exposure, will produce damage to hearing; exposure to intermittent noises of overall levels of 100 to 130 decibels may cause temporary deafness which may persist for several hours.

Criteria for Speech Communication

The ability to communicate by voice varies in requirements from essential for personnel safety to ease of conducting a personal conversation. The following extract from the WADC technical report (1) presents a discussion of this variation together with the limitations of a criterion.

"In many areas, efficient performance of task

is often dependent upon the ability of people to talk to each other. Whether the environment is a conference room or a machine shop, noise conditions should be adjusted to permit communication suitable to the task that is to be performed. The type of communication desired may be of varying kinds, from conversation in a normal voice, at say 20 feet, to shouting danger signals at a distance of 6 inches from the listener's ear. The acceptable levels of the masking noise are dependent, therefore, upon the particular task involved and upon the degree to which speech communication is important in the performance of these tasks, or in the maintenance of adequate morale among employees. In establishing each communication criterion, account is taken of not only the level of the masking noise, but also the vocabulary to be used in the communication, the voice level, the distance from the speaker to the listener, etc. Of primary importance is the spectrum of the masking noise. The concept of the SIL (speech interference level) was originally based on data derived from experiments with continuous masking noise. If the noise is irregular or interrupted in time, the intelligibility is affected in a way in which the SIL does not predict. At the present time, there are insufficient data to delineate the limits of intensity, shape of spectrum, and time character of the noise within which the application of the SIL is valid. It is fortunate, however, that the masking noises encountered in most practical situations have a reasonably smooth spectrum and a uniform time character. In such situations, the SIL does provide a reasonably good approximation of the effectiveness of a noise in masking speech. The validity of the use of the SIL is justified by many observations in the field. With these limitations in mind, it can be concluded that the ability to communicate by voice in the presence of noise is determined essentially by four factors:

- "1. The SIL of the masking noise.
- "2. The voice level used by the talker.
- "3. The distance from the talker's mouth to the listener's ear.
- "4. The nature of the vocabulary used in communications."

Therefore, criteria for speech communications vary with the type of communications

required, established at four levels. The chart is a plot of these criteria.

On the chart, SC-75 indicates overall sound levels in the 8 bands with an index of 75 (the arithmetic mean of the levels in frequencies of 600-1200, 1200-2400, and 2400-4800). At this level, minimum speech communications require a very loud voice at 1 foot.

At SC-65, intermittent communication is possible with a raised voice at 2 feet, very loud voice at 4 feet, and shouting at 8 feet.

At SC-55, continuous communication in work areas, such as business, secretarial, or control rooms, requires a normal voice at 3 feet, raised voice at 6 feet, and a very loud voice at 12 feet.

At SC-45, a normal voice serves at 10 feet in such locations as private offices or conference rooms.

Criteria for Residential Living

The reaction of people to a noise in their home is the most difficult criterion to establish. There are many and varied factors which influence a public reaction, the proper evaluation of which requires experts. The following brief quotation from the WADC technical report serves to outline the problem involved:

"There are essentially two aspects to the analysis of the inter-reaction between an intruding noise and human being exposed to the noise. A physiologist would call these aspects stimulus and response. The stimulus function can, as a first approximation, be defined by a physical description of the noise to which the human beings are exposed. It may, however, also be necessary to describe the physical characteristics of noise to which a particular group of people have been exposed in the past, in order to evaluate the degree to which they have become adjusted to a noisy environment. The response of residents is measured through expressions of annoyance, complaints, or even through legal action. Our task is to be able to predict their response from knowledge of the stimulus function, past and present. The many factors involved in the establishment of residential criteria preclude their discussion in detail in this paper. I would like to mention a few of the considerations which must be taken into account. Experience has shown that there

are at least seven large independent characteristics of a noise stimulus that control the response behavior of a community exposed to the noise, namely:

"1. *Spectrum character.* A noise spectrum that contains audible pure tone or single frequency components appears to be more annoying than a spectrum that is reasonably continuous.

"2. *Peak factor.* A noise that is reasonably continuous in time, at least over periods of a few seconds or more, is assumed to be less annoying than an impulse-type of noise.

"3. *Repetitive character.* In addition to the short-time peak factor discussed above, the repetitive factor of the intruding noise influences a neighborhood reaction to a large degree.

"4. *Level of background noise.* Residents in areas with low background level are more likely to react to intruding noise of fairly low level than those in areas in which the background noise partially masks the intruding noise.

"5. *Time of day.* Most residents agree that intruding noise is more tolerable in the daytime than during the evening.

"6. *Adjustment to exposure.* Experience has shown that residents can adjust to a varying extent to an intruding noise after repeated exposures.

"7. *Other factors.* In addition to the physical factors listed above, factors of a psychological nature influence neighborhood reaction to an intruding noise, though by no means to a constant degree. Such questions as continuation of the noise and public relations between the community and those causing the noise may modify the noise rating to a marked extent."

Environmental Noise Surveys

A noise survey, in essence, is the same as any engineering survey. It requires advance planning to assure that the goal is amply stated, that adequate and properly calibrated equipment and personnel are available. The many variables in a noise survey preclude the establishment of a set procedure equally applicable to all conditions. It is imperative that the engineer planning the survey take into account the peculiarities of the particular problem. Certain guiding principles apply to all surveys.

Noise levels in frequency bands covering proposed criteria for damage risk, speech communication, and residential living.

Of particular importance are records of ambient temperature and humidity, of wind velocity and direction, of the location of facilities and time of testing, of types and serial numbers of equipment with particular reference to microphones and cables used, and, finally, of the individual observers making the measurements. General aspects of the survey are:

A description of the area to be surveyed with ample data concerning the facility. For example, a survey of an office area, hospital, or any interior should note the dimensions and type of surfaces, location and type of doors and windows, type of seal on the doors and windows, and type of use for which the facility is designed. In an area survey, the map should include all residential areas or industrial facilities.

The next major step in the survey is the location of the primary source of the noise. Descriptions of the source of noise should defi-

nately be included with a time schedule of noise production over a 24-hour period, as well as other data pertinent to the cause of the noise or factors which might increase noise from the primary source. The location and adequate data should be provided on each secondary source of noise. The orientation of the microphones with respect to a noise source should be specified in all cases, as well as other peculiarities which affect a noise reading such as temperature of microphone, maintenance and calibration tests of equipment, and temperature and humidity of the environment on the day and at the time the readings are made.

In the selection of equipment it is well understood that microphones should be appropriate to the task. Certain microphones are designed for low sound levels, others for high sound levels. One may be designed for low frequency selectivity, another for high fre-

quency. Cables and the use of cables on the surveys call for similar discrimination. In general, where short cables are used, most microphones can be used without a corrective factor. Where a long cable is necessary, a correction will generally be required. These are but a few of the variables encountered in a noise survey.

Before an engineer attempts a survey, he should avail himself of data as a guide to selection of sound measuring equipment. Uniform practices for the measurement of aircraft noise are contained in the Aircraft Technical Committee Report No. ARTC-2 (3).

Advice on Corrective Action

In general the control of the source of noise is under the direction of the operator. As a consultant to the operator, the sanitary and industrial hygiene engineer submits recommendations for the correction of noise hazards. The engineer is not limited as to any particular aspect of the control program; his advice and recommendations should cover all aspects in which he is technically competent. Engineers in the Medical Service of the Air Force recommend sites for engine test cells, engine runup areas, and barracks or office buildings in relation to sources of noise. Other recommendations include soundproofing measures for buildings which must be in a noisy environment.

In many instances engineers have been able to eliminate or materially reduce noise at the source. This is particularly true of industrial noises or noises emanating from an operating procedure which can be controlled at the source. As to the aircraft engine, since the noise is directly related with the power produced, it is not feasible to reduce the noise at the source, although research is pursued with that objective. Noise is reduced in part through improved performance of aircraft engines, particularly where rough burning of engine fuels has been eliminated. It has been possible also to reduce the noise of the explosion on the afterburner of the jet aircraft.

Where noise cannot be eliminated or sufficiently reduced at the source, the engineer recommends, as a prime measure, the use of

acoustic material. Other methods include changing the relative position between source of the noise and those affected—structural changes to reduce vibration noises, or construction of sound barriers. Corrective action in noise control parallels other environmental conditions. It calls for application of all available disciplines. Each problem must be studied of itself, with the aim of arriving at the most economical and feasible solution.

Personnel Protective Measures

The engineers of the Medical Service of the Air Force have a prime responsibility to assure that the corrective action taken following the location of a noise hazard is adequate and effective. The responsibility here is primarily the protection of personnel. In addition, it is an evaluation to assure that the economical method will suffice.

Personal protective equipment for personnel is limited by obstacles in design. At the present time, the most effective ear defender is a properly fitting earplug. The use of earmuffs and helmets, which with earplugs give some additional protection, is limited by the nature of the seal. All personnel exposed to a hazardous noise level must be fully acquainted with the need for the protection afforded by properly fitted ear defenders. Engineers owe it to the personnel to see that such equipment is available.

In addition to the personal protective equipment, personnel protection is secured through previously noted control measures. Specific examples include a properly designed control booth for operators at engine test cells and sound suppression in control towers, classrooms, and barracks.

The engineer through his contacts in his daily work is an ideal member of the medical service to impress on supervisors as well as workmen the importance and necessity of wearing earplugs and other ear defenders in a noisy environment. In addition, they can serve as ambassadors in acquainting the personnel, both on and off the base, with noise hazards and corrective steps.

Engineers of the medical service must see that properly designed and equipped audiometer

rooms are available for audiometric examinations of personnel exposed to high noise levels. In designing an audiometer room, consideration must be given to its environment. Operating agencies desire the room to be located in the immediate industrial area to save time of personnel. Such a location places an additional burden and expense on the acoustical design. The engineers, through their surveys, establish the areas where personnel are exposed to hazardous noise levels. Such surveys determine the audiometric testing cycle.

This brief review reveals the scope of the problem of noise in modern living. In many areas, knowledge is incomplete, but current and future research may reduce the uncertainties.

1956 Community Health Week

March 18-24, 1956, has been designated Community Health Week, to be headlined under the banner "Let's Do More About Health." The National Health Council and the United States Junior Chamber of Commerce are the sponsoring organizations.

The success of the initial observance of Community Health Week in March 1955 led the sponsoring organizations to their decision to repeat the performance. Last spring, 180,000 Jaycees across the country helped to arrange health fairs and rally the people to attend. Their efforts inspired television and radio shows as well as newspaper features and special news sections telling the people about needs of local health services and the health resources to look for in their own community.

The United States Junior Chamber of Commerce will have available after January 1 a work kit which it has produced as a guide for those engaged in organizing activities for a community health week. The kit will be distributed to Jaycee chapters requesting it from the Tulsa, Okla., headquarters of the junior chamber. In communities without Jaycee chapters, local affiliates of national organizations may request kits from the National Health Council, 1790 Broadway, New York 19, N. Y.

The contents of the kit, prepared by members of the staff of the National Health Council and its member agencies, include leaflets describing "Newspaper Health Supplements," "Health Fairs," and "Movies Tonight"; a checklist of projects which a community may launch during health week, such as accident prevention campaigns, establishment of preschool clinics, fluoridation of municipal water supplies; and a list of National Health Council member agencies to facilitate community cooperation.

A fundamental goal of research in this field is to provide bases for the formulation of public health policy. Using examples of research undertaken at the Robert A. Taft Sanitary Engineering Center and elsewhere, the author discusses the role of statistical concepts in providing these bases.

Statistics Applied to Research in Environmental Sanitation

By EUGENE K. HARRIS, Ph.D.

PROBABLY the most valuable application of statistical concepts in the environmental sanitation field is in determining the extent to which a given situation represents a public health problem. Another job, almost as important, is that of analyzing objectively the technical procedures on which much of public health policy and action is based.

The second task is often the easier. Two investigations, one on milk and the other on shellfish pollution carried out by personnel of the Robert A. Taft Engineering Center, may serve as examples. The first of these, an analysis of variation in the direct microscopic clump count on milk, has been mentioned briefly by Black and Myers (1). The study was small in scale, yielding results which are only indicative. Its purpose was to analyze variation in milk counts into two broad components: variation in the

counts of a single observer and variation attributed to differences between observers.

The Milk Clump Count Study

The most interesting part of the milk clump count study concerns the examination of milk with 100,000 to 200,000 bacteria per milliliter (the upper half of the grade A range in raw milk to be pasteurized). Cooperation was obtained from four men, all with long experience in the direct microscopic count. Each man prepared five replicate films from the same lot of milk, following the procedures of 1948 Standard Methods for the Examination of Dairy Products (2). The number of fields read was determined by each observer on the basis of his counts on the first film examined, using the table in standard methods as a guide.

In this way, 20 counts were generated. Analysis revealed that the variation (standard deviation) attributable to differences between observers amounted to 63 percent of the mean count, while variation "within" the average observer amounted to 34 percent of the mean count.

Variation between observers probably arises chiefly from differences in ability to distinguish bacterial clumps when examining a film.

Dr. Harris, an analytical statistician with the Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati, Ohio, presented this paper before a joint session of the laboratory and epidemiology sections of the Western Branch of the American Public Health Association, meeting in Seattle, Wash., May 11, 1954.

Nevertheless, a test was made of the possibility that mixing of the original sample was incomplete so that readers received portions of varying density or that individual differences in preparing films resulted in varying mean counts. Each observer examined one slide selected at random from each of the sets prepared by his colleagues. In no case did the mean or the variances of the counts on these films differ significantly from the corresponding statistics on his own slides. Apparently, some individuals tend to read "high" and others "low."

For 3 of the 4 readers, the observer variation was about as much as would be expected on the basis of a random distribution of bacterial clumps over a film. The fourth reader, who reported the lowest mean count—about 100,000 per milliliter—showed significant nonrandom variation, due most likely to fluctuations in judgment, attention, and other personal factors.

This small milk count study has been described partly to illustrate a simple statistical design for analyzing the precision of a laboratory method, but more especially to emphasize the importance of the subjective, personal factor in laboratory diagnosis. Improvements in mechanical technique, or in the composition of materials, will be of little worth if the persons applying the methods remain highly variable in their interpretation of what they see.

Finally, what administrative use can be made of these results? They indicate that a single direct microscopic count may not be too reliable a measure of bacterial density, chiefly because of great variation among observers. On the other hand, 3 of the 4 observers exhibited a high degree of internal consistency. It seems, therefore, that from a practical standpoint, the direct count will be most effective when used by a single experienced observer in judging the continuing quality of milk produced over a long time by a given dairy farm. Once the observer has established his own baseline of quality for a certain milk, the direct count will enable him to detect gross deviations from that baseline (that is, counts averaging at least 50 percent greater than his usual observations) regardless of whether he is by nature a "high"

or a "low" reader. The fact that well-operated dairy farms are able to keep raw milk counts far below the grade A limit adds weight to the argument that the direct count is more efficient as a measure of continued quality control than as a criterion for grading any one lot of milk.

Shellfish Pollution Study

Another study which offers some interesting concepts to the health official desiring an objective basis for policymaking is that by the Shellfish Sanitation Laboratory operated as a field station under the center. It concerns the relationship between the density of coliform organisms in water overlying shellfish beds and the coliform density in the shellfish themselves. The data obtained in this investigation are now in the process of final analysis for publication and hence will not be discussed in detail. The study is mentioned here for illustrative purposes only.

The Manual of Recommended Practice for Sanitary Control of the Shellfish Industry (3) classifies shellfish growing areas according to the median most probable number (MPN) of coliform organisms in water samples collected during the harvesting season. A median less than 70 per 100 milliliters defines an approved area; between 70 and 700, a restricted area; and greater than 700, an area closed to shellfish growing. Of course, this is not the only basis for judging shellfish quality; the sanitary survey is doubtless the most effective guide. Nevertheless, numerical standards have a powerful attraction, and, in order to justify certain water standards, we should know the effect on the shellfish of a given level of pollution in the overlying water.

In the laboratory study, hard-shelled clams (*Venus mercenaria*), soft-shelled clams (*Mya arenaria*), and oysters were studied in laboratory flats under widely varying water pollution loads at temperatures ranging from 4° to 23° C. Most probable number determinations were made on both water and shellfish samples at frequent intervals, according to the procedures recommended by the American Public Health Association (4). Most of the experiments ran from 3 to 4 days, some from 2 to 3 days, and one or two slightly longer than 4 days. Since a

Water and clam MPN's in moderate temperature range (8° – 17° C.). Arrows designate MPN's not precisely determined but greater than the charted values.

great many more water than shellfish samples were taken, each shellfish MPN was matched with a geometric mean MPN in water based on samplings made during a prior 12-hour period.

Water and shellfish MPN's were plotted as abscissa and ordinate, respectively, on a logarithmic grid for each species of shellfish in each of three temperature ranges. The resulting scatter diagrams may be subjected to a number of different analyses. Before proceeding, it is well to emphasize that the data of this particular study were obtained from relatively small numbers of shellfish subjected to controlled pollution under laboratory conditions. Nevertheless, this type of data, namely, matching water-shellfish coliform indexes must arise when

studying the relation between water pollution and the sanitary quality of shellfish.

The following plan for analysis of such data appears to be the simplest and probably the most useful to the public health official. For example, from one of the graphs for soft-shelled clams, let us select some prominent MPN's per 100 milliliters in water and clams, say 70 and 2,400. The manual suggests that an MPN of 2,400 or more coliform organisms per 100 milliliters occurring in clams taken from the growing area indicates unfavorable conditions or practices surrounding the production of these clams and necessitates further investigation.

A vertical line is drawn intercepting the X-axis at $X=70$ and a horizontal line intercepting

the Y -axis at $Y=2,400$. As shown in the figure, these lines cut the scatter diagram into four blocks, which may be labeled northeast, southeast, southwest, and northwest.

Let us assume that the sanitary quality of clams in which the MPN exceeds 2,400 coliform organisms per 100 milliliters should be regarded with suspicion. Then, the northwest and southeast blocks represent risks incurred in operating at a mean MPN of 70 for approved waters. The proportion of northwest points to all western points estimates the probability that clams of suspicious sanitary quality will be harvested, while the proportion of southeast points to all eastern points estimates the probability that satisfactory clams will not be accepted immediately but will at least have to undergo further purification. We can reduce the risk of harvesting suspicious clams by lowering the permissible MPN in water, but this increases the risk of rejecting acceptable clams. It becomes necessary to define quantitatively the relative importance attached to each risk.

Suppose, however, that some number other than 2,400 is decided upon as a critical point with respect to the sanitary quality of clams. Then, the numerical estimates of the risks change and with them the bases for a decision of permissible water pollution. The question of proper limits is a very complicated one. This type of analysis merely offers the health official one quantitative criterion by which to estimate the effects of proposed limits.

Hazard Indicators

We have mentioned that statistical concepts achieve their greatest value in public health research when they can be used to determine to what extent a given environmental situation represents a public health problem. This statement needs further definition. As a rule, official recognition of a health hazard results from an outbreak of disease followed closely by epidemiological investigation. However, in order to translate mere recognition of a health hazard into an effective program for its control, two basic conditions must be met. One or more variables must be selected to serve as indicators of the hazard, and the variables must be calibrated so that by measuring them we may

measure the severity of the hazard. This latter condition implies that quantitative research is necessary to determine, at least approximately, that point on the scale at which the hazard becomes sufficiently great to merit official action.

As examples of attempts to measure the relationship between indicator variables and health hazards, two investigations will be summarized briefly. The first consists of a series of studies by A. H. Stevenson and R. S. Smith of the center and T. D. Woolsey of the Division of Public Health Methods, Public Health Service, on the relation between bathing water quality and health (5).

Natural Bathing Water Quality

Three different classes of natural bathing water were studied: a great lake, an inland river and nearby swimming pool, and a coastal water. Selected in each study were two swimming areas which appeared on the basis of past records to differ markedly in bacterial quality but which were used regularly by families of similar socioeconomic levels.

Illnesses recorded during the study were eye, ear, nose, and throat ailments, gastrointestinal disturbances, and skin irritations. The two occurrences of significant positive correlation between illness incidence rate and bathing water quality are of particular interest since in each case the comparison was between extremes of bacterial quality, namely, median MPN's of 2,700 and 2,300 on the one hand, and less than 3 and 43 on the other. In one instance, only gastrointestinal illness rates were concerned; in the other, the correlation extended to all types of reported illness. In view of the general lack of correlation found between illness rates and variations of coliform density in the range up to about 700, the authors believe that "some of the strictest bacterial quality requirements now existent for natural bathing water might be relaxed. . . ."

Apart from the value of the findings, these studies are noteworthy because of the manner in which the data were collected. Each participating family maintained a daily diary of swimming and illness experience, recording the information on a calendar form according to a special code. This way of gathering information is in contrast to the interview method

whereby a trained investigator calls upon the family at scheduled times, eliciting information on morbidity during the preceding interval. The interview method suffers from the disadvantage that frequent visits are required in order to avoid the dangers of bias due to lapses of memory on the part of the respondent, especially for minor illnesses which were of chief concern in the bathing water studies.

On the other hand, a morbidity survey which requires the cooperating family not only to supply but also to record the data is subject to the risks of illegible and inadequate information. These difficulties were avoided in the bathing water studies by providing a simple code printed below the calendar; by carefully reviewing the diary form with the housewife; and, finally, by maintaining contact with the family during the study through telephone, mail, and an occasional personal visit.

Meteorological Factors and Air Pollution

The second example of quantitative research into the effects of environmental factors on health is in the field of air pollution. This project is the first step in a search for the possible health effects of minor changes in weather and atmospheric pollution. With respect to the effects of weekly variations in weather factors, an early study by L. J. Reed (6) of Johns Hopkins University, using statistics of England and Wales for the years 1865 to 1914, is of interest.

Weekly mortality records from the city of Cincinnati are being examined to find out if a pattern of variation exists which may be correlated with local meteorological factors and especially with some measure of air pollution. The mortality data on punchcards have been made available through the cooperation of the city health department. This study initiated by Dr. K. H. Lewis of the center and now being carried on under the writer's immediate supervision is the sort of work which may be undertaken by State or city health departments.

Progress to date of the Lewis study may be outlined as follows. Mortality during the period from January 1952 to December 1954 has been tabulated for 22 causes of death by age group and week of death. From these tabulations, four causes, comprising a group of cardiovascular diseases, have been selected. The

successive weekly totals for all ages have been plotted on graphs for each year. The same has been done with deaths from respiratory causes and total deaths from all causes, but so far analysis has been confined to the cardiovascular group.

The general trend of cardiovascular deaths in any year could be fitted very well by a simple curve. Selected in each year were short periods of time during which significant deviations from the curve were apparent—either peaks or dips. The same techniques are now being applied to various weather factors (temperature, pressure, percent of possible sunshine, and so on) for which weekly medians or totals may be calculated from publications of the Cincinnati office of the United States Weather Bureau, and to a continuous measure of air pollution—the intensity of staining of filter paper in a Hiemeon automatic smoke sampler. Information on this variable has been obtained through the cooperation of the Cincinnati Bureau of Smoke Inspection. It is possible that obvious deviations from the general mortality trend will be clearly associated with similar deviations in one or more environmental factors. More likely, in order to reveal any correlations, it will be necessary to analyze all weekly deviations observed in mortality, weather, and air pollution pictures.

Summary and Conclusions

This discussion has implied the need for careful research in defining the nature and content of control programs in environmental sanitation. Nevertheless, it is a common experience of health officials to be called upon for action in an emergency situation and to have to devote to the operation of an untested control program resources that might otherwise be spent on research leading to a more efficient program. There can be no criticism of this when the need is obvious and when at least the qualitative aspects of the necessary control procedures are known. Eventually, however, every such procedure calls for reevaluation, sometimes in terms of errors of measurement but always in terms of health significance. By means of specific examples, I have tried to illustrate the ways in which research based on

statistical concepts may aid in the evaluation of current sanitation programs and in the planning of new ones.

Harold R. Sandstead, 1904-1955

Dr. Harold R. Sandstead, nutrition expert on the staff of the National Institute of Arthritis and Metabolic Diseases, was killed in the November 1, 1955, airplane crash in Colorado. Dr. Sandstead held the rank of medical director in the commissioned officer corps of the Public Health Service. For the past year he was executive director of the Interdepartmental Committee on Nutrition for National Defense. He joined the Service in 1934.

Dr. Sandstead was honored in 1945 by the Netherlands Government for his work on nutrition in Holland. He also received the Bronze Star for this work from the United States Army. In 1954, the Army awarded him the Bronze Star with Oak Leaf Cluster for his work on nutrition in South Korea. A memorial fund for medical students has been established in Dr. Sandstead's name by Vanderbilt University, Nashville, Tenn., where he served as assistant professor of medicine during 1940-53.

Printed in a recent issue of the Netherlands *Tijdschrift voor Sociale Geneeskunde (Journal of Social Medicine)* was a tribute to Dr. Harold Sandstead. Excerpts from this tribute, freely translated, are published below at the request of Dr. C. Banning, chief medical health officer of the Netherlands.

"Dr. Sandstead's name transports us directly back to the first months after the liberation. In our memories, we see this outstanding American laboring day and night to assist in the rebuilding of the Netherlands.

"On the SHAEF mission, he was prominent among those who hastened to help our country. He was

particularly interested in the problem of starvation and malnutrition. Sandy, as many friends called him, took an important part in investigating malnutrition, especially in the western part of our country.

"With the late Sir Jack Drummond and Prof. G. C. E. Burger, he completed a report on Malnutrition and Starvation in Western Netherlands. In the introduction to this report, our Minister of Social Affairs thanked the composers, calling them the international 'triumvirate.' Concerning Dr. Sandstead, the Minister says that Lt. Col. H. R. Sandstead, as head of the health section of the SHAEF mission to the Netherlands, contributed much to the recovery of the health of the population of our country and to the relief activity.

"No wonder that in October 1945 our Queen honored Dr. Sandstead as Officier in de Orde van Oranje-Nassau met de Zwaarden (Officer of Orange-Nassau with the Swords).

"His more intimate friends know that Sandy not only gave material help and took care of the supply of food, medicine, and equipment, but he was a man of warm feelings who also gave moral support and assistance. This American officer understood and participated in the sorrow the occupation had caused us.

"From my personal experience, I know that Holland had a special place in Sandy's heart. He was deeply interested in everything happening in Holland, and he rejoiced in the swift rebuilding of our country. Holland has lost a great American friend. To his very many friends here, his death has left a great vacuum."

Technical publications

Public Sewage Treatment Plant Construction, 1954

Public Health Service Publication No. 453. 1955. 18 pages. 20 cents.

Public Sewage Treatment Plant Construction for the calendar year 1954 supplements and brings up to date the information contained in the reports for 1952 (PHS Pub. No. 291) and 1953 (PHS Pub. No. 409). The report indicates the progress made by municipalities during 1954 in providing the sewage treatment facilities necessary to prevent pollution of water resources on which downstream water users depend.

Contracts were awarded for 716 projects costing \$227.5 million, an increase, after adjustment for cost index fluctuation, of 21 percent over 1953 construction. Of the 1954 contracts, 366 were for new plants, costing \$143.2 million, and 350 were for additions, enlargements, or replacements of existing plants, costing \$84.3 million. The appendix to the report lists individual projects, by State, giving type of construction and cost of each.

Venereal Disease Clinics Directory

Public Health Service Publication No. 257. Revised 1955. 144 pages. 70 cents.

Names and addresses of the Nation's venereal disease diagnostic and treatment facilities, days and hours of service, and fee basis for use of each facility are listed in this directory.

It is published biennially by the Public Health Service Venereal Disease Program to provide the latest information on these clinics and other facilities. The material included in the 1955 edition has been compiled from information supplied by the health departments of the 48 States; the Territories of Alaska,

Hawaii, Puerto Rico, and the Virgin Islands; and by the Division of Hospitals of the Public Health Service.

Summaries of premarital and prenatal laws as they pertain to venereal disease are given for each State and Territory having such laws, and laboratory facilities available in each State are described.

The current directory shows that 40 States and 3 Territories have premarital laws requiring blood tests and physical examinations for venereal disease, while 42 States and 3 Territories have prenatal laws requiring blood tests for pregnant women.

Nutrition and Healthy Growth

Children's Bureau Publication No. 362. 1955. 36 pages. 20 cents.

Quantities as well as kinds of food that will contribute most to good nutrition during pregnancy and throughout childhood are presented in this pamphlet, which is addressed primarily to teachers, nurses, social workers, and other personnel working with parents. Sample meals for children at varying stages of development are given. Common foods and the contribution each makes to good nutrition are listed in an appendix.

A Comprehensive Program for Water Pollution Control

Lower Portion of Upper Mississippi Basin

Public Health Service Publication No. 450. Water Pollution Control Series No. 71. 1955. 53 pages; illustrated.

Developed in cooperation with water pollution control agencies of Iowa, Minnesota, and Wisconsin and adopted by the Public Health Service, this program is based on data available as of November 1, 1954.

Among the recommendations for municipalities are: sewage treatment plants for 26 municipalities and institutions now discharging untreated sewage to the basin watercourses; replacement of 9 existing plants; enlargement or additions for 33 plants; and connection to existing municipal sewers of 1 plant. For industries, requirements include: 68 new treatment plants; enlargement or additions for 33 existing plants; replacement of 2 plants; and connection to existing municipal sewers of 4 plants.

Industrial Waste Guide to the Wool Processing Industry

Public Health Service Publication No. 438. 1955. 14 pages; illustrated. 15 cents.

Third in a series of Industrial Waste Guides, this one is intended primarily to aid operators of woolen mills and commission processors in using, reducing, and otherwise suitably disposing of their wastes. Like its predecessors in the series (the first was for the milk processing industry, and the second, for the meat industry), it is based on two premises. First, the greatest possible recovery, use, and reduction of wastes is necessary for the most economical production; and, second, protection of the Nation's limited

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

water resources for maximum use is necessary in order to bolster our national health and economic growth.

The guide was prepared for the Public Health Service by the Stream Pollution Abatement Committee of the American Association of Textile Chemists and Colorists under the sponsorship of the National Technical Task Committee on Industrial Wastes.

The Halogenated Hydrocarbons, Toxicity, and Potential Dangers

Public Health Service Publication No. 414. 1955. By W. F. von Oettingen. 430 pages; illustrated. \$2.50.

Intended for physicians, entomologists, engineers, and persons inter-

ested in agriculture, this publication deals with the toxicity and potential dangers of various halogenated hydrocarbons—aliphatic, olefinic, cyclic, aromatic, and aliphatic-aromatic. It covers, therefore, a great number of industrial solvents, refrigerants, fumigants, and insecticides.

Directions are included for the prevention and treatment of poisoning in humans by these chemicals.

PHS Films

Milk Sanitation Series: Cleaning-in-Place for Pasteurization Plants

35 mm. Filmstrip, color, sound, 12 minutes, 63 frames. 1955.

Audience: Sanitary engineers, sanitarians, and dairy science students.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St. NE, Atlanta 23, Ga.

The cleaning-in-place method of cleaning milk lines by recirculating a cleaning solution throughout the piping system is the subject of this filmstrip.

This method is represented, through contrast, to be superior to the manual cleaning method, whereby pipes and connections are cleaned individually. A typical installation for the cleaning-in-place method, consisting of the milk line, separate recirculation unit with return line,

and solution tank and pump are shown. In addition, a step-by-step cleaning-in-place operation, from preparation of cleaning solution and checking flow velocity through post-rinsing with lukewarm water and bactericidal treatment of the entire system before starting the milk flow, is followed.

Installed glass and metal cleaning-in-place piping, fittings, gaskets, and welded connections are pictured. Among the check-points depicted are removable fittings, slopes and supports of pipes, accumulated charts, and the recording thermometer, which gives temperature and circulation time.

Basic Use of Levels by Sanitarians

35 mm. Filmstrip, color graphics, 8 minutes, 45 frames. 1954.

Audience: Sanitary engineers and sanitarians.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE, Atlanta 23, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

The basic uses of engineer's, string, carpenter's, and hand levels and the transverse hose filled with water are pictured in this filmstrip.

To accomplish this, the installation of a septic tank is demonstrated. A specific demonstration relates to the grade board in one section of a drain field. Any one of the five methods demonstrated can give satisfactory results if sufficient time and

care are taken. A knowledge of the use of at least one instrument is essential in sanitation work.

Serving Food

16 mm. Film, color, 10 minutes. 1954.

Audience: Sanitarians and public health workers.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE, Atlanta 23, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

The fundamentals of orientation and induction training to be given a waitress by a restaurant hostess are stressed in this film.

Correct ways of clearing tables and the proper storage of cups, dishes, and glasses are por-

The waitress avoids touching the rims of glasses to protect herself and the customers.

trayed. Safeguarding against disease through the development of satisfactory personal habits and periodic physical examination are advocated to protect the health of the waitress as well as the customer.

Public Health Reports, published since 1878 under the authority of an act of Congress of April 29 of that year, is issued monthly by the Public Health Service pursuant to the following authority of law: United States Code, title 42, sections 241, 245, 247; title 44, section 220. The printing of this publication has been approved by the Director of the Budget September 17, 1954.

For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Index Price 20 cents. Subscription Price to *Public Health Reports* including Index, \$4.25 a year; 75 cents additional for foreign mailing. Single copies vary in price.

X-raying the Heart Cycle

BETHESDA, MD. With the new cardioerontgen actuator, literally a complex trigger for X-ray machines, the taking of X-rays at known times in the heart cycle need no longer be a matter of guesswork.

Superior diagnosis and treatment of heart ailments can often hinge on the cardiologist's sure knowledge that each successive X-ray picture to be compared, sometimes taken years apart, was shot at exactly the same instant in the heart cycle. The ever-changing normal heart volumes and the subtle enlargements of sick hearts are variables that frequently

deserve precise identification and correlation before two X-ray films can be truly compared.

With the new instrument developed by the Public Health Service at the Laboratory of Technical Development, National Heart Institute, the cardiologist can be assured specific mechanical help in this endeavor.

The photograph illustrates the operation of the instrument. The actuator, housed in a special control box (right) operates in conjunction with a conventional electrocardiograph (left) that continuously traces the heart's electrical activity. This activity is correlated with the expansion and contraction of the heart. The electrocardiographic signal triggers the X-ray exposure at any selected time in the heart cycle.

A monitoring photo cell, hanging

below the patient's elbow in the background of the photograph, detects the X-ray exposure and feeds an electrical pulse back into the electrocardiographic curve, marking the exact instant of exposure. A calibrated switch on the actuator permits proper time selection with respect to heart rate so that films can be taken at full expansion, full contraction, or at any intermediate time. In addition, the instrument contains a provision to prevent double exposure.

The actuator is not yet commercially available. A circuit diagram showing the wiring of the instrument and detailed technical information may be obtained from Dr. Bert R. Boone, chief, Laboratory of Technical Development, National Heart Institute, National Institutes of Health, Public Health Service, Bethesda 14, Md.

In preliminary studies, human body lice maintained in the laboratory for many generations on lindane, Lauseto neu, and the pyrethrins developed much less resistance to these insecticides than has been developed to DDT. The lice developed no resistance to a pyrethrum-sulfoxide compound after 30 generations.

Resistance of Human Body Lice to Insecticides

By GAINES W. EDDY, M.S., M. M. COLE, B.S., MAX D. COUCH, B.S.,
and ALLEN SELHIME, B.S.

THAT INSECTS can develop resistance to insecticides has been known for approximately 50 years. However, the subject has been studied extensively in this country only during the last 6 years, following the development of resistance to DDT by houseflies. The literature on the development of insect resistance to insecticides has been reviewed by Babers (1) and Babers and Pratt (2). Several important references are given in the Yearbook of Agriculture for 1952.

The laboratory of the Entomology Research Branch of the United States Department of Agriculture conducted research at Orlando, Fla., from June 1951 to August 1954 on the resistance of the human body louse, *Pediculus humanus humanus* L., to DDT, lindane, Lauseto neu (chloromethyl *p*-chlorophenyl sul-

fone), pyrethrins, and pyrethrins plus sulfoxide (*n*-octyl sulfoxide of isosafrole).

Lindane, Lauseto neu, and pyrethrins were selected for study because of their general effectiveness against both normal and DDT-resistant lice. Lindane is of special interest because it has been adopted by the Armed Forces for the control of body lice in areas where resistance to DDT has developed.

The experimental development of resistance has usually been accomplished under laboratory conditions by selection. A concentration of toxicant that will cause moderate to high mortality is used, and the survivors serve as parents of the next generation. In some of the Orlando studies reported here the lice were exposed to very light deposits of insecticides which caused no apparent mortality or injury. The dosages varied with the insecticides, but most of them were approximately one-tenth those usually required to give a low mortality or moribundity.

Previous Reports on DDT Resistance

A number of workers in the field and in the laboratory have reported on the development of DDT-resistant lice. Bushland and associates in 1945 (3) and Eddy and Bushland in 1948 (4) demonstrated that cloth impregnated

The authors are entomologists with the Entomology Research Branch of the United States Department of Agriculture. Mr. Eddy is entomologist in charge of the Corvallis, Oreg., laboratory of the Insects Affecting Man and Animals Section. Mr. Cole and Mr. Couch, with the same section, are stationed at Orlando, Fla., and Mr. Selhime is with the Fruit Insects Laboratory at Orlando.
